The participants were instructed to listen to all three words and then to repeat the words as they were heard. They also were informed that partial credit would be given for every part of a word that was correct. These instructions were analogous to those suggested by Markides (1978) for use with phonemic scoring.

All tests were administered by a single examiner who was highly trained in and experienced with the tri-word test in order to avoid variability that might be introduced by multiple testers. Auditing errors by the tester were minimized by having the listener face the tester through the booth window so that responses could be seen and heard and by asking for clarification whenever the tester was not certain of the intended response. Right-wrong phonemic scoring was extremely straightforward because none of the test words contain consonant blends. In addition, no distinction was made between /w/ and /ã/ (e.g., witch and which were considered interchangeable) in order to account for regional variations in speech production.

All of the original test outcomes were rescored to obtain phoneme and word recognition scores based on 10, 20, 25, and 50 three-word presentations. The 10-set scores were derived from the participants' performance on the first 10 presentation sets, the 20-set scores were based on the first 20 presentation sets, and the 25-set scores were based on the first 25 presentation sets. Full test scores were based on all 50 presentation sets. Analogous approaches were used by Raffin and Schafer (1980) and Gelfand (2003).

Results

The findings are reported as percent correct scores, and statistical tests employed arcsine transformed units to stabilize the error variance associated with proportional data where appropriate. Table 1 shows the mean percent correct phoneme and word recognition scores and SDs for all SNRs. The mean scores were quite similar for the 10, 20, 25, and 50 sets. Overall performance increased from 2.73%-3.70% at a SNR of -15 dB to 96.57%-96.97% at 20 dB SNR for phoneme scoring, and from 0.42%-0.72% at a SNR of -15 dB to 91.11%-92.28% at 20 dB SNR for word scoring.

The psychometric functions illustrating how phoneme and word recognition scores depend on SNR for the 10-, 20-, and 25-set conditions are shown in Figures 1 through 3, respectively. For ease of visual comparison, each figure shows the mean recognition scores and 95% confidence intervals (CIs) for the shortened test along with those for the full (50-set) test. The psychometric functions of the shortened tests essentially overlapped those of the full test, with similar means and overlapping 95% CIs (except for small deviations at 5 dB SNR for the 10-set word score and perhaps at 0 dB SNR for the 25-set phoneme scores).

Table 2 shows the rates at which performance improved with increasing SNR in percent per decibel (%/dB),

revealing that the mean slopes were quite similar and had overlapping 95% CIs across the four set sizes. Overall, the phoneme recognition scores for the 10-, 20-, 25-, and 50-set conditions increased, with average slopes of 6.265%-6.46% per dB from -10 to 0 dB SNR, and 1.54%-1.74% per dB from 0 to 10 dB SNR; and the word recognition scores had slopes of 4.94%- 5.07% per dB from -10 to 0 dB SNR and 2.76%-2.94% per dB from 0% to 10% dB SNR.

The primary intent of this report is to describe the performance functions for shortened versions of the Tri- Word Test that were not included in the original article (Gelfand, 1998). However, it was considered desirable to provide at least some quantitative perspective on the concord between the abbreviated versions and the full test in terms of effect size estimates. As a result, regression analyses were used to assess the relationships between the full-length test and each of the abbreviated ones. In addition, effect size estimates were calculated based on repeated-measures planned contrasts comparing the slopes of the psychometric functions for each of the abbreviated versions with those of the 50-set test.

The results of the regression analyses are summarized in Table 3. It shows that performance on all of the shortened tests significantly accounted for most of the variance on the full-length tests ($p < .001$), with adjusted R^2 values increasing as the number of three-word sets rose from 10 to 25. Specifically, scores on the abbreviated tests accounted for 98.8% to 99.5% of the variance on the full test with phoneme scoring and 95.8% to 99.2% of the variance on the 50-set test with word scoring.

Table 4 summarizes the findings of the planned contrasts. There were no significant differences between the corresponding slopes of the full test and each of the abbreviated versions. Effect sizes are expressed as ω^2, which is appropriate for the design employed and can be used when sample sizes are small and/or statistical test outcomes are nonsignificant (Ferguson, 2009; Keppel &Wickens, 2004; Robey, 2004). In line with conventional practice, negative values of ω^2 were reported as 0, which is commonly found when F ratios are quite small (Keppel &Wickens, 2004). The ω^2 estimates were 0 for all contrasts except for the 10-set word scores, which were $\omega^2 = 0.021$ for the -10 to 0 dB SNR slope and $\omega^2 = 0.033$ for the 0 to 10 dB SNR slope. These outcomes suggested that using a smaller number of presentation sets accounted for little if any of the variation in the slopes of the functions, constituting "trivial" to "small" effects at most in terms of commonly encountered benchmarks (Cohen, 1988; Ferguson, 2009; Kirk, 1996).

Discussion

Aprevious report (Gelfand, 1998) provided the rationale and characteristics of a speech recognition testing approach intended to optimize reliability by combining 50 presentations of three CNC words each along with phonemic scoring of the listener's responses. It was shown that the proposed approach actually achieved the reliability of a 450-item test predicted by the binomial model and that 50 tri-word presentations with word scoring achieved the predicted reliability of a 150-item test.

A subsequent study (Gelfand, 2003) provided the rationale for using 10, 20, or 25 tri-word presentations as a compromise between the opposing goals of a short but reliable test and showed that the abbreviated tests also met their respective reliability expectations based on the binomial model.

A fundamental aspect of the original report was the provision of complete psychometric functions showing normal-hearing listeners' phoneme and word recognition performance across a range of SNRs from -15 to 20 dB. In addition to describing the operating range of the Tri-Word Test, these functions facilitate comparisons with other speech recognition tests, provide a basis of comparison for performance by other groups, and may serve as performance benchmarks for various applications of the approach. However, that report did not provide psychometric functions for normal-hearing listeners' performance on the abbreviated tests. The purpose of this report was to fill in the missing pieces by describing the corresponding psychometric functions for the abbreviated versions along with those for the full-length test.

It is possible that fewer presentation sets might lead to changes in the psychometric functions compared with those for the full-length version above and beyond the expected increase in variance associated with smaller

numbers of test items. For example, performance might be influenced by differences in short-term practice and/or fatigue effects across various test lengths. While a small but significant short-term learning effect was reported for phonemically scored isophonemic words presented one at a time (Mackersie, Boothroyd, &Minniear, 2001), it was not found across the first through fifth 10-set presentation groups of the Tri-Word Test (Gelfand, 2003). However, the later finding was based on a single-condition test administration to each listener. In contrast, the wide range of SNRs involved in obtaining psychometric functions present the listener with varying levels of difficulty and challenge that might be differentially influenced by learning, fatigue, or other factors. As a result, actual psychometric functions for abbreviated tests should provide a more appropriate frame of reference (compared with those for the full test) when the shorter versions are used with other groups and in various applications, and when compared with other speech recognition metrics.

The mean psychometric functions for both phoneme and word scores for each of the shortened versions of the Tri-Word Test overlapped those for the full test almost exactly, with only a few very small exceptions. In quantitative terms, normal-hearing listeners' performance on the shortened tests accounted for 98.8% (for 10 sets) to 99.5% (for 25 sets) of the variance of the full 50-set tests with phoneme scoring and 95.8% (for 10 sets) to 99.2% (for 25 sets) of the full-test variance with word scoring over a wide range of SNRs. In addition, shortening the tests accounted for only a tiny proportion of the overall variance in the slopes of the functions and may be interpreted as being of little if any practical significance.

The similarity of their psychometric functions supports the confidence with which the abbreviated versions of the Tri-Word Test may be used when an application does not require the optimized level of reliability provided by full, 50-set presentations.

In this context, typical testing times are about 4½ min for a representative 50-item traditional test recording (Auditec of St. Louis CID W-22 List 1A) and roughly 6 min for the full (50-set) Tri-Word Test with responsive listeners (Gelfand, 1998). Thus, a typical traditional speech recognition test requires approximately 4½ min to yield an SRS with 50-item reliability, 23 min for 25-item reliability, and roughly 52 s for 10-item reliability. In contrast, tri-word testing with phonemic scoring can achieve the reliability of a 450-item test in about 6 min (all 50 sets), the reliability of a 225-item test in about 3 min (25 sets), the reliability of a 180-item test in about 2½min (20 sets), or the reliability of a 90-item test in as little as roughly 13 min (10 sets).

Conclusions

The psychometric functions for the 25-, 20-, and 10-set versions were found to be comparable to those of the original 50-set presentation approach for both phoneme and word scoring for healthy young adults with normal hearing. Before applying them clinically, practitioners should await descriptions of the corresponding functions for a variety of clinically relevant groups. Those with sensorineural hearing loss typically have psychometric functions that vary from those with normal hearing for traditional speech recognition tests, and their functions for the Tri-Word Test certainly need to be determined. Performance functions are clearly needed for the elderly and for children, as well. (It is unlikely that the test would be used with young children, but a threeitem, short-term memory task, per se, may not be too demanding for children as young as about 6 years old. For example, a five-item digit span is 1 SD below mean performance for 6.0- to 6.3-year-olds, and a three-item digit span is 2SDs belowthe mean;Wechsler, 2003.) Moreover, there is every reason to expect that the three-word repetition task may be inappropriate for patients with confounding conditions, such as auditory processing disorders, attention deficits and similar disorders, dementia, and brain injury. Studies addressing several of these issues are invarious stages of planning and implementation.

Abstract: Speech perception can be described as the transformation of continuous acoustic information into discrete memory representations. Therefore, research on neural representations of speech sounds is particularly important for a better understanding of this transformation. Speech perception models make specific assumptions regarding the representation of mid vowels (e.g., [e]) that are articulated with a neutral position in regard to height. One hypothesis is that their representation is less specific than the representation of vowels with a more specific position (e.g., [æ]). In a magnetoencephalography study, we tested the underspecification of mid vowel in American English. Using a mismatch negativity (MMN) paradigm, mid and low lax vowels ([e]/[æ]), and high and low lax vowels ([I]/[æ]), were opposed, and M100/N1 dipole source parameters as well asMMNlatency and amplitude were examined. Larger MMNs occurred when the mid vowel [e] was a deviant to the standard [æ], a result consistent with less specific representations for mid vowels. MMNs of equal magnitude were elicited in the high-low comparison, consistent with more specific representations for both high and low vowels. M100 dipole locations support early vowel categorization on the basis of linguistically relevant acoustic-phonetic features. We take our results to reflect an abstract long-term representation of vowels that do not include redundant specifications at very early stages of processing the speech signal. Moreover, the dipole locations indicate extraction of distinctive features and their mapping onto representationally faithful cortical locations (i.e., a feature map).

Purpose: Speech perception can be described as the transformation of continuous acoustic information into discrete memory representations. Therefore, research on neural representations of speech sounds is particularly important for a better understanding of this transformation. Speech perception models make specific assumptions regarding the representation of mid vowels (e.g., [e]) that are articulated with a neutral position in regard to height. One hypothesis is that their representation is less specific than the representation of vowels with a more specific position (e.g., [æ]).
Method: In a magnetoencephalography study, we tested the underspecification of mid vowel in American English. Using a mismatch negativity (MMN) paradigm, mid and low lax vowels ([e]/[æ]), and high and low lax vowels ([I]/[æ]), were opposed, and M100/N1 dipole source parameters as well asMMNlatency and amplitude were examined.
Results: Larger MMNs occurred when the mid vowel [e] was a deviant to the standard [æ], a result consistent

with less specific representations for mid vowels. MMNs of equal magnitude were elicited in the high-low comparison, consistent with more specific representations for both high and low vowels. M100 dipole locations support early vowel categorization on the basis of linguistically relevant acoustic-phonetic features.
Conclusion: We take our results to reflect an abstract long-term representation of vowels that do not include redundant specifications at very early stages of processing the speech signal. Moreover, the dipole locations indicate extraction of distinctive features and their mapping onto representationally faithful cortical locations (i.e., a feature map).
Key Words: vowel processing, auditory-evoked responses, mismatch negativity, N1m dipole distances, representation of speech sounds, speech perception
Determining the representational nature of speech sounds is an integral component in furthering our understanding of the set of perceptual and neurophysiological computations that underlie the mapping between the incoming acoustic signal and lexical representations. Given their tractable nature and well-understood spectral properties (Rosner &Pickering, 1994), vowels have been exploited extensively in investigations of these processes. Typically, vowels are classified on the basis of their first two resonant frequencies (peaks of energy in an acoustic spectrum; Ladefoged, 2001; Stevens, 1998), in which the first formant frequency (F1) inversely correlates with articulatory tongue height, and the second formant frequency (F2) reflects the place of articulation in the horizontal dimension (back to front). Given these dimensions, vowels can be distinguished on the basis of tongue height (high [i] vs. low [a]) and place of articulation (front [e] vs. back [o]; Ladefoged, 2001). Distinctive feature theories (e.g., McCarthy, 1988; for a neurolinguistic account, see Poeppel, Idsardi, &van Wassenhove, 2008) assume that long-term memory representations of vowels are based on symbolic and abstract labels referring to both acoustic cues (F1, F2) and articulatory configurations (tongue height, place of articulation). They thereby connect audition and articulation (for contrasting perspectives, see Browman &Goldstein, 1989; Stevens, 2002). Rooted in distinctive feature theory, Lahiri and Reetz (2002, 2010) have offered a model of speech perception and lexical access (the featurally underspecified lexicon model) in which speech sounds are described as bundles of feature specifications (e.g., high, front [I]) and are also processed on the basis of their abstract features. Underlying (phonological) representations employ the same feature bundles, but crucially, not every feature is expressed or specified. For example, on the basis of particular assimilatory properties of front (coronal) speech sounds (Avery &Rice, 1989), their place of articulation is assumed to be unspecified for coronality (underspecified for place of articulation). Note that the assumption of Lahiri and Reetz (2002), which we adopt here, is that coronal refers to a macro-category of place of articulation. It subsumes dental, alveolar, and alveo-palatal (or postalveolar) places of articulation. These places contrast with bilabial (labial) on the one hand and with velar and uvular (dorsal) places on the other hand. Further, the term underspecification refers to the overall representation of a speech sound and indicates that some feature dimension (e.g., tongue height for [e]) is not specified at all. According to the featurally underspecified lexicon model, a consonant like [t] or a vowel like [I] would not have a long-term memory representation for its phonological place of articulation feature, [coronal]. As a consequence, themapping fromacoustic signal to underlying features is asymmetric: For noncoronal sounds, bottom-up signal information is evaluated against more detailed long-term memory representations, whereas for coronal sounds, signal information is mapped onto less detailed (i.e., underspecified) memory representations.
Regarding vowel height, it has been proposed that some tongue heights are not encoded underlyingly; that is, mid [e] is underspecified for height (Lahiri &Reetz, 2002, p. 657). This contrasts with the specification [high] for [I] and [low] for [æ].
In this article, we investigate the representational nature of mid vowels in American English, which have the precarious status of being neither [high] nor [low] in traditional distinctive feature analyses; for example, they are characterized by the conjoined lack of a positive specification (cf.Avery&Idsardi, 2001).We use the brain's magnetic response to acoustic signals derived from contrasts in tongue height as a neurophysiological measure

in a classical mismatch negativity (MMN) study (Näätänen, 2001). The aim is to examine long-term vowel representations and processes involved in translating a continuous acoustic signal into a discrete mental sound representation under the assumption that this representation does not yield a one-to-one correspondence to the physical acoustic properties of the corresponding speech sound. Although we tested American English speakers with no hearing deficits, the framework may have important clinical implications, particularly for cochlear implant (CI) patients whose vowel spaces differ in characteristic ways fromthose of healthy controls (Harnsberger et al., 2001; Löfqvist, Sahlén,&Ibertsson, 2010; Neumeyer, Harrington, &Draxler, 2010).

Neurophysiological Investigations of Vowel Perception

The cortical processing of vowels has been extensively investigated using electro-encephalography (Diesch, Eulitz, Hampson, &Ross, 1996; Diesch &Luce, 1997a, 1997b;Hill, McArthur,&Bishop, 2004; Jacobsen, Schröger, &Alter, 2004; Poeppel et al., 1997; Roberts, Flagg, &Gage, 2004; Shestakova, Brattico, Soloviev, Klucharev, &Huotilainen, 2004), that is, the brain's electric response underlying the perception and processing of vowel sounds in human cortex. Because vowels have relatively robust acoustic cues in F1 and F2, they are ideal candidates for the elicitation of early auditory-evoked components, such as the N1 or its magnetic equivalent, the N1m/M100. The M100 is a pronounced peak around 100 ms after the onset of an auditory stimulus that appears to encode basic speech processing in auditory cortices (Diesch et al., 1996; Shestakova et al., 2004). It is considered an index of temporal and topographical coding. Measures on the surface of the scalp (sensorspace) as well as measures of the source estimates producing a particular scalp electric distribution (source-space) are systematically modulated by the spectral characteristics of different vowel stimuli. For (pure) sinusoidal tones, the M100 latency inversely correlates with tone frequency (Poeppel &Marantz, 2000; Roberts, Ferrari, Stufflebeam, &Poeppel, 2000 [and references therein]), whereas for vowels, the latency of the M100 seems to track F1 (Diesch et al., 1996; Poeppel et al., 1997; Roberts et al., 2000, 2004; Tiitinen, Mäkelä, Mäkinen, May, &Alku, 2005). Recentwork, however, suggests an additional sensitivity to vowel formant ratios in dense vowel spaces (Monahan&Idsardi, 2010), inwhich larger ratios between the first and third vowel formant frequencies (F1/F3) elicit earlier M100 latencies.

Source-based parameters of the M100 are also sensitive to spectral characteristics of complex tones, vowels, and consonants (Diesch &Luce, 1997a, 1997b, 2000; Eulitz, Diesch, Pantev, &Hampson, 1995). The latter studies parallel earlier findings that showed a tonotopic organization of auditory cortex (Pantev et al., 1988; Pantev, Hoke, Lutkenhöner, &Lehnertz, 1989), that is, a spatial representation of frequency differences (frequency maps). M100 dipole locations reflect a categorical distinction of speech sounds on the basis of their formant frequencies (Mäkelä, Alku, &Tiitinen, 2003; Obleser, Elbert, Lahiri, &Eulitz, 2003; Shestakova et al., 2004). Spectral acoustic distances, as determined by Euclidean distances on the basis of two or three vowel formants, were paralleled in spatial dipole locations in a number of studies (Obleser, Elbert, et al., 2003; Shestakova et al., 2004). The crucial finding was that if two stimuli had a large spectral acoustic distance, the underlying sources of cortical activity to these stimuli had a relatively large spatial separation in auditory cortex. Conversely, the cortical sources of stimuli with a small acoustic distance were more closely collocated. Moreover, it has been found that M100 source dipoles differed along the anterior-posterior dimension according to differences in place of articulation, where [coronal] vowels reliably localized to more anterior positions in auditory cortex than [dorsal] vowels, seemingly parallel to their oral articulation (Obleser, Lahiri,&Eulitz, 2003, 2004). This pattern was replicated with CV syllables in German that contained either a dorsal ([o]) or a coronal vowel ([ø]), irrespective of the initial consonant (Obleser, Lahiri,&Eulitz, 2003). Finally, absolute dipole locations were modulated when attention was shifted away from the linguistic characteristics of the stimulus (Obleser, Elbert, &Eulitz, 2004), whereas the relative anterior/ posterior distinction was maintained. Taken together, these findings suggest that M100 source parameters are modulated by acoustic and, in particular, by linguistically relevant acoustic characteristics of speech sounds.

Neurophysiological assessments of speech sound underspecification have primarily been made on the basis of

components temporally subsequent to the M100, such as the MMN, an automatic and preattentive brain response to acoustic change or rule violation (Näätänen, 2001; Näätänen &Alho, 1997; Näätänen, Paavilainen, Rinne,&Alho, 2007;Winkler, 2007). The response is usually elicited in passive oddball paradigms, during which participants listen to frequent (standard) stimuli interspersed with infrequent (deviant) stimuli. The MMN is a fronto-temporal negativity in the difference waveform obtained by subtracting standard responses fromdeviant responses to the same acoustic stimuli and peaks between 150 and 250 ms poststimulus onset.

Designs testing coronal underspecification exploit the opposition of frequently occurring standard stimuli and rarely occurring deviant stimuli on the basis of the following logic: Standard repetitions activate memory traces, corresponding to underlying representations of speech sounds (Näätänen et al., 1997), affixes (Shtyrov &Pulvermüller, 2002a), or words (Pulvermüller et al., 2001; Pulvermüller, Shtyrov, Kujala, &Näätänen, 2004; Shtyrov &Pulvermüller, 2002b) in long-term memory. Standard repetitions set up expectations regarding feature specifications that might be violated by rarely occurring deviants with conflicting features (Eulitz &Lahiri, 2004; Winkler et al., 1999). Conflicting features are those that are mutually exclusive, such as [high] versus [low] and [coronal] versus [dorsal]. It should be noted that acoustic differences between standards and deviants will always yield some electrophysiological responses (Eulitz &Lahiri, 2004) given a minimum acoustic distance (cf. Näätänen, Tervaniemi, Sussman, Paavilainen, &Winkler, 2001). However, if acoustic differences are accompanied by featural differences (i.e., featural mismatches), the resulting MMN is expected to be larger than if there are no featural deviances. That is, the observedMMNis the result of a combination of differences from acoustic (bottom-up) information and from more abstract (top-down) distinctions.

Testing German vowels, Eulitz and Lahiri (2004) found that a coronal deviant [ø] that is preceded by a dorsal standard [o] elicited earlier and larger MMN responses than the reverse presentation, that is, a dorsal deviant [o] preceded by a coronal standard [ø]. These findings are predicted if the dorsal standard activates its fully specified place of articulation feature [dorsal], whereas the underspecified deviant fails to satisfy the prediction that a place of articulation feature is specified. Conversely, a coronal standard activates an underspecified representation in long-term memory, for which the dorsal deviant does not provide a featural mismatch. Further, underspecified standards do not generate specific predictions as to the specification of place of articulation. Thus, the observed MMN reflects a combination of these two difference measures, one pertaining to the acoustic difference between [o] and [ø] (and equivalently vice versa, [ø] and [o]) and the other one to the phonological difference between the two vowels (i.e., specified vs. underspecified). The MMN elicited by the deviant [o] was relatively small because it only reflected the acoustic dissimilarity to the standard, whereas the larger MMN elicited by the deviant [ø] additionally reflected a featural mismatch (see Bergelson &Idsardi, 2009, for similar results from music perception; see Hwang, Monahan, &Idsardi, 2010, for asymmetries in voicing of consonants).

The similar featural mismatch logic should hold for tongue height differences in English front vowels. We follow Lahiri and Reetz (2002) in the assumption that mid vowels are entirely underspecified for height, that is, never provide mismatching features to their low or high vowel counterparts. However, as before, a fully specified low or high vowel in standard position should generate a strong expectation regarding tongue height specification that might be violated if the deviant to this standard sequence is an underspecified mid vowel. Hence, in an MMN design, the mid vowel [e], preceded by the low vowel [æ], should elicit a largerMMNresponse than in the reverse case, that is, if the lowvowel [æ] is preceded by the mid vowel [e]. In the former (but not the latter) case, the standard generates a strong prediction regarding its tongue height specification that is then violated by the deviant. Further, assuming a low vowel standard and a high vowel deviant would lead to a featural mismatch between [low] and [high]. This mismatch, however, should be observed in the reverse case as well. The hypotheses discussed above are compatible with the model adjustment hypothesis (Näätänen &Winkler, 1999; Winkler, Karmos, &Näätänen, 1996) as well as the predictive coding approach to the neural source of MMN generation at frontal and temporal cortical locations (Baldeweg, 2006; Friston, 2005; Garrido, Kilner,

Stephan, &Friston, 2009). Note that the model adjustment hypothesis is part of the predictive coding account. In both approaches, the MMN results from violations of inference predictions on the basis of the repetitious standard presentations. The predictive coding account, combining the model adjustment approach with an adaptation approach ofMMNgeneration (Garrido et al., 2009), proposes that standard presentation resembles perceptual learning during which hierarchical sensory levels receive bottom-up sensory input from lower levels and receive top-down predictions from higher levels. As a result of the repetition of standard presentations, prediction errors are reduced by repetitive suppression or adaptation. A deviant presentation then leads to a violation of bottom-up prediction that is reflected in MMN generation. Applied to vowel underspecification, underspecified standards (such as mid [e]) make weaker predictions with regard to their tongue height features. As a result, the violation of such an expectation from deviant sensory information should be less severe, and the MMN ought to be reduced compared with the reverse condition, in which the underlying, specified representation of the standard can generate a stronger featural prediction.

We tested these predictions in a magnetoencephalography (MEG) MMN experiment with the American English short (lax) front vowels [æ], [e], and [I]. The choice of these vowels was determined by the observation that short front vowels in American English are less likely to be diphthongized (Hillenbrand, Getty, Clark, &Wheeler, 1995), such that our featural assumptions are more straightforward. For instance, it is not clear how to specify the diphthong [ai] in terms of tongue height features: It could subsume [low] and [high], [low] only, [high] only, or neither feature specification.

Testing Vowel Height Differences in American English

Rationale

Using an MMN design with MEG enables us to test our featural mismatch predictions and to simultaneously investigate M100 source parameters. These measures enable us to examine the neural bases of speech sound category access during the transformation of an acoustic signal into a mental representation. Note that MEG allows us to estimate the underlying source dipole of the observed magnetic field at the scalp with greater accuracy than EEG (e.g., Leahy, Mosher, Spencer, Huang, &Lewine, 1998; Lopes da Silva, Wieringa, &Peters, 1991; Nakasatp et al., 1994).

Materials

Twenty acoustically distinct exemplars of each of the American English vowels [æ], [e], and [I] were produced by a female native speaker of American English with phonetic training. This dialect and this speaker did not merge any of these vowels (cf. Labov, Ash, &Boberg, 2006) and made a robust three-way height distinction. Detailed spectral acoustic measures are provided in Table 1.

Note that the motivation of using multiple acoustic vowel exemplars is twofold: First, we want to guarantee a more natural listening situation. Second, using single vowels without any acoustic variation may result in response patterns that solely depend on the particular acoustic quality of the stimulus. In contrast, multiple exemplars in a many-to-one oddball paradigm increase the likelihood that the participants will form more abstract memory traces against which the deviants can be compared (Phillips et al., 2000; Winkler et al., 1999).

All stimuli were recorded and digitally sampled at 44.1 kHz with an amplitude resolution of 16 bits within the phonetic sound application PRAAT (Boersma &Weenink, 2009). Ten vowels of each category with similar pitch and intensity were selected as experimental stimuli. Their F1 and F2 values confirmed the threeway height distinction (see Figure 1). Stimuli intensity was normalized and corresponded to a presentation level of 60 dB (sound pressure level). An onset and offset ramp (cosine-square) of 15 ms was applied to all vowels (duration: 100 ms) that reduced sharp onsets and offsets.

Design

Stimuli were organized in a passive standard/deviant many-to-one oddball paradigm (Phillips et al., 2000; Winkler et al., 1999). The crucial mid vowel comparison was made between the low vowel [æ] and mid vowel [e]. As a control, we included the standard-deviant pair of the low vowel [æ] and the high vowel [I], both of

which are underlyingly specified for height. The vowels [æ] and [e], as well as [æ] and [I], were distributed over 2 ×2 blocks in which they occurred in either a standard (p = .875,N= 700) or a deviant (p = .125,N= 100; see Table 2) position. The different category exemplars were pseudorandomly drawn from the corresponding sets. We ensured that all exemplars occurred equally often. The number of standards between two deviants varied randomly in each block. The interstimulus intervals pseudorandomly varied between 500 and 1,000 ms to prevent participants from entraining to a specific presentation rhythm that may confound our event-related potential measures of interest. Each block contained a total of 800 trials and lasted approximately 15 min. Block order was permutated across participants. Trials were presented binaurally at a comfortable listening level (È60 dB SPL) with the software package Presentation (Neurobehavioral Systems, 2012).

Expectations

Following Eulitz and Lahiri (2004), we predict asymmetric MMN responses to the deviants [e] and [æ]. This prediction is based on the assumption that [e] is underspecified for tongue height, whereas [æ] is not. As laid out above, underspecified deviants after specified standards ought to elicit a larger MMN response than in the reverse case. In contrast, the test conditions with [æ] and [I] should show similarMMNresponses because the standard/deviant opposition always includes the specified features [low] and [high], or [high] and [low]. Furthermore, we also expect the MMN response to be modulated by the size of the acoustic differences as well, such that the larger formant distance between [low] and [high] vowels should enhance their MMN response. On the basis of previous M100 findings, we additionally expect source- and sensor-space differences between the M100 responses of all three vowels (e.g., Obleser, Lahiri, &Eulitz, 2003). This would provide further evidence for an early extraction of linguistically relevant acoustic information to access discrete long-term memory representations of speech sounds (here: vowels).

Participants and Procedure

Fifteen students from the University of Maryland (9 women, 6 men; mean age = 21.1 years, SD = 3.2; all native speakers of American English), without any reported history of hearing or neurological problems, participated for class credit or monetary compensation. All participants provided informed written consent and tested strongly right-handed (>80%) on the Edinburgh Handedness Inventory (Oldfield, 1971). Participants' head shapes were digitized before the experiment with a POLHEMUS 3 Space Fast Track system. Together with localization data from two preauricular and three prefrontal electrodes, these data allowed us to perform dipole localization analyses, as reported in the Data Analysis section.

During MEG recording and stimulus presentation, participants lay supine in a magnetically shielded chamber.Magnetic fields were recorded by a whole-head, 157 axial-gradiometerMEGsystem (Kanazawa Institute of Technology, Kanazawa, Japan) at a sampling rate of 500 Hz. Auditory stimuli were delivered binaurally via Etymotic ER3A insert earphones. Earphones were calibrated to have a flat frequency response between 50 Hz and 3100 Hz within the shielded room. This guaranteed an optimal acoustic delivery of the first three vowel resonance frequencies (Stevens, 1998). An online, 200-Hz, low-pass filter and a 60-Hz notch filter were applied to the raw data.

Prior to the main experiment, participants took part in a tone perception pretest that served as a control for dipole estimations as well as the basis for determining regions of interest on the surface of the scalp. Note that pure sinusoidal tones have been shown to engage neural circuitry in the auditory cortices, reflecting magnetic activity to the leftand right temporal scalp areas. Further, the (base) frequency of sinusoidal tones parametrically determines the center of neural activity because of the tonotopic principle of auditory cortex (Pantev et al., 1988, 1989, 1995).

During the tone pretest, participants were instructed to silently count high (1000 Hz) and low (250 Hz) sinusoidal tones (È300 total) presented over headphones in a pseudorandom order. The scalp distribution of the resulting averaged evoked M100 field was consistent with the typical M100 source in the supratemporal auditory cortex (Diesch et al., 1996). Only participants with a reliable bilateral M100 response were included in further analyses,

resulting in the exclusion of one participant.

For the main experiment, participants passively listened to vowel stimuli presented in blocks, as illustrated in Table 2. The use of acoustically variable standard vowels (10 tokens of each vowel) ensured that standards activated more abstract representations, such that a pure acoustic explanation of the resulting MMN can be excluded (Phillips et al., 2000). Block order was counterbalanced between subjects, and there was always a short break after each block. Participants viewed a silent movie during the passive listening task to reduce excessive eye movements and to maintain an awake state (Tervaniemi et al., 1999). The movie was projected onto a screen approximately 15 cm above the participants. Together with the head shape construction and the tone pretest, the entire experiment lasted approximately 90 min.

Data Analysis

Environmental and scanner noise were removed from the MEG raw data using a multishift, principal components analysis, noise-reduction algorithm (de Cheveigné &Simon, 2007, 2008). Epoch averaging used a 100-ms prestimulus interval and a 500-ms poststimulus interval. This allowed us to look at the first 500-ms poststimulus onset during which we expected the two eventrelated potential measures of interest: M100 and MMN. Epochs were baseline corrected using the 100-ms prestimulus epoch, guaranteeing that effects were truly stimulus based and not elicited by events prior to stimulus presentation. Although we used a denoising algorithm prior to averaging to reduce environmental magnetic influences, participants always produced artifacts by eye movements or muscle activity that masked our components of interest. For this reason, we rejected certain artifacts by visual inspection on the noise-reduced continuous data. Epochs were rejected if amplitudes were higher than 3 pico-Tesla (10-12 Tesla) or contained more than three consecutive eye blinks. Because of excessive noise and artifacts in the raw data, leading to exclusion rates of >15% of standards and deviants, one participant was excluded from further analyses (leaving a total of 13 participants for the analyses). Otherwise, no more than 15% of standards or deviants were excluded in any of the remaining participants. Averaged data were baseline corrected as elucidated above and were band-pass filtered by a Hamming-window digital filter with frequency cutoffs at 1 Hz and 30 Hz. The 10 strongest channels from the tone pretest were selected for subsequent amplitude and peak latency analyses separately for each hemisphere. Channels stemmed from scalp areas where the magnetic field was oriented toward the cortex (sink) and areas where the magnetic field was oriented emerging from the cortex (source). Following the usual time course of auditory-evoked MEG components (Ackermann, Hertrich, Mathiak, &Lutzenberger, 2001) and a visual inspection of the grand average waveform, several time windows with a length of 50 ms were selected. The first window (80-130 ms) covered the M100, whereas the three later windows (150-200, 200-250, and 250-300 ms) accounted for the MMN (see Figure 2). These windows were selected on the basis of previous findings (Näätänen et al., 2007; Winkler, 2007) regarding an MMN latency range between 150 and 300 ms and a particular latency difference in a window from 150 to 200 ms, which has been found to be crucial for testing underspecification (Eulitz &Lahiri, 2004).

Root-mean-squared magnetic field strengths over the selected 10 left- and right-hemispheric channels were analyzed separately for each time window of interest in mixed effect models with subject as random effect (Baayen, 2008; Pinheiro &Bates, 2000). M100 latencies were determined by visual inspection of the averaged epochs per condition and subject. MMN latencies were calculated from the difference waveforms of acoustically identical stimuli in deviant and standard positions (i.e., deviant - standard). Because of the few-to-many design of the oddball paradigm, we randomly selected 100 standard epochs to guarantee that the root-mean-squared values did not involve unequal variance between the standard and deviant stimuli.

Dipole Fitting

The fitting of equivalent current dipoles (ECDs) followed the procedure described in Obleser, Lahiri, and Eulitz (2004). An ECD is the simplified cortical source of the M100 response. It corresponds to the activity of some 10,000 neurons in auditory cortex, producing a local field potential and accompanying magnetic activity, and it

can be considered the center of cortical activity in response to an auditory stimulus. To determine the cortical location of ECDs elicited by our vowel stimuli, we first defined an orthogonal left-handed head frame, on the basis of the dimensions x and z; x projected from the inion through to the nasion, and z projected through the center-midline location according to the 10-20 system. The x coordinates defined the lateral-medial dimension, the y coordinates defined the anterior-posterior dimension, and the z coordinates defined the superior-inferior dimension. Then, a sphere, whose center position and radius were calculated in head framecoordinates,was fit for each participant covering the entire surface of his/her digitized head shape. A single ECD model in a spherical volume conductor was used for source modeling analysis of the neuromagnetic data (cf. Diesch &Luce, 1997a; Sarvas 1987). Left- and right-hemispheric dipoles were modeled separately (Sarvas, 1987). Tone and vowel source parameters were calculated from the median of the five best ECD solutions (minimally 90% goodness-of-fit) on the rising slope of the M100. Fittings after the respective peaks were not included (cf. Scherg, Vajsar, &Picton, 1990).

Results

Tones

The latency analysis (in ms) for the tone pretest included the effects hemisphere (left/right), frequency (250 Hz/1000 Hz), and the Hemisphere ×Frequency interaction. There was a main effect of hemisphere, $F(1, 36) = 11.06$, $p < .001$, and frequency, $F(1, 36) = 20.91$, $p < .001$. The M100 in the right hemisphere peaked approximately 5 ms earlier than left-hemispheric M100, and 1000-Hz tones elicited a 6-ms earlier M100 than 250-Hz tones. Both findings are consistent with previous results (e.g., Roberts, Ferrari, &Poeppel, 1998; Roberts &Poeppel, 1996). The peak amplitude analysis (in femto Tesla [f T]; 10-15 Tesla), using the same model, showed no significant effects (all Fs <2).

Tone source parameters included location in the lateral-medial, anterior-posterior, and superior-inferior dimensions (in millimeters). ECDs distinguished the high-frequency tone with a more medial location from the low-frequency tone with a more lateral ECD location (cf. Pantev et al., 1989). The spatial difference of approximately 4mmwas marginally significant,$F(1, 34) = 3.73$, $p = .06$, and was consistent with the expected spacing based on Pantev et al. (1989).

Vowels

M100 analysis. The M100 analyses were composed of the fixed effects vowel ([æ]/e / , [æ]/I /, [e]/æ / , and [I]/æ / ; the subscript denoting the context provided by the standard), position (standard/deviant), and hemisphere (left/ right) in a full-factorial design. M100 amplitudes showed a main effect of position, $F(1, 180) = 18.21$, $p < .001$, reflecting larger amplitudes for deviants than for standards. Additionally, there was a marginally significant Vowel ×Position interaction, $F(3, 180) = 2.31$, $p = .07$. In the low/mid comparison, M100 amplitudes differed between deviant and standard only for [e] ($t = 3.20$, $p < .01$) but not for [æ] ($t = 0.14$, $p = .89$). Put differently, if [e] was a deviant preceded by the standard [æ], the M100 amplitude was significantly larger compared with the M100 elicited by [e] in standard position. In contrast, the deviant [æ] preceded by [e] did not elicit a larger M100 compared with the corresponding M100 of [æ] as a standard.

First MMN window (150-200 ms). Turning now to the analysis of the latency and amplitude of the MMN component, amplitudes did not differ in the first MMN window (150-200 ms). The MMN peak latency analysis with the effects hemisphere (left/right) and opposition (low/high vs. low/mid) showed a significant effect of opposition, $F(1, 88) = 13.71$, $p < .01$, reflecting earlierMMN peak latencies (È10 ms) for the low/high contrast as compared with the low/mid contrast. Within the low/mid condition, latencies were earlier for the deviant [e] than for the deviant [æ], but this difference (È6 ms) did not reach statistical significance, $t(84) = 1.49$, $p = .13$.

SecondMMN window (200-250 ms). The amplitude analysis for the second MMN window (200-250 ms) revealed a significant effect for position, $F(1, 180) = 34.96$, $p < .001$, and a Position ×Vowel interaction, $F(3, 180) = 3.16$, $p < .05$. On average, deviant amplitudes were 12 f T higher than standard amplitudes (see Figure 3). The Position ×Vowel interaction was driven by larger differences between standards and deviants if [æ] was the

standard and [e] was the deviant than in the reverse case, that is, if [e] was the standard and [æ] was the deviant (t = 2.44, p <.01). This difference did not hold for either [æ] or [I] in the low/high contrast (t = 1.26, p = .21); that is, theMMNwas of similar size for the low/high contrast in both directions. Peak latencies did not differ in the second MMN window (all Fs <1).

Third MMN window (250-300 ms). The third MMN window (250-300 ms) showed a similar amplitude pattern. Deviants elicited a 10 f T larger amplitude than standards, F(1, 180) = 44.87, p <.001. Again, position interacted with vowel, F(3, 180) = 3.00, p <.05, reflecting the amplitude asymmetry between the low/mid condition, in which standard-deviant differences were significantly larger if [e] was the deviant than if [æ] was the deviant (t = 2.78, p <.01). No asymmetry was observed for the low/high conditions (t = 0.18, p = .86). As before, peak latencies did not differ in this MMN window. The results remain consistent when the second and third MMN windows are collapsed (i.e., 200-300 ms).

ECD Source Analysis

ECD source parameters for the M100 responses across participants in the lateral-medial dimension showed a significant Position ×Hemisphere interaction, F(2, 93) = 13.88, p <.05. In the lefthemisphere, deviants elicited ECDs that were 6mmmore medial to their standards. Dipoles in the anterior-posterior dimension differed between vowels in deviant position, F(2, 93) = 3.66, p <.05. In particular, [I] elicited a dipole that was located 7.5 mm more anterior to the dipole of either [e] or [æ] (t = 2.29, p <.05). Dipole locations for the deviants [e] and [æ] did not differ (t = 0.60, p = .55). The superior-inferior dimension analysis showed amain effect of vowel, F(2, 93) = 6.13, p <.01. The dipoles for [I] were approximately 7mm more superior to the dipoles for [æ] (t = 3.42, p <.001). Locations between [I] and [e] (t = 1.74, p = .09) and between [e] and [æ] (t = 1.30, p = .20) did not differ.

Dipole orientations differed in the horizontal dimension (i.e., deviating from the lateral-medial axis). This was reflected in a main effect of hemisphere, F(1, 93) = 7.65, p <.01. Dipoles on the right hemisphere were oriented more toward frontal areas than on the lefthemisphere. Additionally, we found a significant Vowel ×Position interaction, F(3, 93) = 4.41, p <.05. Interestingly, ECDs were oriented more toward frontal regions for the deviant [æ] if preceded by the standard [e], whereas the deviant [e] did not differ from deviant [I].

Figure 4 illustrates ECD locations in the lefthemisphere. Because the M100 source estimates appear to reflect the vowels' acoustic properties, we were interested in relating these measures. Therefore, we calculated Euclidean distances in the three-dimensional vowel space on the basis of the first three formants and related this measure toEuclidean distances in cortical space on the basis of lateral-medial, anterior-posterior, and inferior- superior locations. To obtain a correlation measure, we used a fixed effect model with the effects hemisphere (left/right), position (standard/deviant), and acoustic distance in a fully factorial design. The fixed effect acoustic distance was significant, F(1, 31) = 4.21, p <.05, showing that acoustic vowel distances were reflected in cortical ECD distances, as reported previously (e.g., Obleser, Lahiri, &Eulitz, 2004). The relation of feature distance, dipole distance, and acoustic distance is illustrated in Table 3.

On the basis of statistical model comparison and model criticism (cf. Pinheiro &Bates, 2000), we calculated a second fixed effect model to which we added the fixed effect feature difference (1 vs. 2; see Table 3). Adding additional fixed effects to such modelsmay result in a better fit to the data. The goodness-of-fit is usually indicated by an information-theoretic score (such as the Akaike information criterion [AIC] or the Bayesian information criterion [BIC]). A reduction in these scores means that the addition or removal of a fixed effect or interaction results in a better fit to the data beyond what would normally be expected by adding additional parameters. Our second model with the additional effect feature difference resulted in lower AIC and BIC scores (AIC: 337.69 vs. 326.97; BIC: 355.06 vs. 345.82). For this reason, we conclude that the second model (with the additional featural effect) should be preferred. Adding featural phonological information to the model results in a more accurate fit to the data, suggesting that ECD distances are determined by acoustic properties that bear specific importance for the corresponding long-term featuralmemory representations of the vowels. That is,

even early cortical responses are composite, deriving from both information directly from the incoming signal and the influence of expectations based on long-term memory representations.

General Discussion

From our neuromagnetic experiment on the representational nature of front mid vowels in American English, we report two main findings:

1. The M100 as index of cortical processing of acoustic stimuli provided us with source- and sensor-space measures that suggest an early processing of vowels on the basis of their spectral properties that are particularly relevant for linguistic categorization.
2. The MMN as automatic change detection response of the brain supported our claim for mid vowel underspecification in showing asymmetric change responses between low/mid and low/high vowels.

With respect to our M100 findings, the early extraction of specific acoustic structures even in variable contexts has been known for quite some time (e.g., Saarinen, Paavilainen, Schröger, Tervaniemi, &Näätänen, 1992). The physiology of auditory cortex is particularly adept at encoding acoustic distinctions by spatially distinct centers of activation (Pantev et al., 1988, 1989), as measured by M100/N1 dipole source modeling. In speech, this socalled tonotopic principle extended to formant frequency distinctions (Diesch et al., 1996; Diesch &Luce, 1997a; Eulitz et al., 1995; Mäkelä et al., 2003; Shestakova et al., 2004), particularly for F2, encoding place of articulation (Obleser, Lahiri, &Eulitz, 2003, 2004). Obleser and colleagues (Obleser, Elbert, &Eulitz, 2004; Obleser, Lahiri, &Eulitz, 2003, 2004) found that ECDs, underlying the surface field pattern of theM100, spatially distinguished coronal (front) and dorsal (back) vowels and consonants. The difference in centers of activation was found in the anterior-posterior dimension: Front segments elicited dipoles anterior to the dipoles elicited by back segments. This is in line withOhl and Scheich (1997) and Diesch and Luce (1997a), who have argued that this alignment is a F2-F1 difference map perpendicular to the tonotopic gradient along the medial-lateral axis (Pantev et al., 1989). Obleser, Lahiri, and Eulitz (2004) have argued that the ECD location pattern in their study does not support a linear F2-F1 M100 mapping. It rather suggests that the mapping is better accounted for by the assumption of more abstract, yet acoustically based, features. Vowel distances appear to be warped toward perceptually salient properties and not pure acoustic F2-F1 differences. This is also reminiscent of Stevens's quantal theory of speech production and perception, in which distinctive features express stable acoustic patterns based on salient articulatory configurations (Stevens, 1989; Stevens &Blumstein, 1978). Note that saliency of articulatory configurations appears to be particularly relevant for CI users. Whereas it has been observed that the vowel space of CI users is commonly reduced (as measured in the F2/F1 plane; cf. Harnsberger et al., 2001; Löfqvist et al., 2010),Neumeyer et al. (2010) observed that this reduction mainly affects acoustic dimensions for which there are no clearly visible (hence, salient) articulator positions. The authors found that the range of F2 (expressing place of articulation differences) was smaller in CI users compared with healthy controls, whereas the range of F1 (expressing tongue height differences) did not show significant differences between the two participant groups. They argued that CI users could still rely on visible jaw height positions for F1 in maintaining category differences, whereas there was less of a visual cue accompanying F2 differences.

Our study adds to previous findings, illustrating the correlation between acoustic distance and ECD location in the auditory cortex. The high vowel [I] differedfromthe other two vowels along the anterior-posterior and the superior-inferior axes. Note that the anterior-posterior distinctions follow the observation that more front vowels elicit more anterior dipoles. The vowel height differences, on the other hand, seem to be expressed by superior-anterior distinctions, although the directionality of our stimuli was not the same as found in Obleser, Elbert, et al. (2003). Although we cannot provide direct evidence that our dipole locations are better accounted for by abstract features, westill showthat dipole distances are statistically better explained by feature differences than by acoustic distances. Furthermore, the fact that no single spatial dimension directly correlated with one of the first formant frequencies of our stimuli provides additional evidence for the view that the auditory cortex is

particularly sensitive to more complex interactions of frequency components (e.g., Ohl &Scheich, 1997). Again, we would like to propose that these interactions are the acoustic bases for distinctive features. Localizing M100 sources obtained from the CI user promises to shed more light onto the interaction of spectral-acoustic and articulator-configuration information during vowel category formation in perception. Here, we would expect a stronger influence of articulator positions on the localizations of cortical vowel sources compared with normalhearing controls. A model comparison as reported in this article could provide the necessary statistical means by which this difference may be established. Again, this is a promising study for future work, the results of which are potentially very useful for the design and improvement of CIs as well as for possible strategies to retain perceptually robust vowel categories.

Our second main finding relates to the MMN data that provide evidence for the underspecification of tongue height in the vowel [e]. Crucially, we found the MMN in response to the mid vowel deviant [e] after the standard vowel [æ] to be significantly larger than vice versa, that is, when the mid vowel [e] was the standard and [æ] was the deviant. We assume that the low vowel [æ] in standard position activated its specified featural tongue height representation and set up a relatively high expectation for the subsequent mid vowel deviant to be specified as well. Its tongue height underspecification, however, violated this expectation and led to a larger MMNthan one would assume on the basis of acoustic differences between standards and deviants alone. It is important to bear in mind that the MMN response will always be elicited in response to a detectable acoustic change. Our claim is that the size of the MMN furthermore depended on the featural oppositions between standard and deviant vowels. Importantly, theMMNfor [e] in [æ] context was larger than if [e] was the standard and [æ] was the deviant. In this case, we assume that the mid vowel [e] in standard position did not activate a tongue height specification and, consequently, created a low expectancy as to the tongue height of the deviant. Necessarily, the [low] specification of the deviant was a less severe violation.We would expect similar results for the deviant [I]; however, because of duration limitations of MEG experiments with regard to participants' comfort levels, we could not include this condition in our current study. Clearly, the testing of the latter condition will be a necessary enterprise for future work.

The detected asymmetry in the mid/low vowel opposition was not found in the control condition that contrasted the low vowel [æ] with the high vowel [I]. This important finding enables us to reject alternative explanations for the low/mid contrast asymmetry. Here, MMNs did not differ and were of similar magnitude for the deviant [æ] and the deviant [I]. This pattern is expected on the basis of mismatching features. Both low and high vowels in standard position activate their fully specified representations for which the corresponding deviants provide a conflicting feature, that is, resulting in mutually exclusive feature oppositions of [low] versus [high], and [high] versus [low]. The fact that the MMN responses in the low/high conditions did not differ from MMN responses in the low/mid conditions furthermore suggests that the MMN amplitude is not solely driven by the acoustic distance between the standard and the deviant. This is in line with previous MMN research on vowels that suggests an interaction of auditory-sensory and phonological-categorical processing (Winkler et al., 1999), once again confirming that the size of the MMN does not linearly correlate with acoustic differences as measured as distance in formant space.

The finding that MMN latencies in the 150-200 ms window were shorter for the low/high conditions than for the low/mid conditions is consistent with earlier observations indicating that feature mismatches in passive oddball paradigms are not only reflected by higher MMN amplitudes but also by earlier MMN peak latencies (Eulitz &Lahiri, 2004; Scharinger, Eulitz,& Lahiri, 2010).

Our proposed correlation of standard-deviant feature opposition and magnitude of the resulting MMN is compatible with both the model adjustment hypothesis (Näätänen&Winkler, 1999;Winkler et al., 1996) and the predictive coding approach that incorporates the former (Baldeweg, 2006; Friston, 2005; Garrido et al., 2009). According to the model adjustment hypothesis, the MMN results from the need to update an acoustic model of the environment to incorporate (or assimilate) the respective deviant. This acoustic model, consisting of auditory

memory, is instantiated by a sequence of standard sounds and generates inferences regarding future sound events, that is, a continuation of the standard sequence. Importantly, the model can have high or low inference values, which means that a deviant is less readily or more readily incorporated in the model (Winkler et al., 1996). Put differently, the model can be more or less confident in inferring future sound events and, consequently, will show larger mismatch responses if a highly confident inference is violated.We suggest that featurally specified vowels provide relatively high inference values, that is, high expectations that the next vowel in the standard sequence is also specified for the same feature. Encountering a deviant with a different feature extracted from the acoustic signal will then require a model update and thereforewill elicit anMMN.In contrast, an underspecified vowel has a low inference value-that is, the expectation for a future sound to be specified is lower. Consequently, a deviant is more readily incorporated in the model and therefore will elicit a smaller MMN.

The predictive coding approach combines the adaption mechanism with the model adjustment hypothesis discussed above. According to the adaption mechanism, the MMN is an emergent phenomenon by subtracting adapted responses to standards from nonadapted responses to deviants (Jääskeläinen et al., 2004).Within the predictive coding approach, standard presentations help the suppression of prediction errors while integrating bottom-up sensory information with top-down predictions. Neurally, this is achieved by plastic changes in synaptic connections (adaptation). Upon encountering the deviant, the sensory bottom-up information fails to meet the top-down prediction. The consequence is the elicitation of an MMN (Näätänen &Winkler, 1999; Winkler et al., 1996). Note that the model adjustment hypothesis suggests two mechanisms for the elicitation of theMMN. One mechanism with generators at temporal locations signals deviation from the learned regularity through the standards and involves a comparison of the sensory auditory input with the memory trace of the previous stimuli. The other mechanism with generators at frontal locations relates to an automatic (involuntary) attention switching process (Escera, Alho, Winkler, &Näätänen, 1998; Escera, Schröger, &Winkler, 2000; Giard, Perrin, Pernier, &Bouchet, 1990) that modulates deviance detection (Escera, Yago, Corral, Corbera, &Nunez, 2003).

Our results are also compatible with the predictive coding approach. In a similar way to that argued above within the model adjustment hypothesis, underspecified standards-by virtue of their less specified status- should evokeweaker bottom-up predictions. In particular, underspecified [e] should not evoke specific predictions regarding the tongue height information supported from the signal. As a consequence, the deviant [æ] provides a relative weak predictive error and, consequentially, elicits a weak MMN. In contrast, specified [æ] in standard position makes strong and specific bottom-up predictions, such that the deviant [e] supplies a stronger predictive error than in the reverse case. On the other hand, underspecified [e] in standard position yields the only case in which there is no tongue height expectation, such that the low deviant [æ] provides novel information regarding a specific level of tongue height (low). The fact that we found a more frontal orientation of the M100 dipole for this deviant suggests that there might be more frontal processing already before the onset of the MMN. This would be in line with the involuntary attention switching process. Previous research has shown that the strength of the attention switching process depends on the novelty of the deviant (Escera et al., 1998; Rinne, Särkkä, Degerman, Schröger, &Alho, 2006). Thus, it could be the case that on the basis of the predictive model of the underspecified standard, the extraction of a discrete tongue height value from the deviant resulted in a stronger involuntary attention switch than in the other conditions in which the fully specified standards provided a predictive model in which the extraction of a discrete tongue height feature was more predicted. This attention switch, furthermore, might already be visible in a different M100 source configuration as reflected in a more frontal ECD orientation. Although these considerations have to remain speculative at this point, they can be taken as valuable hypotheses for future research.

Other MMN studies on vowel height differences suggest that early MMN effects are actually driven by acoustic stimulus properties. For example, Hill et al. (2004) reported that MMNs did not differ between 100 and 200 ms

poststimulus onset between a vowel condition with [e] and [I] and a tone condition matched for the vowel's F1. The vowel and tone conditions diverged only between 200 and 350 ms after stimulus onset. Although our crucial amplitude interaction in a later time window (200-250 ms) seems to support this view, care has to be taken with the interpretation of their results because they used synthetic vowels, whereas we employed spoken vowels with natural variation. Nevertheless, their results conform to our hypothesis according to which neural vowel processing is first subject to a specific acoustic analysis that focuses on formant (resonance) frequency regions and is later characterized by acoustic-phonetic feature integration and evaluation against long-term memory representations of discrete (vowel) sounds. Tone and vowel conditions in Hill et al.'s study differ at later latencies because these latencies probably reflect the comparison between acoustic-phonetic information and memory representations that differ between tones and vowels.

Hill et al.'s (2004) findings are challenged by the work of Jacobsen and colleagues (Jacobsen, Schröger, &Alter, 2004; Jacobsen, Schröger, &Sussman, 2004), who have provided evidence that language-relevant information is extracted even from complex nonspeech sounds. Jacobsen, Schröger, and Alter (2004) showed that complex tones with speech-like formant structure reliably elicited MMNs in the 100-200-ms time range after stimulus onset. In contrast, similarly complex tones without speech-like formant structure failed to elicit significant MMNs. Thus, the authors provided evidence that speech-relevant acoustic information is extracted preattentively from the incoming signal. Because the speech-relevant acoustic information, as expressed by formant structures, determines or constitutes distinctive features, we take these findings together with the results of our experiment as evidence for the brain's early and preattentive sensitivity to abstract phonetic features.

Again, ourMMNfindings may speak to the observation of reduced vowel spaces in CI users. Within underspecification theory, the higher confusability of vowels in CI users-as, for example, found by Löfqvist et al. (2010)- can be modeled by an increase in underspecified vowels. Possibly, specified vowels such as low [æ] can become underspecified if the spectral cue (F1) is consistently degraded or shows greater variation. Note that underspecified vowels are supposed to be more confusable because their long-term memory representation is compatible (i.e., not mismatching) with all the vowels that have no other mismatching feature dimensions. For example, [e] may be confused with both [æ] and [I] (underspecified vs. specified), but [æ] will be less confused with [I] (both specified). CI users might counteract the emerging confusability of vowels by focusing on feature dimensions (e.g., F1) for which an alternative (visual) cues exists. Eventually, the visual cue can restore the full representation of a vowel's tongue height. Again, this is a speculative remark at the moment, but it provides a possible starting point for fruitful future research.

Conclusion

Taken together, theMMNpattern of our experiment supports the idea of distinctive features that determine the representation of vowels and guide the perception of speech sounds. We found support for tongue height underspecification in American English mid vowels and showed that underspecification predictions for the MMN are in line with current models accounting for its underlying mechanisms. The M100 results, on the other hand, suggest that the auditory cortex categorically deals with acoustic cues to these features very early during spoken sound processing.

Acknowledgments

The research for this study was funded by National Institutes of Health Grant 7ROIDC005660-07 to the third author and David Poeppel. We thank David Poeppel and Aditi Lahiri for invaluable comments on this research. We are similarly indebted to the sound group at the University of Maryland and the audience of the 12th Conference on Laboratory Phonology (July 2010, Albuquerque, New Mexico) for helpful discussion. We also thank Ariane Rhone for helping prepare the stimuli and Max Ehrmann for laboratory assistance.

Abstract: The purpose of this study was to examine the effects of an intensive voice treatment (Lee Silverman Voice Treatment, commonly known as LSVT LOUD) for children with spastic cerebral palsy (CP) and dysarthria. A nonconcurrent multiple baseline single-subject design with replication across 5 children with spastic CP was used. Auditory-perceptual analysis of speech, acoustic measures of vocal functioning, and perceptual ratings by parents of participants were obtained at baseline, posttreatment, and 6-week follow-up recording sessions. Listeners consistently preferred the speech samples taken immediately posttreatment over those taken during the baseline phase for most perceptual characteristics rated in this study. Changes in acoustic measures of vocal functioning were not consistent across participants and occurred more frequently for maximum performance tasks as opposed to speech. Although parents of the treated participants reported an improved perception of vocal loudness immediately following treatment, maintenance of changes at 6-week follow-up varied across the participants. No changes were observed in the 5th participant, who did not receive treatment. These findings provide some preliminary observations that the children with spastic CP in this study not only tolerated intensive voice treatment but also showed improvement on select aspects of vocal functioning. These outcomes warrant further research through Phase 2 treatment studies.

Full text: Headnote

Purpose: The purpose of this study was to examine the effects of an intensive voice treatment (Lee Silverman Voice Treatment, commonly known as LSVT LOUD) for children with spastic cerebral palsy (CP) and dysarthria.

Method: A nonconcurrent multiple baseline single-subject design with replication across 5 children with spastic CP was used. Auditory-perceptual analysis of speech, acoustic measures of vocal functioning, and perceptual ratings by parents of participants were obtained at baseline, posttreatment, and 6-week follow-up recording sessions.

Results: Listeners consistently preferred the speech samples taken immediately posttreatment over those taken during the baseline phase for most perceptual characteristics rated in this study. Changes in acoustic measures of vocal functioning were not consistent across participants and occurred more frequently for maximum

performance tasks as opposed to speech. Although parents of the treated participants reported an improved perception of vocal loudness immediately following treatment, maintenance of changes at 6-week follow-up varied across the participants. No changes were observed in the 5th participant, who did not receive treatment. Conclusions: These findings provide some preliminary observations that the children with spastic CP in this study not only tolerated intensive voice treatment but also showed improvement on select aspects of vocal functioning. These outcomes warrant further research through Phase 2 treatment studies.
Key Words: cerebral palsy, voice treatment, LSVT LOUD
Speech disorders have been reported to occur in children with spastic cerebral palsy (CP; Workinger &Kent, 1991); however, reliable prevalence figures have not been documented (Pennington, Miller,&Robson, 2009). The most common perceptual characteristics include consistent hypernasality, breathy voice quality, monotonous speech, reduced loudness, and uncontrolled rate and rhythm of voice (Workinger &Kent, 1991). Disordered respiration characterized by short vowel durations, shallow inspirations, and forced expirations also has been reported (Clement &Twitchell, 1959; Solomon &Charron, 1998). In addition, disordered articulation has been described in these children (Clement &Twitchell, 1959; Hixon &Hardy, 1964). There are limited efficacy data on speech treatment for children with CP; hence, there is a great need for research in this area (Pennington et al., 2009).

Advances in clinical neurorehabilitation have documented key elements of motor learning and principles that drive activity-dependent neuroplasticity (i.e., modifications in the central nervous system in response to physical activity), such as intensive treatment, repetitive active practice, and sensory feedback associated with movement. These elements may have merit in the context of successful treatment paradigms for adults and children with neurological disease or impairments (Garvey, Giannetti, Alter, &Lum, 2007; Kleim &Jones, 2008; Kleim Jones, &Schallert, 2003; Maas et al., 2008). Moreover, there is a growing focus in speech treatment research to translate principles of both motor learning and activity-dependent neuroplasticity into protocols for treatment of motor speech disorders in children and adults (Ludlow et al., 2008; Maas et al., 2008).

Previous studies have documented that children with CP are capable of intensive treatment regimes and that initial fatigue may be due to deconditioning effects that often decrease over time (Bower, McLellan, Arney, &Campbell, 1996; Schindl, Forstner, Kern, &Hesse, 2000). Research also has shown that the use of task-specific, repetitive practice and active practice along with increased numbers of practice trials results in marked improvements in gait (Damiano, Kelly, &Vaughan, 1995; Schindl et al., 2000), grip force production (Valvano &Newell, 1998), and anticipatory grip force precision (Gordon &Duff, 1999) in children with CP. In addition, enhanced sensory input and active attention to sensory feedback during practice may facilitate neuroplastic changes of cortical sensorimotor maps, which is thought to foster internal representations for movement important for carryover and maintenance of the new target behavior, such as reaching (Hadders- Algra, 2000; Hadders-Algra, van der Fits, Stremmelaar, &Touwen, 1999; Lenz &Byl, 1999).

Current speech treatment methods for children with CP and dysarthria are varied but typically use a systems approach to address respiration, phonation, articulation, and resonance (Pennington et al., 2009). Recently reviewed observational studies of speech interventions for children with dysarthria indicated that teaching slow, loud speech may be associated with improvements in speech intelligibility, voice quality, and clarity (Pennington et al., 2009). For example, Pennington, Miller, Robson, and Steen (2010) reported on 16 children with CP and dysarthria who received intensive treatment consisting of three 35- to 40-min sessions a week for 6 weeks, focusing on controlling breath support, phonation, and rate. Improvements were documented in single-word and connected speech intelligibility for both familiar and unfamiliar listeners.

A model of speech treatment, known as LSVT LOUD (Lee Silverman Voice Treatment), has been developed for individuals with Parkinson's disease (PD) and has documented efficacy for that population (Ramig et al., 2001). The training mode of LSVT LOUD is consistent with principles that drive activity-dependent neuroplasticity and motor learning (Fox et al., 2006). LSVT LOUD incorporates enhancement of the voice source, consistent with

improving the carrier in the classic engineering concept of signal transmission (Titze, 1993) and using vocal loudness as a trigger for distributed effects across the speech production system (Dromey &Ramig, 1988; Sapir, Spielman, Ramig, Story,&Fox, 2007). The extent towhich the effects of LSVT LOUD are specific to hypokinetic dysarthria is not clear. However, positive outcomes in acoustic measures (e.g., vocal sound pressure level [SPL]) and listener perceptions (e.g., articulatory precision) have been reported post-LSVT LOUD from single-subject and case studies of adults with spastic and ataxic types of dysarthria (Sapir et al., 2001, 2003).

The idea of targeting vocal loudness or respiratory- phonatory effort in treatment of dysarthria is not new. Establishing a respiratory-phonatory foundation before addressing other speech subsystems is consistent with approaches recommended for treating motor speech disorders that (a) create a single-motor organizing theme, (b) have a maximum impact on other aspects of speech production, and (c) increase effort across the speech mechanism (Duffy, 1995; Rosenbek &LaPointe, 1985; Yorkston, Beukelman, &Bell, 1988). Moreover, it has been recommended that treating respiratory-phonatory support for speech should occur first or at least co-occur with any focused articulation treatment in children with motor speech disorders (Strand, 1995). The unique aspect of LSVT LOUD is the singular target of training healthy vocal loudness (respiratory-phonatory effort) to the exclusion of targeting rate, articulation, and resonance.

The singular training target of healthy vocal loudness may be desirable for children with spastic CP. These children have disordered voice characteristics, which may be due to muscle weakness or incoordination of respiratory and laryngeal subsystems (Ansel &Kent, 1992;Workinger&Kent, 1991). The single focus on vocal loudness limits cognitive demands associated with treatment, which may be important for children with low-average to below-average cognitive functioning. Finally, the target vocal loudness trained in LSVT LOUD is elicited through modeling behavior (e.g., "do what I do"), which minimizes explicit verbal instructions and may allow the child's system to implicitly self-organize in order to achieve the goal (Schmidt &Fitzpatrick, 1996). Further, LSVT LOUD addresses criticisms of previous behavioral treatment studies in children with CP, for example, that (a) treatment was not delivered in a standardized manner, (b) dosages of treatment were not discrete, and (c) techniques were often combined (Butler &Darrah, 2001). LSVT LOUD minimizes these issues through a protocol of specific daily exercises prescribed for the entire treatment regime, a finite period of treatment, and a single treatment focus on vocal loudness.

The purpose of this Phase 1 treatment study was to examine any therapeutic effects of delivering LSVT LOUD in children with spastic CP and dysarthria (Robey &Schultz, 1998). The specific questions related to this purpose are as follows: (a) Do listeners prefer posttreatment over baseline speech samples of children with CP on a number of perceptual characteristics of voice and speech; (b) will intensive voice treatment affect the vocal motor system of children with spastic CP and dysarthria as evidenced by changes in acoustic measures of voice; (c) do parents perceive changes in perceptual voice and speech characteristics after intensive voice treatment; and (d) do treatment effects, if any, last over time?

Method

Participants

Five children between the ages of 5 and 7 years with a medical diagnosis of predominantly spastic CP were recruited. Characteristics of each participant are detailed in Table 1. Additional selection criteria included (a) dysarthria; (b) hearing that was within normal limits or aided to normal limits; (c) no vocal fold pathology as determined by an otolaryngologist; (d) ability to follow directions for the study tasks; and (e) stable medications, if applicable. Children with severe velopharyngeal incompetence, structural disorders of the speech mechanism, or a concomitant speech disorder (e.g., stuttering) were excluded. The medical diagnosis of spastic CP was confirmed by review of medical records. The characteristics and severity of dysarthria were determined by consensus of two certified speech-language pathologists from audio and video samples of participants with CP. Ayoked group of typically developing, sex- and agematched children was recruited to participate in this study. This allowed for a direct comparison between performance of participants with CP and their matched peers,

because data were collected using the same tasks and methodology. The typically developing peers had no known neurological disease or condition and no history of speech or voice disorders. Their ages and pairings with participants with CP are listed in Table 1.

Design

This study used a nonconcurrent multiple baseline design with replication across subjects (Barlow &Hersen, 1984; Watson &Workman, 1981). In this design, the treatment variable (intensive treatment) was applied sequentially to the same behavior (vocal output) across different but matched subjects sharing the same environmental conditions. In a nonconcurrent design, the length of the baseline phase is varied (some short and some longer) and predetermined (Watson &Workman, 1981). When participants became available, they were randomly assigned to one of the predetermined baseline conditions. This provided flexibility for conducting the research within real-world constraints while maintaining the internal validity achieved with a concurrent design (i.e., controlling for history or maturation variables; Watson &Workman, 1981).

Procedures

Participant Selection

A telephone screening questionnaire was completed with parents of potential participants followed by a faceto-face screening session with the child. All the parents signed a consent form, and children signed an assent document agreeing to participate. This study received approval from the University of Arizona Institutional Review Board. The screening session included (a) a brief voice and speech screening, (b) an assessment of abilities to follow directions related to the study tasks, and (c) a hearing screening (500 Hz, 1000 Hz, 2000 Hz, and 4000 Hz at 25 dB HL). In addition, a laryngeal examination was conducted by an otolaryngologist to ensure that no laryngeal pathology (e.g., vocal nodules or paralysis) existed. All five participants completed the entire study.

Study Conditions

Participants were randomly assigned to one of four study conditions with varying durations of baseline phases according to the nonconcurrent study design. A minimum of four baseline recordings were planned across ConditionsA(2-week baseline),B(3-week baseline), and C (4-week baseline). Participant assignment to study conditions and the actual number of recording sessions are summarized in Table 1. These conditions all included 16 treatment sessions (4 sessions a week for 4 consecutive weeks), two recording sessions 1 week immediately following treatment (POST), and two recording sessions 6 weeks after the conclusion of treatment (FUP). ConditionD matched Condition A except no treatment was delivered. Treatment was administered to the participant in Condition D following the final FUP recording session. The inclusion of an untreated participant with CP was to document potential maturational changes that may occur during the study period and affect interpretation of the results (Stiller, Marcoux,&Olson, 2003).

Recording Sessions

Equipment and setup. Data collection procedures were identical for all baseline (BASE), posttreatment (POST), and follow-up (FUP) recording sessions. Duration of recording sessions ranged from 30 min to 1 hr. Data were collected in an Industrial Acoustics Company sound-treated booth, and all sessions were videotaped. Four of the participants were comfortably seated in their ownwheelchairs.One participant sat in an adaptive chair. Audio recordings were made with the participant wearing a small omni-directional condenser microphone (Audio-Technica,Model AT 803b) taped to his or her forehead and secured with a soft, elastic cloth headband. The distance fromthe corner of the child's mouth to his or her forehead was measured for placement of the microphone at each recording session. This allowed for a constant mouth-to-microphone distance of 4 in. within and across recording sessions. Microphone signals were recorded onto a digital audiotape (DAT) recorder (Panasonic Digital Audio Tape Deck, Model SV-3500). Calibration signals were recorded at the beginning and end of each session by securing the omni-directional condenser microphone and sound level meter (SLM) microphone to a Styrofoamhead at a distance of 4 in. from the mouth of the head,mimicking the setup on the

child.Atone generator (KORGAut°Chromatic Tuner, AT-12) was placed in the same plane as the Styrofoam head's mouth. The generated tone (960.5 Hz) was recorded to the DAT, and the exact sound pressure level (dB SPL) reading from the SLM was recorded.

Data were collected by four graduate students and the first author, who were well trained in the experimental protocol. The investigator who delivered treatment (the first author) did not collect POST or FUP data. All attempts to keep the student data collectors blinded to the purpose of the study were made; however, there were occasions when the participants revealed aspects of the treatment they received. All data collectors were trained to keep the same demeanor and instructions regardless of the participants' comments.

Voice and speech tasks. The protocol included two maximum performance tasks, including a sustained vowel and maximal frequency range for vowels, as well as a sentence repetition task (Kent &Kent, 2000; Kent, Kent, &Rosenbek, 1987; Rvachew, Hodge, &Ohberg, 2005). For the maximal performance tasks, instructions were "Take a deep breath and say 'ah' for as long as you can," and "Take a deep breath and say 'ah' as high/low as you can." The data collectors were careful to use specific instructions that encouraged maximum performance for duration and frequency range but never gave any specific instructions or cues related to vocal loudness. Multiple repetitions of each task (average of six trials)were elicited during each recording session to ensure that maximum performancewas captured (Kent et al., 1987). The speech task involved repeating the sentences "Buy Bobby a puppy," "The potato stew is in the pot," and "The blue spot is on the key" three times at each recording session. The instructions were as follows: "I am going to say some sentences. After I say the sentence, I will point to you and I want you to repeat what I say." Data collectors were careful to model the sentences consistently across sessions and without exaggerated loudness, articulation, or pitch inflection. These sentences were not trained during the treatment phase of the study. The order of presentation of maximum performance and sentence repetition tasks was randomized across all recording sessions.

Parent rating forms.Avisual analog scale (Kempster, 1984; Schiffman, Reynolds,&Young, 1981) was filled out by one of the participant's parents at BASE, POST, and FUP sessions. This scale obtained ratings on 10 variables related to voice (loud, nasal, hoarse/scratchy, monotone, breathy, strained), speech (speaks so others can understand), and spoken communication (talks when playing with other kids, starts talking with other kids, frustrated when talking). The scale required the parent to place a vertical slash through a solid horizontal line (15.2 cm) that represented a continuum ranging from continuous presence of a characteristic, "Voice is always loud enough," to complete absence of a characteristic, "Voice is never loud enough." Parents were instructed to make their ratings based on perceptions of their child's speech "most of the time" versus their perception on the day of the recording session.

Intensive Voice Treatment

LSVT LOUD treatment consisted of 16 individual 1-hr treatment sessions delivered on 4 consecutive days each week for 4 consecutive weeks. Homework and carryover exercises were assigned every day during the month of treatment. All treatment was delivered by an expert LSVT LOUD clinician (the first author). All treatment sessions were conducted in the participant's home. The first half of each treatment session consisted of three daily tasks: (a) maximum duration sustained vowels, (b) maximum frequency range, and (c) repetition of 10 functional phrases (generated by the participant and his or her family) five times each. The second half of treatment sessions was spent on a speech hierarchy progressing in difficulty from single words to conversational speech. In the case where a child had reduced verbal output (one- to four-word phrases), the progression went from structured to less structured tasks (e.g., naming pictures to playing games requiring spontaneous speech output). All exercises included a minimum of 15 repetitions of each training task while incorporating sensory augmentation, such as cueing increased vocal effort and loudness, and sensory awareness by asking the children, "Did you feel your voice? Did you hear how you sounded?" Children practiced one homework session on treatment days (lasting 5-10 min) and two homework sessions on nontreatment days (lasting 10- 15 min). Daily carryover exercises were specific assignments to use the new

target voice with someone in the child's daily living environment-for example, "Say good morning to the bus driver using your 'loud' voice." The impact of the carryover assignment was discussed in the next treatment session (e.g., "Did the bus driver understand you yesterday?"). Family members assisted the child in completing homework and carryover assignments. All participants and family members were encouraged to continue homework routines at the conclusion of treatment.

Participation of Typically Developing Peers

The typically developing peers participated in two recording sessions in 1 week's time, completing the same tasks as the participants with CP. These children did not participate in the laryngeal examination or the treatment phase of this study.

Analysis

Auditory-Perceptual Data (Listener Task)

A group of seven certified speech-language pathologists who had extensive experience in the areas of motor speech disorders and voice served as judges in a paired comparison listening task. Three repetitions of the sentences "Buy Bobby a puppy," "The blue spot is on the key," or "The potato stew is in the pot" from the final BASE, POST, andFUPrecording sessions were included for speech samples. These final sessions were chosen to ensure that each child would have the greatest familiarity with the task across the study phases. Speech samples containing three repetitions of each of the sentences were constructed for BASE, POST, and FUP sessions. The order of presentation of speech samples was randomized across study phases (e.g., BASE vs. POST or FUP vs. BASE).

Listening task. Paired speech samples were presented to listeners via a computer and external speakers. They rated which sample they "preferred" for the following variables: (a) overall loudness, (b) loudness variability, (c) overall pitch, (d) pitch variability, (e) overall voice quality, and (f) articulatory precision. Listeners marked on a rating form which sample they "preferred," Sample A, Sample B, or no preference. A listening CD was created for each participant. Practice speech samples, consisting of two randomly selected pairs for that child, were provided, during which the listener could adjust the volume control on the speakers to a loudness level that was comfortable. Once the volume control was set for a given participant, it did not change at any time during the listening task for that participant. Listeners were allowed to replay the samples as many times as they wanted prior to making their decision and were given the option to provide comments about why they chose one speech sample over another. The listening task took approximately 2 hr to complete. The number of times a speech sample was preferred from the BASE session, POSTsession, or FUP session or there was "no preference" (NP) was tabulated.

Statistical analysis. Auditory-perceptual data were analyzed using two chi-square tests on the categorical assignment of preference for each participant. The first chi-square test assessed the categorical assignment of preference for BASE versus POST versus NP. The second chi-square assessed the categorical assignment of preference for BASE versus FUP versus NP. Differences in the proportional distribution of preference for three preference categories were examined for each participant, based on an a priori probability model of equal likelihood of all three categories.

Acoustic Data

Data preparation and digitizing procedures. All acoustic data were reviewed, and problematic samples, such as clipped signals (approximately 10-15 samples across all participants and sessions) and faulty microphone signals (one recording session for two participants), were excluded. Data from the DAT tapes were digitized at 22.05 kHz with the commercial software program Praat (Boersma &Weenick, 2002). Each sample of a sustained vowel, high vowel, low vowel, or sentence repetition was saved in an individual .wav file. The calibration tone for each recording session was analyzed for dB SPL. The value of the calibration tone from Praat was subtracted from the recorded SLM value, creating a correction factor. The correction factor was applied to all dB SPL values produced by Praat, providing calibrated dB SPL at 4 in. across all participants and

recording sessions.

Measurements. Vowel samples (longest, highest, lowest) from each session were displayed using Praat. Both the acoustic waveform and spectrogram, including intensity (dB SPL) and pitch (F0 in hertz) contours, were displayed for analysis. All acoustic measures were derived from standard Praat algorithms. The following measures were made for sustained vowel phonation: (a) maximum vowel duration (s) from the first to the last glottal pulse, (b) mean dB SPL (and SDs) from the first to the last glottal pulse, and (c) harmonics-to-noise ratio (HNR) selected from the middle 0.30-s segment of each vowel. For the highest and lowest vowel phonations, the acoustic waveform and pitch contours were inspected for any variations in voicing that interfered with the pitch tracking analysis, such as glottal fry. Aberrant segments were cut, and the F0 range was derived (maximum F0 - minimum F0) from the remaining pitch contour. Each digitized sentence repetition was filtered through a customized analysis program (Mathworks, code written by B. Story, 2002) that removed pauses and voiceless consonants. The acoustic waveforms, intensity contour (dB SPL), and pitch contour (Hz) of the filtered files were displayed using Praat. Pitch contours were inspected for any variations in voicing that interfered with the pitch tracking analysis, and aberrant segments were cut. The remaining voiced segment of the sentences was analyzed for mean (with SD) dB SPL and F0 range (maximum F0 - minimum F0) at each recording session.

Using the measures described above, we identified and graphed for visual analysis the following values from each recording session: (a) the duration of the single longest sustained vowel (s), (b) the maximum F0 range (Hz) from the single highest and lowest vowels, (c) the mean (and SD) dB SPL of the three longest vowels, (d) the mean (and SD) HNR of the three longest vowels, (e) mean (and SD) dB SPL of nine sentence repetitions, and (f) mean F0 range of nine sentence repetitions. The three longest duration vowels from each recording session were chosen for dB SPL and HNR of sustained phonation analysis to capture variability in trial-to-trial performance, versus only including the single "best" performance of the task (longest duration). Grand means (and SDs) also were calculated for each participant across BASE, POST, and FUP sessions. These data were used to compare performance of each participant with CP to mean (and SD) data of his or her yoked typically developing peer.

Visual analysis. Visual inspection was completed by three independent judges who did not have any contact with the children in the study. A total of 30 data graphs (six graphs per participant) of acoustic variables were visually analyzed for trend and overlapping data points (Barlow &Hersen, 1984). On the few occasions when there was disagreement between judges, the majority ruled (two of three).

Statistical analysis. Statistical analysis was applied according to the following rules: (a) if there was clear visual evidence of no treatment effect, defined as no variability in baseline data, no visual trends, and overlapping data points across all study phases, then no statistic was applied; (b) if there was clear visual evidence of a treatment effect, defined as a visual trend with no overlapping data points between study phases, statistics were used to confirmthe effect; and (c) if there was unclear evidence of a treatment effect, defined as a visual trend with overlapping data points, or no visual trend with variable baseline data, statistics were applied to ascertain whether there was a possible treatment effect not evident through visual inspection of the graphed data.

We began our statistical analysis by checking for serial dependency in the data by running a lag-1 auto-correlation (Pearson) on neighboring data points in the baseline. If there was no significant auto-correlation, then we averaged data in each phase and conducted a one-way, repeated-measures analysis of variance (ANOVA). Least significant differences were used for post hoc comparisons. If baseline data were significantly correlated, then a split-middle binomial probabilities test was applied (Siegel, 1956). A lenient post hoc analysis and p value of $<.05$ for significance was chosen, allowing liberal tolerances for Type I errors, consistent with Phase 1 treatment research goals (Robey&Schultz, 1998). Effect size calculations were derived using a modified Cohen's d statistic (Busk&Serlin, 1992), as suggested by Beeson and Robey (2006) for use with single-subject research designs. For comparison of participants with CP with their typically developing peers, a

difference in mean beyond 2 SDs was considered significant.

Parent Rating Forms

Standard procedures for analysis of visual analog scales were used (Boeckstyns &Backer, 1989). The total distance of the line (15.2 cm) representing the continuum of presence or absence of a characteristic was measured. The distance of the slash on the line from right end of the continuum was measured and calculated into a percentage based on the total distance of the line (Fox &Ramig, 1997). This percentage represents the parents' perceived presence of a particular characteristic in the child with CP "most of the time." Difference scores from BASE to POST and BASE to FUP were calculated. Given that there was only a single data point at BASE, POST, and FUP for parent ratings, statistical analyses were not applied.

Reliability

Auditory Perceptual Analysis

We determined intrarater reliability for the seven listeners by repeating 30% of the paired speech samples per participant in the listening task. Intrarater reliability across listeners ranged from 74% to 89%.

Acoustic Analysis

We calculated measurement reliability by having 20% of the data reanalyzed by a second measurer. Mean difference scores (MDs) and Pearson product- moment correlations (r) were calculated. Intermeasurer reliability scores were as follows: duration,MD= 0.005 s, r = .99; F0 range, MD = 28.5 Hz, r = .99; dB SPL of sustained phonation, MD = 0.03 dB SPL, r = .99; HNR of sustained phonation, MD = 0.01 dB SPL, r = .94; dB SPL of sentences, MD = 0.08 dB SPL, r = .99; F0 range of sentences, MD = 6.03 Hz, r = .90. These values represent good intermeasurer reliability.

Visual Analysis

We determined intrarater reliability for the three judges who visually examined data by randomly selecting 10 of the 30 graphs for repeated analysis. The intrarater reliability ranged from 98% to 100%. We determined interrater reliability by comparing agreements among the three raters. Interrater reliability was 94.7%.

Parent Ratings

We determined intrarater reliability of parent perceptual ratings by repeating a visual analog scale at one additional BASE, POST, or FUP recording. Intrarater reliability was available for all participants' parents except Participant 1 (P1). Mean difference scores (MDs) and Pearson product-moment correlations (r) were calculated. Intrarater reliability fell in the following ranges: MD = 7.00%-0.47% (0%-100% scale), r = .68-.90.

Results

Auditory-perceptual data and chi-square analyses are displayed in Table 2. The number of preference choices per BASE, POST, FUP, or NP (3 Sentence Pairs ×7 Listeners = 21 total choices per perceptual variable) and the accompanying statistic are listed. All acoustic data are displayed in Table 3. Effect size (ES) was commensurate with observed direction of change and statistical significance in all but one case (P1, dB SPL for sustained phonation). Judgments regarding magnitude of the ES were not made due to the Phase 1 nature of the study (Beeson &Robey, 2006). Difference scores across study phases of parent perceptual ratings (expressed in percentages) are displayed in Table 4. Positive and negative values reflect perceptions of improvement or deterioration, respectively.

Data for P1

Listener Ratings

Chi-square analysis revealed statistically significant preferences for the POST over BASE samples across all perceptual variables except loudness variability. These preferences were not maintained at FUP. Listener comments for preference of POST samples included "louder," "more variable," "pitch more stable," "natural," "less strain," "decreased nasal emissions," "more crisp," and "less effort." Comments for preference of BASE samples included "more consistent loudness," "louder," and "less gurgle."

Acoustic Analysis

The measures for which a visual treatment effect was observable and for which a statistically significant difference was found included maximum F0 range from BASE to POST and maximum duration "ah" from BASEtoFUP. P1 was 2SDs below the mean values of his matched typically developing peer at BASE, POST, and FUP for all variables except dB SPL and F0 range of sentence repetition at all phases.

Parent Ratings

Perceptual variables with the greatest percentage increase from BASE to POST included "always loud enough" (44%) and "never breathy voice" (31%). These percentage increases from BASE to FUP were not maintained at 5% and 2%, respectively.

Data for P2

Listener Ratings

Chi-square analysis revealed statistically significant preferences for both POST over BASE and FUP over BASE samples for overall loudness, loudness variability, pitch variability, and overall voice quality. Listener comments for preference of POST or FUP samples included "louder," "more variable," "not strained," "less monotone," "more precise," and "less hoarse." Comments when a BASE sample was preferred over FUP included "not yelling," which referred to her FUP repetition of "Buy Bobby a puppy."

Acoustic Analysis

The measures that had a visual treatment effect and also were statistically significant included maximum duration "ah," maximum F0 range, dB SPL of sustained phonation, dB SPL of sentence repetition from BASE to POSTand BASE to FUP, and F0 range for sentence repetition from BASE to FUP. P2 was 2 SDs below the mean value of her matched typically developing peer for all variables at BASE, POST, and FUP except dB SPL of sustained phonation, and F0 range of sentence repetition at POST and FUP. She was 2 SDs above the mean value for dB SPL of sentence repetition.

Parent Ratings

Perceptual variables with the greatest percentage increase from BASE to POST included "always loud enough" (39%) and "never breathy voice" (39%). These percentage increases from BASE to FUP were maintained at 40% and 39%, respectively.

Data for P3

Listener Ratings

Chi-square analysis revealed statistically significant preferences for the POST over BASE samples for all variables except overall pitch. Preference for loudness variability and overall voice quality were maintained at FUP. Listener comments for preference of POST or FUP samples included "more precise," "louder," "consistent loudness," "less breathy," "less strain and strangle," and "clearer voice quality."

Acoustic Analysis

The measure that had a visual treatment effect, which also was statistically significant, was maximum sustained "ah" from BASE to FUP. P3 was 2 SDs below the mean value of his matched typically developing peer for all variables at BASE, POST, and FUP, except for HNR of sustained phonation and dB SPL and F0 range of sentence repetition at all study phases.

Parent Ratings

Perceptual variables with the greatest percentage increase from BASE to POST included "always loud enough" (33%) and "never strained voice" (28%). These percentage increases fromBASEtoFUPwere somewhat maintained at 23% and 19%, respectively.

Data for P4

P4 was unable to repeat entire sentences; therefore, he repeated the last word of each sentence ("puppy," "pot," "key") during the sentence repetition task. There are no data for sentence repetition at BASE 2 due to P4's unwillingness to perform the task and at FUP 2 due to microphone failure.

Listener Ratings

Chi-square analysis revealed statistically significant preferences for the POST over BASE single-word repetition samples across all six perceptual variables rated. Preference for overall loudness, loudness variability, and overall voice quality were maintained at FUP. Listener comments for preference of POST or FUP samples included "louder," "more variable," "less breathy," "less pressed," "easier for child to produce," "more precise," and "more natural pitch."

Acoustic Analysis

The measures that had a visual treatment effect and also were statistically significant included maximum F0 range from BASE to POST and maximum F0 range, HNR of sustained phonation, and dB SPL of his singleword repetition from BASE to FUP. P4 was two SDs below the mean value of his matched typically developing peer for all variables at BASE, POST, and FUP, except for maximum F0 range at all phases and dB SPL of sentences at POST and FUP.

Parent Perceptual Ratings

The perceptual variable with the greatest percentage increase from BASE to POST was for "always loud enough" (33%). The second largest percentage change was in a negative direction reflecting an increase in the perception of a "hoarse, scratchy voice" (-31%). Data for FUP measures from the same parent who completed the BASE and POST ratings were not available.

Data for P5

P5 was an untreated comparison participant in this study. Therefore, the study phases of POST and FUP were actually additional BASE recordings following 1 month and an additional 6 weeks of no treatment.

Listener Ratings

Chi-square analysis revealed statistically significant preferences for the NP category for all variables rated from BASE to POSTand for overall loudness, overall pitch, and articulatory precision at the FUP session.

Acoustic Analysis

The measure that had a visual treatment effect and also was statistically significant was a decreasing performance for maximum F0 range from BASE to POST. P5 was 2 SDs below the mean value of her matched typically developing peer for all variables at BASE, POST, and FUP except maximum duration at all phases, maximum F0 range at BASE, and dB SPL of sustained phonation at BASE and FUP.

Parent Ratings

The perceptual variable with the greatest percentage increase from BASE to POSTwas for "never hoarse, scratchy voice" (26%). The next largest percentage change was a decrease (worsening) for the perception of "always speaks so others can understand" (-30%). Data for FUP measures from the same parent who completed the BASE and POST ratings were not available.

Discussion

This Phase 1 treatment study examined the effects of an intensive voice treatment in children with spastic CP and dysarthria. A nonconcurrent single-subject multiple baseline design with replication across participants was used. Listeners preferred POST speech samples for loudness, pitch variability, and voice quality over BASE speech samples in all four treated participants. Treated participantsmade a significant gain in at least one acoustic measure during maximum performance tasks; improvements were not as frequently observed for speech. All parents rated an improved percentage for "always loud enough" from BASE to POST. Maintenance of these perceptual and acoustic changes atFUP varied across participants and are detailed below. The untreated participant did not make improvements over the course of the study. The implications of these findings and directions for future research are discussed below.

Listener Preferences

Listeners preferred POST over BASE speech samples from the sentence repetition task for most of the perceptual variables rated, including five of six for P1, four of six for P2, five of six for P3, and six of six for singleword repetitions for P4. These listener ratings support an immediate therapeutic effect of the intervention.

However, these findings should be interpretedwith caution for a number of reasons. First, a lenient p value, which is consistent with Phase 1 treatment research goals, increased the potential for Type 1 error (treatment effect identified when none exists). Second, perceptual variables rated in this study were not specifically defined for the listeners. Although loudness, pitch, voice quality, and articulatory precision are standard perceptions, listeners may have interpreted these variables differently. Third, the intrarater reliability for some of the listeners was borderline acceptable. Finally, themodel for sentence repetitionwas provided by verbal output fromdata collectors. Although these data collectors were well trained on presentation style of the sentences, we cannot eliminate the possibility that differences in models may have affected the participants' speech. Future research using prerecorded samples, perhaps with animated characters to engage children (e.g., Test of Children's Speech by Hodge, Daniels, &Gotzke, 2006) would standardize this task presentation.

Acoustic Measures

Overall there were minimal changes in acoustic measures across study phases, with the exception of P2. In addition, most participants with CP were still 2 SDs below the mean performance of their typically developing peers for maximum performance tasks after treatment. These findings are consistent with those of Wit, Maassen, Gabreels, and Thoonen (1993), who reported that children with spastic CP were significantly reduced in their performance envelope compared with typically developing peers. These findings also are different from the pattern of results found in adults with PD who nearly always have large and significant changes in maximum performance tasks, which are trained targets in LSVT LOUD (Sapir, Ramig, &Fox, 2011). This was most likely related to the different etiology of the dysarthria in PDversus CP. In PD, the softvoice is often due to deficits in scaling amplitude of motor output and sensory perception of normal loudness (Sapir et al., 2011). Targeting vocal loudness in people with PD may cue or access a relatively intact motor system that is capable of scaling up output to produce normal vocal loudness. In CP, the softvoice is related to generalized weakness of respiratory and laryngeal systems, coupled with a lack of coordination between the respiratory and laryngeal subsystems (Ansel &Kent, 1992; Workinger &Kent, 1991). Thus, unlike in PD, there may be inherent neuromuscular limitations in CP that impact gains on tasks targeting the maximum performance envelope.

The acoustic variables measured for sentence repetition (mean vocal SPL and F0 range) may not have been adequate to capture what the listeners perceived in speech, when they preferred POST speech samples. Selecting different or additional acoustic measures in future studiesmay better capture potential changes in vocal motor functioning that underlie the listener-perceived changes. For example, including the entire speech envelope in vocal SPL analysis for sentences versus a focus on the voiced segments may capture the "whispered" elements of some participants' speech at the end of sentences. Although the acoustic measures did not document significant changes for most participants, written comments from listeners often indicated that children spoke with "less effort," "less strain and strangle," or "less of a struggle." These perceptions of decreased effort and strain are not reflected in measures of vocal SPL or F0 range and may have been the basis of listener preference of POST samples.

Using multiple strategies to detect change in singlesubject designs may provide the best interpretation of data. For example, P1 revealed no visual trend, no mean differences, and no effect size for dB SPL of sustained phonation, yet the split-middle technique revealed a statistically significant difference. In this case, the statistical detection of a true change is suspect. Conversely, P2 exhibited a visual trend, a statistically significant difference, and a relatively large effect size for POST and FUPduration of sustained phonation. In this case, a true change is likely. The interpretation of effect size in this study is limited. The ability to interpret effect sizes in single-subject designs requires averaging them across studies in order to establish meaningful effect size magnitudes for specific variables of interest for a given treatment approach (Beeson &Robey, 2006). Including effect size calculations in the current study will contribute to interpretation of outcomes from future studies.

Changes in Parent Ratings

Qualitative information from parent ratings identified improvement on some perceptual variables, which may

indicate a possible impact in the participant's daily living, outside of the laboratory setting. Parent ratings corroborated many of the listener perceptions of improvement immediately posttreatment. Although the parent ratings must be interpreted with caution, given the lack of replication, moderate intrarater reliability, and descriptive level of analysis, they are a step in the direction of assessing external validity of the findings. Future work should continue to address the perceived impact of treatment on family, friends, and teachers in the environment.

Did Treatment Effects Last?

Maintenance of listener preferences at FUP varied across participants. Listeners did not perceive P1 to have maintained any of the improvements in perceptual characteristics from BASE to FUP, but listeners perceived P2 to have maintained all of the improvements from BASE to FUP, P3 to have maintained two of the five improvements from BASE to FUP, and P4 to have maintained three of the six improvements from BASE to FUP. Perceptions of improvement that were maintained included those most closely related to the treatment target of voice (e.g., overall loudness, loudness variability, and overall voice quality). All acoustics measures showed maintenance or improvement of skill from BASE to FUP with the exception of F0 range for P1. Parent perceptual ratings at FUP were not maintained at POST levels for P1, but they were maintained for P2 and somewhat maintained for P3. FUP data were not available from the parents of P4.

The maintenance of treatment effects may have depended on multiple factors, such as acceptance of the treatment techniques and family support. Although we did not systematically log home practice in the 6-week interval between POST and FUP, parents reported on their child's progress. P2's parent indicated that she frequently reminded herself to use her loud/strong voice and she did so regularly in daily communication. P3's mother reported that if she could not understand her son, cueing him to repeat with his "strong voice" was a helpful strategy. P4 had four older siblings who constantly cued him to use his "big voice." For P1, changes in speech were not maintained according to listener and parent ratings. The parent reported that P1 was unwilling to practice on his own or with family members.

General Comments on Treatment Mode and Target

The intensive treatment protocol consistent with select principles of motor learning and activity-dependent neuroplasticity was well tolerated by all participants,with 100% compliance during the treatment phase. These findings are similar to those of Schindl et al. (2000) for an intensive gait-training program and Pennington et al. (2010) for intensive speech therapy for children with CP. According to parent report, physical fatigue occurred in most participants at the start of treatment; however, over time they reported that fatigue diminished. P1's parent even reported in later treatment sessions that he was "energized" and performed better on other tasks, such as physical therapy, when they occurred on the same day. Repeated active-practice trials in therapy were also well tolerated by participants with CP. Most of the treatment sessions were completed without breaks for rest.

The treatment target of vocal loudness was highly salient to the participants. At BASE, all parents reported concerns about their child's vocal loudness, citing "softspeech," "breathy, quiet voice," "maintaining loudness at end of sentences," and "whispered voice." At the same time, the speech-language pathologists reported that some of these children also had occurrences of "harsh voice quality" and "strained voice quality." We speculate that the poor voice quality that occurred prior to treatment may have been the result of compensatory strategies to overcome generalized weakness of respiratory and laryngeal musculature (Ansel &Kent, 1992). With treatment, the need for compensatory behaviors may have been diminished at POST and replaced with improved vocal strategies as indicated by listener comments of "less strain [or pressed or strangled]" for all four treated participants. This is similar to findings in individuals with PD after treatment with LSVT LOUD (Countryman, Hicks, Ramig, &Smith, 1997). To confirm these speculations, further study is needed in children with CP and dysarthria. Severity of dysarthria also may play a role in treatment success. The child with CP who demonstrated the greatest improvements across all acoustic measures in this study (P2) had the mildest rating of dysarthria. P3 differed slightly from the other participants in that he was described as having spastic- ataxic

dysarthria characterized by variable loudness. For this participant, listeners preferred POST and FUP speech samples on the measure of loudness variability, which is consistent with reported improved control over variable loudness post-LSVT in an adult with ataxic dysarthria (Sapir et al., 2003). For P4, the parents rated increased hoarseness at POST. This may be explained by the fact that, after therapy, P4 was voicing versus whispering, which may have made parents more aware of vocal quality. Increased hoarseness was not reported by listener perceptions of improved voice quality on single-word repetitions at POST and FUP or with reported HNR values.

Study Limitations and Future Directions

The single-subject design used for this study precludes generalization of these results to the population of children with spastic CP. The liberal tolerance of Type I errors may have overestimated some of the treatment outcomes. Adding a spontaneous speech task with a peer or parent interaction in a naturalistic environment would have been desirable. The inclusion of systematic monitoring of homework practice sessions would have been helpful for the interpretation of skills maintenance. Furthermore, there is a need for including ratings of speech intelligibility at a single-word and connected speech level (Pennington et al., 2010).

Future studies may investigate additional acoustic parameters of voice and speech. Examining potential physiological changes that may accompany treatment will provide insight into the mechanism of change. In addition, examination of alternative treatment targets (e.g., oromotor exercises or articulation) administered in a parallel mode and intensity will help delineate key elements of treatment success. Future studies are also required to determine duration of treatment effects (e.g., more than 6 weeks) and to delineate the most effective dosage. Finally, studies that engage a larger number of children with spastic CP are required to determine generalizability of treatment outcomes for this population.

Summary

Improving speech in children with CP is challenging. Many of these children have a range of medical problems, multiple speech mechanism disorders, and cognitive deficits, all of which may limit the magnitude and long-term effects of treatment outcomes. This Phase 1 treatment study (Robey &Schultz, 1998) examined a standardized treatment approach (LSVT LOUD) in children with spastic CP and dysarthria. Findings provide some preliminary support for intensive voice treatment to improve select aspects of vocal functioning in the children with spastic CP and dysarthria who participated in this study. Future Phase 2 treatment research studies are warranted.

Acknowledgments

This work was supported, in part, by National Multipurpose Research and Training Center Grant DC-01409 from the National Institute of Deafness and Other Communication Disorders and by the Final Project Fund from the Graduate College at the University of Arizona. This article is based on a doctoral dissertation completed by Cynthia Marie Fox at the University of Arizona under the direction of Carol Ann Boliek and Jeannette Hoit. We thank Jeannette Hoit, Brad Story, Leslie Tolbert, Becky Farley, and Lorraine Ramig for their expert advice. Special thanks go to the children and families who participated in this study.

Temporal and speech processing skills in normal hearing individuals exposed to occupational noise

Author: Kumar, U; Ameenudin, Syed; Sangamanatha, A

Publication info: Noise & Health 14.58 (May 2012): 100-5.
ProQuest document link

Abstract: Prolonged exposure to high levels of occupational noise can cause damage to hair cells in the cochlea and result in permanent noise-induced cochlear hearing loss. Consequences of cochlear hearing loss on speech perception and psychophysical abilities have been well documented. Primary goal of this research was to explore temporal processing and speech perception Skills in individuals who are exposed to occupational noise of more than 80 dBA and not yet incurred clinically significant threshold shifts. Contribution of temporal processing skills to speech perception in adverse listening situation was also evaluated. A total of 118 participants took part in this research. Participants comprised three groups of train drivers in the age range of 30-40 (n= 13), 41 50 (= 13), 41-50 (n = 9), and 51-60 (n = 6) years and their non-noise-exposed counterparts (n = 30 in each age group). Participants of all the groups including the train drivers had hearing sensitivity within 25 dB HL in the octave frequencies between 250 and 8 kHz. Temporal processing was evaluated using gap detection, modulation detection, and duration pattern tests. Speech recognition was tested in presence multi-talker babble at -5dB SNR. Differences between experimental and control groups were analyzed using ANOVA and independent sample t-tests. Results showed a trend of reduced temporal processing skills in individuals with noise exposure. These deficits were observed despite normal peripheral hearing sensitivity. Speech recognition scores in the presence of noise were also significantly poor in noise-exposed group. Furthermore, poor temporal processing skills partially accounted for the speech recognition difficulties exhibited by the noise-exposed individuals. These results suggest that noise can cause significant distortions in the processing of suprathreshold temporal cues which may add to difficulties in hearing in adverse listening conditions.

Full text: Introduction

One of the major causes of cochlear hearing loss especially in adults is noise. Prolonged exposure to high levels of noise results in noise-induced hearing loss. The prolonged exposure to high levels of noise causes damage to the hair cells in the cochlea and results in permanent noise-induced cochlear hearing loss. Noise damage to hearing is a health risk which is associated with both civilian and military occupations as well as certain leisure activities. Psychophysical evidence indicates that presence of cochlear hearing loss causes deficits in temporal processing. [1] Temporal processing encompasses a wide range of auditory skills including temporal resolution or temporal discrimination (i.e., gap detection and fusion), masking (i.e., backward and forward masking), temporal integration (i.e., temporal summation), and temporal ordering (i.e., temporal sequencing), as well as localization and pitch perception. [2] Normal perception of the temporal aspects of the stimulus is crucial for understanding speech in quiet and adverse listening conditions. [3] It has been shown that individuals with cochlear hearing loss perform poorly on tasks such as gap detection, modulation detection, and temporal integration. [1] One of the important factors that contribute to the poor performance hearing-impaired listeners on temporal processing tasks is audibility of high-frequency signals. [1] Apart from audibility, the suprathreshold distortions can also contribute to the poor performance of hearing-impaired listeners on temporal processing tasks. These suprathreshold distortions may be caused by changes in the central auditory system secondary to cochlear damage. Long-term exposure to high levels of occupational noise is shown to result in hemispheric reorganization for speech processing. [4] Brattico [5] showed that well-known left hemisphere dominance in speech discrimination became right hemisphere preponderant in individuals exposed to occupational noise. Chang et al[6] in animal model showed that when infant rat pups were reared in moderate levels of noise, it resulted in delay of organizational maturation of the auditory cortex.

Recently, it has been shown that cochlear damage can occur without significant reduction in sensitivity. Fneg et al[7] measured the temporal resolution and speech perception in adults with sloping high-frequency sensory neural hearing loss in regions of normal hearing. Temporal resolution was evaluated through amplitude modulation detection and gap detection in noise. Speech perception was assessed trough hearing in noise test. Results showed that individuals with sensory neural hearing loss performed poorly on both gap detection and modulation detection even though the stimulus was restricted to the regions of normal hearing. They hypothesized that the deterioration in temporal resolution in individuals with high-frequency sensory neural hearing loss is caused by central auditory deficits secondary to cochlear damage or subclinical cochlear damage in the lower frequencies. Evidences from the animal research also suggest that the cochlear lesion can occur without significant change in the hearing sensitivity. [8]

Consequences of cochlear hearing loss on speech perception and psychophysical abilities have been well documented. The aim of this study was to evaluate the speech recognition and temporal processing abilities of train drivers with normal hearing sensitivity who were exposed to continuous noise of more than Leq8h of 80 dBA of the engine for a period of more than 10 years.

Methods

We evaluated (1) gap detection in noise; (2) modulation detection for sinusoidally amplitude modulated noise at 8, 20, 60, and 100 Hz; and (3) duration pattern and speech recognition in the presence of multi-talker babble at -5 dB signal to noise ratio in individuals who were exposed occupational noise of more than Leq8 h of 80dBA. Results were compared with matched control group. Contribution of temporal processing skills to speech perception in adverse listening situation was also measured.

Participants

A total of 118 participants took part in this research. Participants comprised three groups of train drivers in the age range of 30-40 (n = 13), 41 50 (= 13), 41-50 (n = 9), and 51-60 (n = 6) years and their non-noise-exposed counterparts (n = 30 in each age group). Because both the temporal processing and speech perception are influenced by age, participants were subgrouped depending on age. Our earlier study has shown that temporal processing skills of individuals below 40 years were significantly different from those of elderly group. [9] All the members of the experimental group were exposed to railway engine noise for about 8-10 hours a day for a period of more than 10 years. The amount of leisure time varied between 1 and 3 hours. Noise survey showed that the engine noise at the level of the train driver's ear was Leq of 86 dBA. Participants of all the groups including the train drivers had hearing sensitivity within 25 dB HL in the octave frequencies between 250 and 8 kHz. None of the subjects reported any otological or neurological problems, usage of ototoxic drugs, or exposure to organic solvents.

Stimulus and procedure

Psychophysical tests

Gap detection and modulation detection were measured using "mlp" tool box which implements a maximum likelihood procedure in Matlab. [10] The maximum likelihood procedure uses a large number of candidate psychometric functions and after each trial calculates the probability (or likelihood) of obtaining the listener's response to all of the stimuli that have been presented given each psychometric function. The psychometric function yielding the highest probability is used to determine the stimulus to be presented on the next trial. Within about 12 trials, the maximum likelihood procedure usually converges on a reasonably stable estimate of the most likely psychometric function, which then can be used to estimate threshold. [11],[12] Stimuli were produced at 44,100 Hz sampling rate. A two-interval alternate forced choice method using a "maximum likelihood procedure" was used to track an 80% correct response criterion. During each trial, stimuli were presented in each of the two intervals: One interval contained a reference stimulus and the other interval the variable stimulus. The participant indicated after each trial which interval contained the variable stimulus. Stimuli for the duration pattern test were generated using Audacity software 1.3.5 (beta version 2008). In all of the

psychophysical tests, stimuli were presented binaurally at an intensity of 80 dB SPL. Stimuli were presented via a laptop computer (Lenovo 3000 G530) connected to EAR-3A earphones. Output of the earphones was calibrated at the beginning of the experiment and regularly thereafter to produce 80 dB SPL for a 1 kHz pure tone in a 2cc coupler. For this purpose, a 1 kHz pure tone was generated at the same root mean square (rms) level as the test signal. Output of the ear phone was routed to a 2cc coupler which was connected to a sound level meter (Quest 1800) and a microphone (Quest 4180). The volume control of the computer was adjusted to produce 80 SPL on the sound level meter. Subjects were given three to four practice trails before the commencement of each test. All psychophysical tests were carried out in a quiet room.

Gap detection in white noise

In this subjects, ability to detect a temporal gap in the center of 750 ms broadband noise was measured. Duration of gap was varied according to the listener performance using maximum likelihood procedure. The noise had 0.5 ms cosine ramps at the beginning and end of the gap. In two interval alternate force choice tasks, the standard stimulus was always a 750 ms broadband noise with no gap, whereas the variable stimulus contained the gap.

Modulation detection thresholds

Temporal modulation refers to a reoccurring change (in frequency or amplitude) in a signal over time. A 500 ms Gaussian noise was sinusoidally amplitude modulated at modulation frequencies of 8, 20, 60, and 200 Hz. Noise stimuli had two 10-ms raised cosine ramps at onset and offset. The subject had to detect the modulation and determine which interval had the modulated noise. Modulated and unmodulated stimuli were equated for total rms power. Depth of the modulated signal was varied according to the participant's response up to an 80% criterion level. The modulation detection thresholds were expressed in dB by using the following equation:

Modulation detection thresholds in dB = 20 log 10 m

where m = modulation detection threshold in percentage

Duration pattern test

The duration pattern test was administered in the manner described by Musiek et al. [13] A 1000 Hz pure tone was generated at 44,100 sampling frequency with two different durations (i.e., short 250 ms and long 500 ms) using Audacity software (ver. 1.3.5). By combining these two durations in three-tone patterns, six different patterns were generated (Short Short Long, Short Long Short, Long Long Short, Long Short Short, Short Long Long, Long Short Long). Interstimulus interval was 250 ms within a tone sequence and 6 s between two tone sequences. Following practice trails, 30 test items were administered. Participants were asked to verbally repeat the sequence.

Speech recognition with multi-talker babble

Speech recognition ability of the subjects was tested using a set of custom-made sentence material. Eighty sentences were constructed with a reasonable degree of homogeneity, complexity, and sentence length. Each sentence had four to five key words. These 80 sentences were provided to five native Kannada speakers (age range: 20-40 years) who had at least 15 years of formal education in Kannada. These five Kannada speakers served as judges. They were instructed to underline the key words and also to rate the complexity levels of the sentences on a five point rating scale (1, very difficult; 2, moderately difficult; 3, difficult; 4, easy; 5, very easy). Ten sentences were selected from this pool based on judge's ratings. The selected sentences had a 100% agreement among all the five judges in terms of the key word identification and the complexity level ratings. There were a total of 44 key words. Sentences used in the test are provided in Appendix I. A 23-year-old native male Kannada speaker spoke these sentences. Using the Praat software the spoken sentences were digitally recorded on a Presario C700 Compaq laptop in a sound treated room via a JVC MV 40 microphone. The sampling frequency was set at 44,100 Hz. Using a custom-written Matlab code, four-talker babble was added to the sentences at -5 dB SNR. The Matlab program first calculated the rms amplitude of the speech stimulus and then adjusted the rms of the four-talker babble to achieve the desired signal to noise ratio. These sentences

were randomly presented to the subjects at 80 dB SPL intensity through an insert EAR-3A earphones which were connected to a computer. Subjects were instructed to repeat the sentences. The repeated sentences were recorded and used for further analysis. Each correctly repeated key word was given a score of "1" and the total number of correct responses was calculated for each subject separately.

Results

Psychophysical tests

Gap detection in noise

[Figure 1] shows the mean and 1 SD error bars for gap detection thresholds in the experimental and control groups across different age groups. Two-way ANOVA was done to test the significance of differences between the mean gap detection thresholds of different groups. ANOVA did not reveal a significant main effect of noise exposure on the gap detection thresholds [$F(2,124) = 1.08$, $P > 0.05$].{Figure 1}

Modulation detection thresholds

[Figure 2]a shows the mean modulation detection thresholds for 8, 20, 60, and 200 Hz modulation frequencies along with the 1 SD of variation in experimental and control group in the age range of 30-40 years. The mean and standard deviation values of the modulation detection thresholds for 41-50 years and 51-60 years group are shown in [Figure 2]b and c, respectively. MANOVA was done to find the significance of differences between the means of modulation detection thresholds between experimental and control groups. MANOVA showed the significant main effect of participant groups on the modulation detection thresholds [$F(4,122) = 4.78$, $P0 < 0.01$]. Post hoc analysis with Bonferroni correction revealed that noise-exposed group had significantly poor modulation detection thresholds in higher frequencies (at 60 and 200 Hz modulation frequencies) in 30-40 years and 41-50 years.{Figure 2}

Duration pattern test

[Figure 3] shows the mean and 1 SD error bars for duration pattern scores. From [Figure 3], it can be seen that the experimental group had poorer duration pattern scores compared with control group in all the three groups. Two-way ANOVA showed a significant main effect of subject group on the DPT scores [$F(1,125) = 49.9$, $P < 0.01$]. Follow-up non-parametric independent sample t test revealed that the experimental group had significantly poorer duration pattern scores than their age-matched control group across all the three age groups [($t = 2.159$ and $= 2.159$ and $P0 < 0.05$ for 30-40 years age group), ($t = 2.323$ and $= 2.323$ and $P < 0.05$ for the 40-50 years age group), and ($t = 2.906$ and $= 2.906$ and $P < 0.05$ for the age group of 50-60 years)].{Figure 3}

Speech recognition with multi-talker babble

The speech recognition scores were converted into rationalized arcsine transferred scores [14] and all the statistical analysis was done on arcsine-transferred scores. [Figure 4] shows mean and standard deviation values for speech identification scores in experimental and control group. Two-way ANOVA revealed a significant main effect of subject groups on the speech perception scores [$F(1,125) = 51.8$, $P < 0.01$]. Follow-up non-parametric independent sample t test showed that the individual's ability to recognize speech in presence of noise was poor in noise-exposed participants compared with their age-matched control groups [($t = 4.836$ and $= 4.836$ and $P < 0.05$ for 30-40 years age group), ($t = 3.481$ and $= 3.481$ and $P < 0.05$ for the 40-50 years age group), and ($t = 2.422$ and $= 2.422$ and $P < 0.05$ for the age group of 50-60 years)].{Figure 4}

To study the relationship between speech recognition scores and temporal processing abilities, Pearson's Product Moment correlation analysis and multiple regression analysis were performed. For this purpose, data from all the age groups were combined. [Table 1] and [Table 2] show the results of multiple regression and correlation analysis. From the [Table 1] and [Table 2], it can be seen that gap detection in noise, modulation detection threshold at 200 Hz and duration pattern scores are significant predictors of speech recognition scores.{Table 1}{Table 2}

Discussion

Primary goal of this research was to explore temporal processing and speech perception skills individuals who

are exposed to occupational noise and not yet incurred clinically significant threshold shifts. Results revealed that both the temporal processing and speech perception skills were adversely affected in noise-exposed group. Given the present data, the observed deterioration in the temporal and speech processing skills in the noise-exposed individuals, in the presence of normal hearing sensitivity probably due to changes in the central auditory system was caused due to prolonged exposure to occupational noise. It has been reported that long-term noise may have persistent effect on brain function and behavior, even when the peripheral hearing sensitivity is within normal range. Persistent effects of long-term noise exposure on central auditory system were evaluated using auditory evoked potentials. Kujala et al. [4] assessed the performance in visuo-motor target tracking task and simultaneously recorded the mismatch negativity for /pa/ and /ka/ contrasts on healthy individuals who were exposed to high levels of occupational noise. All their subjects had hearing thresholds that were comparable to the control group. Results showed impaired syllable-discrimination in the left hemisphere of noise-exposed individuals in silence and increased N2b complex for the novel sounds. Furthermore, attention control and ability to focus on visuo-motor tasks were aberrant in noise-exposed group. These results suggest that long-term exposure to occupational noise effects both sound discrimination mechanism and attention control mechanism. Brattico et al[5] measured the neural responses in normal hearing, noise-exposed, and non-exposed participants to speech and non-speech deviants. Brain electrical source modeling suggested that speech sound contrast was lateralized to left hemisphere in non-noise-expose group but in right hemisphere in noise-exposed group. This group differences were not found for the non-speech deviants. These studies show that long-term occupational noise can have a detrimental effect on the central auditory system. This detrimental effect has been observed even when the peripheral hearing sensitivity is intact. The observed deficits in the temporal and speech processing abilities in normal hearing, noise-exposed individuals in this study may be due to compromised central auditory system in these individuals. However, we cannot totally exclude the deleterious effects of distorted cochlear input as a factor. Normal hearing sensitivity does not necessarily mean the normal functioning of the cochlea in noise-exposed individuals. Evidences from the animal research suggest that cochlear functioning can be affected even in the presence of normal-hearing sensitivity. [8] Since in this study otoacoustic emission testing was not carried out due to technical and logistic issues, it is difficult to rule out the possibility of subtle cochlear dysfunction. Kujawa and Liberman [8] reported a rapid and irreversible degeneration of spiral ganglion cells by the noise exposure which resulted in the temporary threshold shifts. Even after, hair cells and hearing sensitivity were recovered and neuronal loss persisted. Effects of such neuronal losses on auditory and speech processing are detrimental.

In general, a trend of reduced temporal processing skills was observed in individuals with noise exposure. Although gap detection thresholds and modulation detection thresholds for low modulation frequencies were not statistically different between noise-exposed and non-exposed group, nevertheless mean modulation and gap detection thresholds were slightly lower in the noise exposed group. Modulation detection thresholds for the high modulation frequency and duration pattern scores were significantly poorer in noise-exposed group compared with control group. In the auditory system, modulations are represented by phase locked neural discharges of the auditory nerve fibers to individual cycles of modulation frequency. Data from the animal research have shown that acoustic over exposure can cause acute loss of afferent nerve terminals and degeneration of cochlear nerve. This might cause disruption in the phase locking and synchronization in the discharge patterns of auditory nerve fibers causing poor modulation detection thresholds. Poor modulation detection thresholds for higher modulation frequencies suggest that noise-exposed individuals had difficulty in perceiving rapid fluctuations in the stimulus. Any complex broadband signals such as speech can be decomposed by auditory filters into relatively slow variations in the amplitude over time called envelop and relatively rapid oscillations called temporal fine structure. Importance of slowly varying temporal envelope in speech perception is well documented. [15] Recently, it has also been demonstrated that temporal fine structure plays a crucial role in hearing in the presence of background noise. [16] It is necessary to perceive the rapid

oscillations to derive benefits of temporal fine structure cues. Difficulty in perceiving rapid amplitude fluctuations in noise exposed group may also pose problems in coding temporal fine structure. This may be one of the reasons for poor performance of noise-exposed individuals in speech perception measures. It is also been suggest that speech is comodulated at the rate of fundamental frequency (in this study mean fundamental frequency of the target stimulus was 211 Hz). It is important to perceive these comodulations to perceptually separate target speech and background babble as different acoustic streams. Difficulty of noise-exposed individuals in perceiving the rapid amplitude fluctuations may limit their ability perceptually segregate target and background babble. [17] Duration pattern assess the auditory sequencing abilities. Auditory short-term working memory and auditory attention are crucial for good performance on duration pattern test. There is good evidence that noise exposure impairs working memory and attention. [18] These deficits in the attention and working memory capacities might have caused poor performance in duration pattern test in noise-exposed individuals.

The second goal of this study was to see whether there is a relationship between temporal processing abilities and speech perception measures. The overall speech recognition scores were poorer in noise-exposed group compared with control group. Multiple regression analysis with speech recognition scores as dependent variable showed that temporal processing skills can account for the 26% of the variability seen in the speech recognition scores. Gap detection thresholds, modulation detection threshold for 200 Hz modulation frequency, and duration patter scores were significantly related to speech perception in noise. Overall, results suggest that speech recognition in noise was adversely affected in individuals who are exposed to occupational noise, although the peripheral hearing sensitivity was intact and this deficit in speech recognition in noise was partially accounted by the poor temporal processing abilities. While interpreting the results of this study, it should be kept in mind that we did not subgroup the participants based on the duration of noise exposure as this would reduce the number of participants in each group. Duration of noise exposure along with other conditions such as cardiological problems (arrhythmia, anemia), hypertension, hyper-cholesterol, and heavy smoking could have potentially influence the results.

In summary, results of this study indicated deterioration in temporal and speech processing abilities of individuals who were exposed to occupational noise. These deficits were observed despite normal peripheral hearing sensitivity. These results suggest that noise can cause significant distortions in the processing of suprathreshold temporal cues which may add to difficulties in hearing in adverse listening conditions.

Abstract: According to the learning theory, adults learn best when information is practical and relates meaningfully to their lives [11]. *The program is self-administered. [...]137 individuals used the booth more than once-a finding determined by responses to the question, "Have you used this program in this booth before?" (Table 2).

Full text: INTRODUCTION
According to the Veterans Benefits Administration, more than 672,000 Veterans were service-connected for hearing loss and more than 744,000 Veterans were service-connected for tinnitus as of fiscal year 2010 [1]. Hearing loss and tinnitus are the most prevalent disabilities experienced by Veterans who served during peacetime, Operation Iraqi Freedom/Operation Enduring Freedom, World War II, and the Korean war. In fiscal year 2010, the Department of Veterans Affairs (VA) provided 561,212 hearing aids at an estimated cost of $196.7 million and audiological services to Veterans at a cost of $227.4 million.* Therefore, hearing loss and

tinnitus prevention should be a priority for the VA. At least one type of hearing loss-noise-induced hearing loss (NIHL)-can be prevented if appropriate protective strategies are implemented.

Citing the high prevalences of hearing loss and tinnitus among Veterans, Fausti et al. concluded that programs aimed at preventing hearing loss should include education concerning the effects of both occupational and recreational noise exposures, as well as counseling on the hearing protection methods available to individuals at risk for NIHL [2]. Subsequently, authors Saunders and Griest worked with a video production company (Craftmaster Productions; Portland, Oregon) to implement this recommendation by developing a computer-based hearing loss prevention program (HLPP) for Veterans that could be accessed by patients in VA medical clinics [3].

HEARING LOSS PREVENTION PROGRAM

The HLPP uses the constructs described in the Health Belief Model (HBM) developed by Rosenstock [4] to explain individual differences in decisions to practice particular health behaviors. To varying degrees, the HBM predicts health-related behaviors, such as prenatal care visits [5], breast cancer self-examination [6], continued enrollment in diabetes-related pharmaceutical services [7], and hepatitis B vaccination [8]. The principles outlined in the HBM were described by Folmer et al. [9, p. 12] as follows:

1."Perceived Susceptibility: The feeling of being vulnerable to a condition and the extent to which the individual believes he/she is at risk of acquiring the condition.

2.Perceived Severity: Belief in the seriousness of the consequences incurred if [a person is] affected by the condition both medically (e.g. death, disability, pain) and socially (e.g. effects on family life, personal relations).

3.Perceived Benefits: The belief that intervention will result in positive benefits.

4.Perceived Barriers: The barriers an individual believes he/she needs to overcome in order to effectively conduct some form of intervention. This includes costs, negative side effects, social stigma, and time needed for implementation.

5.Perceived Efficacy: Belief the individual has that he/she can successfully use the intervention.

6.Cue to Action: A cue that prompts an individual to take action. This could be internal, such as symptoms of a health problem, or external, such as media communications, interpersonal communications, or information from healthcare providers."

One goal of the HLPP is to increase participants' knowledge about auditory system damage that can be caused by loud sounds and methods of hearing protection, which in turn would change participants' understanding and attitudes about noise exposure and hearing protection. The ultimate goal of this, and all HLPPs, is to motivate participants to change their behaviors in noisy situations so they implement appropriate hearing protection strategies. Most Veterans were exposed to loud sounds during their military service. Additional unprotected noise exposure will contribute to hearing loss in this population. Indeed, evidence exists that ears with prior noise damage age differently than those without significant noise exposure. Specifically, hearing loss progresses more quickly in noise-exposed ears than in ears not exposed to noise and loud sounds cause greater damage to already-exposed ears [10]. Given this knowledge, it follows that Veterans, whose ears were probably exposed to high levels of noise during military service, must now protect their ears to avoid exacerbating cochlear damage and thus accelerating the progression of age-related hearing loss. The VA does not provide a hearing loss prevention education program for Veterans, although such instruction would be beneficial.

The HLPP is a self-administered, multimedia, computer-based program developed for Veterans and designed for use in an outpatient clinic or in a communal area of a hospital. It has the following specifications (as described by Folmer et al. [9, p. 15]):

*The HLPP "is modular in design so that users can select topics in which they are interested. According to the learning theory, adults learn best when information is practical and relates meaningfully to their lives [11].

*The program is self-administered. It does not require a professional to supervise or train users.

*The program is low maintenance and does not require upkeep from healthcare professionals. The software can be modified to implement changes to the program's content.
*The presentation volume level is adjustable to accommodate hearing-impaired individuals, since many Veterans [already] have [some] hearing loss.
*The visual components of the program are clearly visible [e.g., large text fonts are used] in accordance with published guidelines [12]."
*All written content of the program has a reading level of between grades 5 and 8 so that it is understandable to a large proportion of the adult population [13].
In 2007, authors Leek and Fausti received a Joint Incentive Fund (JIF) award to develop a stand-alone hearing loss prevention education program for Veterans and military personnel. JIF is a VA and Department of Defense (DOD) collaborative program that is designed to facilitate the mutually beneficial coordination, use, or exchange of health care resources, with the goal of improving the access to and quality and cost-effectiveness of the healthcare provided to beneficiaries of both departments. Leek and Fausti worked with the other authors of this article to redesign and adapt the HLPP for both Veterans and Active Duty military personnel. The new version of the JIF HLPP includes the following elements, which were described by Folmer et al. [9, p. 12]:
*A sound-attenuated enclosure-called the Hearing Education Center (HEC)-"(6 feet wide by 8 feet long by 8 feet high) in which one participant at a time interacts with the program (Figure 1).
*"On a booth exterior wall, a 402 flat screen LCD [liquid crystal display] displays silent video clips and text describing [what] the booth [is] and activities available inside" (see Figure 1).
*One exterior wall of the booth features a life-size human outer ear that is made of flexible plastic and attached internally to a sound level meter (Figure 2). When participants insert an iPod or MP3 ear bud into the ear, the digital display shows the intensity of the music in decibels sound pressure level (SPL). Text in the wall panel instructs participants that 80 dB SPL or lower is a safe level for extended listening.
*The inside of the enclosure (Figure 3) has a work station with a computer touch screen monitor, a pair of high-quality headphones, a chair, and a printer that is inside a locked cabinet. The personal computer that powers the touch screen is also inside the locked cabinet and not accessible to users of the program. The touch screen allows participants to select among a variety of activities, and the printer allows them to print informational handouts and test results.
*On-screen video and audio instructions show participants how to place headphones on their ears correctly and to set the volume of the program at a comfortable listening level.
Effective health communication programs should be easily understandable, user-friendly, and culturally relevant [14]. For this reason, we worked with the Oregon Museum of Science and Industry (OMSI) in Portland, which designed and built the sound-attenuated booths and the "check your iPod" module and provided the graphical user interface and computer programs that deliver the audio and visual content. OMSI was selected to provide these program elements because the museum has a great deal of experience designing and building interactive exhibits for public use. Among its projects, OMSI built the "Dangerous Decibels" hearing conservation exhibit that was on display at the museum from 2002 to 2010 (www.dangerousdecibels.org). We also worked with a video production company (Craftmaster Productions) to develop new program content specifically for Active Duty soldiers and to produce a 3 min informational video on tinnitus. In versions of the program designed for Army personnel, content includes examples of noise exposure and hearing loss prevention strategies related to military training, combat, weapons fire, military vehicles, and recreational and occupational activities. Key messages include the importance of hearing for soldiers' readiness for duty, ability to carry out missions, and survival. By contrast, the version of the program designed for Veterans focuses more on quality of life and interpersonal communication difficulties that people with hearing loss experience, along with strategies for managing those difficulties.
After participants enter the booth, put on headphones, and set the volume of the program to a comfortable

listening level, they are asked to answer the following questions via the touch screen interface:
*Have you used this program in this booth before? (yes or no).
*I am a Veteran (yes or no).
*My age (<18, 18-29, 30-39, 40-49, 50-59, 60-69, 70-79, or 80+).
*I am (male or female).
*During the last year, I (check all that apply):
- Have been around loud sounds that made my ears hurt or "ring."
- Used power tools or loud machinery.
- Fired a gun.
- Listened to loud music.
*I wear ear plugs or ear muffs (hearing protectors) when I am around loud sounds (always, sometimes, never).
A 2 min video then introduces the program and provides some basic information about hearing, noise exposure, and hearing protection (Video). When the introductory video concludes, the program shifts to the main menu screen (Figure 4). Participants may then select from among the following activities:
*Module 1: Learn why, when, and how to protect hearing. This 4 min video provides an overview of basic information related to hearing loss prevention.
*Module 2: How do loud sounds damage hearing? This 2 min video contains 3-dimensional animations that show how hearing normally works and how loud sounds can damage inner ear structures. The animated segment was taken (with permission) from the 2004 video "Sound Advice" distributed by the Naval Medical Education and Training Center (Bethesda, Maryland).
*Module 3: How loud is too loud? First, a brief video describes how sound intensity is measured and shows examples of typical sound levels in the environment. The screen then shifts to an interactive activity that allows participants to select different listening situations of interest, including occupational and recreational settings. Participants are shown the typical sound levels for each example, safe exposure times, and appropriate hearing protection strategies to use in these situations.
*Module 4: Take a hearing screening test. Participants can conduct a self-administered hearing screening of high-frequency pure tones from 20 to 60 dB HL (hearing level). The Quick Test screens 4000 Hz (takes 2 min or less); a more complete test screens 3000, 4000, and 6000 Hz (takes 6 min or less). Participants have the option to print out test results and recommendations.
*Module 5: What does hearing loss sound like? This module begins with a brief video that demonstrates how hearing loss adversely affects communication abilities and social interactions. The screen then shifts to an interactive activity that allows participants to select from among different simulations of hearing impairment in a variety of listening situations, including speech, music, and environmental sounds. A 2 min segment from a "Flintstones" cartoon (with the audio portion filtered) demonstrates the progression from normal hearing to mild, moderate, and severe hearing loss. All these hearing loss simulations were produced by Sensimetrics Corporation (Malden, Massachusetts).
*Module 6: Learn about different types of hearing protection. Interactive screens provide information about different types of hearing protectors, with examples of what each type is most suited for. Participants have the option to print out information sheets to take with them. Brief videos show participants how to insert/fit and care for the protectors.
*Module 7: Do my ear plugs fit properly? This interactive module allows participants to evaluate the fit of their own ear plugs. The module is based on the National Institute for Occupational Safety and Health (NIOSH) "Quick Fit Test" that determines whether users are receiving at least 15 dB of attenuation from their ear plugs. The NIOSH test is available online at http://www.cdc.gov/niosh/mining/topics/hearingloss/quickfitweb.htm.
*Module 8: Learn about tinnitus (ringing in the ears). This 3 min video provides basic information about tinnitus, including strategies that will help sufferers successfully manage the condition.

*Module 9: Learn about hearing healthcare services at [booth location]. Two screens of basic information (including telephone numbers, addresses, Web sites, and clinic hours) describe hearing healthcare services available at each facility where a booth is installed. Participants have the option to print out an information sheet to take with them.
*Module 10: Learn about the National Center for Rehabilitative Auditory Research (NCRAR). Two screens briefly describe the NCRAR, the only Center of Excellence in the VA system dedicated to auditory research.
It would take participants 30-40 min to review all of the material in these 10 modules. However, participants can choose to interact with fewer modules if their time is limited.
Initial installations of HECs are at the Portland (Oregon) VA Medical Center; Joint Base Lewis-McChord, Washington; and Fort Stewart, Georgia. Access to the booths is free of charge and open to the public and does not require an appointment. The booths are located in relatively high-traffic areas, preferably where the target population may be spending some "down" time. For example, at the Portland VA Medical Center, the booth is located in a multiclinic waiting area where outpatients wait to be called for their medical appointments. At Fort Lewis, the HEC is located in the front corridor of Waller Hall, a large welcome/processing center that also contains Starbucks coffee and Subway sandwich shops. The booth at Fort Stewart is located near a food court and a large furniture/appliance store on base. The external video screen on the booth, as well as posted signs, encourage potential participants to enter the booth and use the program inside. No identifiable information is requested of program users, so there are no HIPAA [Health Insurance Portability and Accountability Act of 1996] or institutional review board issues regarding participant privacy.

DATA COLLECTED FROM PROGRAM PARTICIPANTS AT PORTLAND VA MEDICAL CENTER

At the start of the program, participants are presented with a series of questions regarding demographics, noise exposure, and use of hearing protection, responses to which are stored by the computer for later examination. Responding to questions in the program is voluntary; therefore, participants may skip (not answer) any questions if they so choose. After the preliminary questions are answered or skipped, participants watch an introductory video that provides information about hearing, noise exposure, and hearing protection. After the video, participants select among the 10 modules shown in Figure 4. When participants elect to exit the program, three additional questions are presented onscreen that ask about their experience in the HEC.
Table 1 shows the sex and age distribution for participants who visited the booth at the Portland VA Medical Center between July 1, 2010 (the day it was installed) and December 1, 2011. The fact that twice as many men versus women used the program is not surprising, given its location in a VA facility.
Table 2 shows distributions of responses to the following questions: "I am [male/female]," "Have you used this program in this booth before?" and "I am a Veteran [yes/no]." A large percentage (93.4%) of respondents reported that it was their first time using the program. Of the 2,068 individuals whose data are shown in Table 2, 1,218 were male Veterans, 150 were female Veterans, 175 were male non-Veterans, and 525 were female non-Veterans.
Table 3 contains responses to questions about participants' noise exposure during the previous year. These questions were asked before any educational content was presented. Participants were able to select more than one source of loud noise exposure. In the general population, males are more likely than females to participate in noisy activities, such as firing guns or using power tools. Data collected in the Portland HEC agrees with this trend: 512 (25%) of the total respondents (2,035) fired a gun during the previous year; the male:female ratio of shooters was >5:1, whereas the sex ratio for all booth participants was 2:1. The male:female ratio for respondents who used power tools or loud machinery during the last year was >4:1. This tendency for more males than females to engage in noisy activities is one of the reasons that male hearing sensitivity declines faster than that of age-comparable females.
Table 4 contains information related to participants' use of hearing protection devices (HPDs) when they are around loud sounds. This question was also asked before any educational content was presented. Only 13.6

percent of all respondents always wear HPDs when they are around loud sounds, a very low percentage that probably contributes to the prevalence of NIHL in this population. A relatively high percentage (48%) of females answered "Never" to this question (compared with 30% of males who answered "Never"). Some female participants possibly answered "Never" because they are seldom, if ever, exposed to extremely loud sounds, such as machinery, power tools, or gun fire.

Combining participants' responses to some questions in Tables 3 and 4 yielded the results shown in Table 5. Overall, these results indicate fairly low use of HPDs, which is typical in the general population. Particularly alarming is that only 19 percent of individuals always wore hearing protection when firing a gun, because gun fire is so loud that a single exposure without hearing protection can cause damage to inner ear structures, resulting in hearing loss and/or tinnitus. Also disappointing is the finding that only 14.6 percent of respondents always wore hearing protection when using power tools or loud machinery. These results illustrate the need for increased hearing loss prevention efforts among Veterans and the general public.

Table 6 contains participants' responses to three questions that appear on screen when participants elect to exit the session. Of more than 2,000 total program participants at the Portland VA Medical Center, approximately 50 percent of them took the time to answer these three questions. An overwhelming majority (98%) of responders thought the program was a good way to provide information about hearing protection and a similarly large percentage (97%) would recommend the program to family, friends, or coworkers. We were pleased to see that 92 percent of these responders would "now be more likely to protect" their hearing from loud sounds. Although actual implementation of hearing protection strategies is a better measure of compliance (or behavioral change), the participants' stated willingness to do so is encouraging.

Data from HECs at the two Army bases will be analyzed after a greater number of participants utilize the programs there.

DISCUSSION

According to Folmer et al. [9, p. 16], "previous studies of hearing loss prevention education programs found that it is relatively easy to increase participants' knowledge about how hearing works, how hearing is damaged by loud sounds, and how and when to employ protective strategies. However, it is more difficult to inspire participants to change existing behaviors and to implement new strategies in real-life situations" [15]. Clearly, our sample of individuals found the program to be enjoyable and useful. In fact, 137 individuals used the booth more than once-a finding determined by responses to the question, "Have you used this program in this booth before?" (Table 2).

We hope that this interactive, multimedia education program will encourage Veterans to implement hearing protective strategies in their daily lives. Author Saunders and colleagues at NCRAR are currently conducting a VA Rehabilitation Research and Development (RR&D)-funded formal evaluation of the program. The study employs personal noise dosimeters to measure real-world noise exposure; ecological momentary assessments to measure real-time reported behavior; and a questionnaire to assess knowledge, attitudes, and behaviors of participants before and after they use the HLPP.

This HLPP will require wide dissemination and utilization if it is to reduce the prevalence of NIHL and tinnitus at all. As stated by Folmer et al. [9, p. 17], we hope to make this program available to all Veterans, military personnel, and other members of the public by providing access "through the internet and medical centers throughout the country. Most of the educational content of the program can be delivered via computer anywhere and does not require sound-attenuated enclosures." Disseminating a computer-based HLPP through the Armed Forces could decrease the number of military personnel developing NIHL from noise exposure in training, combat, occupational, and recreational settings. In the long run, this would also decrease the number of Veterans experiencing and receiving compensation for hearing loss and tinnitus.

Full text: [Image removed: Image]Titan. It's a ballistic missile and one of Saturn's moons. The word also plays a huge role in Greek mythology and in normal use refers to something of enormous power and influence. So it's understandable, then, why HTC seems to prefer it as a name for its phones. So much so, in fact, that the release of the LTE-enabled Titan II on AT&T actually marks not the second, but fourth iteration of the name: if you recall, the company once released two Windows Mobile devices called the TyTn.We had mixed feelings as we watched the latest Titan get introduced at AT&T's Developer Summit in January. On the one hand, we were intrigued by the idea of a smartphone with a monstrous 16-megapixel camera, as well as LTE -- something the world previously hadn't seen on a Windows Phone device. But the announcement also took place a mere two months after its predecessor launched on AT&T's network, which gave us the sinking feeling Ma Bell's new strategy was to crank out a plethora of refreshed phones boasting only a couple of new features (see: the Samsung Galaxy S II Skyrocket). So what of this sequel we have before us? Will it come out victorious like Remember the Titans or a disaster like Titanic? Is it worth it to new customers to shun the free Nokia Lumia 900 and shell out $200 for this guy instead? Follow us down the page and we'll fill you in.

Gallery: HTC Titan II review

[Image removed:][Image removed:][Image removed:][Image removed:][Image removed:] Hardware It's amazing to witness the contrast in design philosophy between HTC's Windows Phones and its latest generation of Android devices (i.e., the One series). While one feels fresh, experimental, the other hearkens back to some of the Taiwanese company's older handsets. And it shouldn't be that difficult to figure out which one is which.We suppose it shouldn't come as too much of a surprise. After all, HTC likely views its Android phones as its cash cow, which is why it's invested so heavily in the success of the One X, the One S and their respective variants. The Titan II, on the other hand, doesn't appear to have received quite the same level of tender lovin' care from

HTC (or AT&T, for that matter), evidenced by its Easter Day launch, and a price at least double that of the Nokia Lumia 900 (depending on what kind of deal you find), its fiercest Windows Phone competitor. Nokia recruited Nicki Minaj to perform at a free concert in Times Square; HTC did... nothing.Of course, launch details have absolutely zilch to do with how the phone's features or performance, but we mention it to highlight one important aspect of the business: with the exception of Nokia, phone manufacturers aren't betting on Windows Phone handsets as a major source of revenue. And perhaps they won't be until the next generation of devices arrive on the scene, bearing Windows Phone 8 (Apollo). But because of this, these phones aren't given the same VIP treatment as their Android brethren. [Image removed: Image]Stepping off of our soapbox, let's dive into the ins and outs of the Titan II. It sensibly adds to the spec sheet of its predecessor in a few critical areas, such as connectivity, camera optics and battery life. Unfortunately, improvements like these never seem to have a flattering effect on the weight and size of a device. The phone measures 10.2mm (0.4 inches) at its thinnest point, 0.3mm thicker than the last-gen model. As for its thickest spot -- the hump that makes room for that larger camera sensor -- we pulled out a ruler and estimated it to be around 13mm (0.5 inches), and that doesn't even include the fact that the camera protrudes about a millimeter beyond the frame. If you believe the OG Titan's 9.9mm thickness was borderline acceptable, a 30 percent increase in thickness could be tough to swallow. The phone also tips the scales at 6.1 ounces (173g), a rather significant change from the first version's 5.64 ounces. Purchasing this phone will most certainly be a matter of compromise: it's thicker and heavier than the original (and in our opinion, its design is a touch uglier as well), but in return you're getting a larger battery, LTE connectivity and a 16-megapixel sensor instead of an 8-megapixel one.You heard it right: newer design doesn't always equate to better. The older Titan is sleeker, thinner, lighter and more elegant, while its sequel just feels more awkward and chunky in comparison. Despite its bulkier frame, the Titan II is still relatively easy to hold, especially if you're blessed with larger hands. It's still not as comfortable in our palms as the One X with its curvaceous, slightly thinner build, but at least the concave back is coated in soft-touch plastic that offers a degree of extra tactility. Still, where the One X was doable for smaller paws, this particular phone may be just a little too unwieldy for anyone with petite hands to fully appreciate it. [Image removed: Image]Quickly glancing at the front of the Titan II, you might not see much of a difference between this and the last-gen Titan: they sport the same display, along with three capacitive buttons and a front-facing camera with an Inspire 4G-style recessed speaker grille up top. Look closer, though, and you'll see the glass curves up slightly once it reaches the navigation keys at the bottom, forming a small chin.The micro-USB charging port still sits by its lonesome on the left side of the phone, while a volume rocker and two-stage camera shutter button play together on the opposite end. Up top you'll find the power / lock button, mic and 3.5mm headphone jack, which is actually designed with the signature HTC bump around it. This design flourish wasn't present on the first Titan and frankly, we preferred it that way; the bump just feels like an interruption of those smooth curves you'll find on the back side. It's a similar story around the micro-USB opening, though the effect is far more subtle. [Image removed: Image]The back side is where the phone becomes more interesting. Instead of choosing a one-piece removable battery cover that encompasses the entirety of its rear (as it did on the first Titan), the Titan II's back is separated into three sections, and only one -- the cover protecting the SIM card panel near the bottom of the device -- is removable. But be warned: removing the cover will automatically turn off the handset. This is thanks to some antenna contacts that are printed on the inside of that cover and have matching contacts in the phone's chassis. A silver microswitch labeled ALPS detects that it's been removed and powers down the device. It can come in handy if your phone freezes and you want to perform a soft reset, but woe to you if you happen to be in the middle of something incredibly important when you want to swap out your SIM. As for the cover itself, it's the only section of the handset that's textured in any way, with hundreds of shallow little divots. Despite this design choice, it doesn't offer much additional traction for your slippery hands, though we found it to be quite helpful when sliding the cover off.Moving up the back, the middle section emulates the signature HTC unibody style that was prevalent in so many models last year, but it's interrupted by another piece on the top that covers the

camera sensor, dual LED flash and speaker grille. Both sections are non-removable and each uses a different shade of grey, which isn't an unusual design choice for the Taiwanese company (why, the grey / blue One S takes a similar tack, only the fading colors are arranged inversely to this).If you're looking for heaps of storage space, you're not going to find it here. The Titan II contains 16GB of internal memory and, just like the vast majority of WP7 devices, is lacking in any external storage options. Unless you prefer to stash all of your important files away in the cloud, you'll have to be rather picky about what goes on your phone at a given time, since you only get 13.5GB of user-accessible storage. This may sound like plenty of room for some of you, but remember that as camera resolutions have increased, image files have grown much larger (roughly 4MB to 5MB per photo), and these super-sized pics are likely to eat up your available space as an appetizer.In case you're interested in the full spread of specs, we've put together a nice little table to compare the Titan II's offerings with what you'll find on the original version as well as the Lumia 900, the phone's main competition in the Windows Phone sphere, particularly on AT&T.

HTC Titan II	HTC Titan	Nokia Lumia 900	Dimensions
5.2 x 2.7 x 0.4 inches (132 x 69 x 10.2mm)	5.18 x 2.78 x 0.39 inches (131.5 x 70.7 x 9.9 mm)	5.03 x 2.7 x 0.45 inches (127.8 x 68.5 x 11.5mm)	Weight
6.1 oz (173g)	5.64 oz (160g)	5.64 oz (160g)	Screen size
4.7 inches	4.7 inches	4.3 inches	Screen resolution

Display [Image removed: Image]We're not going to dwell much on the Titan II's display, because it offers absolutely no improvements over the original's 4.7-inch WVGA (800 x 480) LCD panel. The Microsoft-mandated limits of Windows Phone are to blame for the lack of progress in this area, so we won't fault HTC or AT&T this time.But we can't let the issue go without a fair amount of criticism: now that we've come to expect 4.7-inch displays with 720p resolution and pixel densities topping 315ppi, it's getting more and more difficult to excuse a WVGA model that delivers a subpar 199ppi. However, while the pixelation is painfully evident, we're at least happy with the superb viewing angles and above-average color saturation. We found we could see the screen well enough in direct sunlight, but only when the brightness was dialed up to its highest setting. Go lower and hardly anything is still readable.The bottom line is that whether you were satisfied or unimpressed with the OG Titan's display, you'll feel exactly the same way now. And if you're looking to grab a Windows Phone with a sharper screen, your best bet is to either wait for Apollo to come out (at which time, we hope, higher-res displays will be fully supported) or opt for a device with a smaller screen. Performance and battery life [Image removed: Image]The Titan II runs on a 1.5GHz single-core Snapdragon S2 45nm CPU (MSM8255) with an Adreno 205 GPU and 512MB of RAM. This is one of the better processors you can get on a Mango device, but it's the same exact setup as the original Titan. For better or worse, Windows Phones are utterly predictable in terms of performance; the lack of multi-core support on the platform means that newer devices probably won't be getting any faster or smoother until Microsoft lifts its restrictions. At the same time, there's an argument to be made that the OS is already efficient, that a cap on processing power contributes to comparatively long battery life. And don't forget, if a Kardashian is using a Lumia 900, that must mean it's good enough for us, right?In truth, though, while power users will always demand instantaneous response from their phones, the Titan II should be more than sufficient for casual users. Pinch-to-zoom feels smooth, and we love the responsiveness of the touchscreen, though as with other Windows Phones, you might end up waiting an extra second or two for the various animated transitions to run their course before you move on to your next task. We also found that

the back of the phone gets warm during CPU-intensive tasks, but not much hotter than other devices. The temperature isn't so high that the phone becomes uncomfortable to hold, though it's definitely something you'll notice with enough use.Compared to Android, Windows Phone is lacking in benchmarking tools. WP Bench and SunSpider are the main tools available to us for measuring performance, but let's face it: given that the top-end Mango devices have nearly hit a plateau for processing power, it's not like the numbers would vary too widely anyway. Nevertheless, we've tossed in a few scores for your perusal.

HTC Titan II	HTC Titan	Nokia Lumia 900	WP Bench
94.5	96	92	Battery rundown (CPU-intensive)
2:50	3:00	4:29	SunSpider (ms, lower numbers are better)

The Titan II is powered by a 1,730mAh battery -- an improvement over the original's 1,600mAh offering. Unlike its predecessor, however, this particular model doesn't come with a user-removable juicepack. It seems that this trend isn't going away anytime soon, but we're less concerned with battery life on Windows Phones than any other platform. We found absolutely no reason to be worried about the speed at which the new Titan sucks down power, since our average use (that's the usual suite of email, Twitter, Facebook, push notifications, messages and other day-to-day activities) gave us nearly a day and a half of life. Naturally, lower usage will likely make it possible to eke out a full two days before requiring a new charge.In terms of benchmark comparison, our CPU-intensive battery rundown test on WP Bench held out for two hours and 50 minutes before the phone took its last electronic breath -- a bit shorter than the original Titan, of course, but understandably so given the addition of an LTE radio. In short, we'll make this perfectly clear: if battery life is your number one priority on a smartphone, independent of processing power, a Windows Phone is going to be your best option outside of a Motorola Droid RAZR Maxx.When testing the LTE network, we found the Titan II performed just a smidgeon better than the Lumia 900, grabbing speeds of 21Mbps down and around 14 up during our tests in San Francisco. These tests were performed with four out of five bars of reception, so it's quite possible that we're not even hitting the phone's maximum capacity. Though it's in line with the AT&T Samsung Galaxy Note's next-gen tests, it's not the fastest device we've tested on the carrier's LTE network -- it's still leaps and bounds better than the carrier's HSPA+ service, however, which netted us around 4Mbps down and 1.5Mbps up.We love the Titan II's speakers for making calls and listening to music and podcasts. We placed the phone on a desk backside-up, walked into a room 20 feet away and could still hear everything with crystal-clear clarity. As for call reception and quality, we found the phone holds a strong signal and the mics and internal speakers are some of the loudest we've tested in a while. We heard the other callers so well, in fact, that there were several instances in which we had to turn down the volume. If you're hard of hearing, we doubt you'd have to worry too much, because the device offers a hearing aid compatibility setting in which the in-call volume kicks up a notch. Cameras [Image removed: Image]A 16-megapixel camera with an f/2.6, 28mm lens, backside-illuminated sensor and dual LED flash. On a phone. Such a thought is enough to shatter the mind into

smithereens. Without a doubt this is the single most marketable improvement the Titan II has to offer, and essentially the only reason you might consider purchasing this thing above the less-expensive Nokia Lumia 900. So do the extra pixels pack a picturesque punch? Is it worth another Benjamin to go with this particular Windows Phone?

Gallery: HTC Titan II sample shots

[Image removed:][Image removed:][Image removed:][Image removed:][Image removed:]First, one of our absolute favorite features made available on Windows Phones is the inclusion of a dedicated shutter button. This is becoming an incredibly rare find on most new Android devices, and we fear its extinction on the platform is nigh. Not so with Microsoft's mobile OS: here, the feature is alive and well. The Titan II's version is double-detent, which means you can hold the button halfway to lock in focus. Curiously, though, you're still not allowed to lock the exposure, which nearly defeats the whole purpose of this feature. We also noticed that our hands had to be incredibly steady when shooting pictures this way, since there's so much travel on the button itself that it's easy to shake the phone and take a blurry shot by accident. If this is the case for you, your best bet is to take advantage of the camera's image stabilization feature. If you're not a fan of the shutter button, you can alternatively tap the screen itself to autofocus and take the image. Fortunately, you can also focus anywhere on the viewfinder instead of being confined to the center.The variety of settings within the UI is also quite promising if you're willing to do some tweaking to get the perfect shot: ISO, panorama, macro focus, backlight aids, smile capture, face detection, white balance, red eye reduction, image stabilization and flicker adjustment are all on the menu. It improves on the One series by adding the ability to switch metering mode (center, average and spot are all included here), and it still offers adjustment settings for brightness, contrast, sharpness and saturation. The camera also allows for burst shooting, which in this case means being able to snap five shots in a row. It also adds in a full deck of 18 various scene options, complete with auto and "intelligent auto" modes, which proved adept at picking out the best scene for us. [Image removed: Image]And now, we're going to pick a few nits, since our expectations for the camera were so high. Many of the photos we shot in direct sunlight ended up slightly overexposed, which is naturally all too easy with most smartphone cameras. Shots taken indoors, however, turned out great. The cam also fares decently well in low-light scenarios with the flash turned off, but we noticed the autofocus continually struggles in these situations, and we ultimately encountered too much noise for our liking. We would've preferred to see HTC throw in a f/2.2 lens to add more light, much like it did with the original Titan.Aside from these small frustrations, we were impressed with how detailed the vast majority of our shots turned out. When the flash is enabled, it does an incredible job accurately capturing color, and the pair of LED lights is powerful enough to light up an entire room. We also love how well macro focus images came out, no matter the shooting conditions. All told, we captured some amazing shots, but we can't declare the Titan II the ultimate cameraphone champion of the universe -- the Nokia N8 still keeps the crown in this regard, and we weren't able to tell a large enough difference between it and the Amaze 4G's camera to even call it the best of HTC's lineup. It just goes to show that higher megapixel counts doesn't just inherently make a camera better. With that said, we were still quite pleased with the overall results and would be happy to use this camera on a regular basis. [Image removed: Image]The front-facing camera is about what you'd expect for a 1.3-megapixel shooter -- it's definitely nothing to write home about. Heck, it's barely anything to write about in this review. Self-portraits turned out wildly overexposed; believe us, this editor's pale face doesn't need any help in that department. Video taken with the front shooter records at 640 x 480, and you can't make any adjustments to how it looks. In fact, the settings button is completely greyed out, rendering it completely useless. The movies taken this way actually appear pretty smooth, but our overarching complaints about overexposure remain. Where the original Titan failed by compressing the JPEG down to a manageable 1.5MB or so per photo, its successor triumphs. The pictures come sized as 4640 x 3480, and as mentioned earlier, our images ended up being anywhere between 3.5MB and 5MB each, depending on the amount of information captured. In comparison, this is about the same size of the pictures we've taken with our 16.2-megapixel Sony

NEX-C3. Oh, and how about vids? On the Titan II, a minute-long video using 720p resolution took up 75MB (similar to the first Titan), whereas the One S hogged a grand total of 37MB, despite recording the same subject, at the same resolution for the same length of time. Speaking of video, how does the Titan II handle its 720p max resolution? It does a pretty good job capturing motion without too many choppy bits, and the audio is crystal-clear, too. Software [Image removed: Image]If you've read through the full review to this point, it's pretty obvious what kind of software to expect: it's a Windows Phone through and through, running on version 7.5 (Mango). In other words, if you're a fan of Ballmer's operating system, you already know exactly what to expect, and you'll most likely be in love with what the Titan II has to offer -- if you're on Team Android or iOS, however, this phone probably won't tempt you to switch sides unless you have an intense desire to take the camera for a spin.With Mango comes a full suite of features, one of which is Internet Sharing -- what Microsoft refers to its mobile hotspot capability -- and it's present and accounted for in the Titan II, giving you the opportunity to hook up to an AT&T tethering plan and share that 5GB of download capacity with five other devices.The Titan II also comes with a few extra settings and apps that you won't find on every Windows Phone. First, the HTC Hub gives you your own customizable set of panels consisting of stocks, news, weather and featured apps. The Hub's first panel is the time and weather, and it lets you reminisce by using the stereotypical Sense-style weather widget at the top. Clicking on it takes you into an AccuWeather panel that highlights your local forecasts and other conditions.Speaking of featured HTC apps, the Marketplace reserves a section specifically for manufacturer-made programs. Here you'll find a total of 15 apps, such as Tango video chat, Dock Mode, Converter, Connected Media, Locations, Lists, Notes, Flashlight, Compass and more. You'll also find the Photo Enhancer app pre-loaded on the Titan II (which is uninstallable, if you'd prefer to get rid of it), which lets you choose any picture in your camera roll and add a filter to it -- with 14 options available, you have plenty to pick from if you want to experiment a little.Finally, there's also the usual litany of AT&T apps that everyone loves or hates: U-Verse Mobile, Navigator, Code Scanner, YPmobile, Radio and myWireless. If that's not enough carrier love for you, there are a few more available for your downloading on the Marketplace, which leads us to ponder exactly why the included bloatware couldn't be accessed the exact same way. We suppose we shouldn't complain too much, however, since every last one of them can be uninstalled by simply long-pressing the selection on the app screen and choosing the correct action in the drop-down menu. Wrap-up [Image removed: Image]Overall, we have very few qualms with the HTC Titan II. Despite its clumsier design, it certainly has more to offer than its predecessor, which was already considered a great phone when it was released on AT&T a scant five months ago (six months if you count the European launch). But is there any reason to fork out $200 for a Windows Phone that has roughly the same feature set as the less expensive Nokia Lumia 900, which is getting subsidized beyond our wildest dreams? Unless you're a camera enthusiast, we think your money could be put to better use elsewhere.

Auditory Long Latency Responses to Tonal and Speech Stimuli

Author: Swink, Shannon; Stuart, Andrew

Publication info: Journal of Speech, Language and Hearing Research (Online) 55.2 (Apr 2012): 447-459.
ProQuest document link

Abstract: The effects of type of stimuli (i.e., nonspeech vs. speech), speech (i.e., natural vs. synthetic), gender of speaker and listener, speaker (i.e., self vs. other), and frequency alteration in self-produced speech on the late auditory cortical evoked potential were examined. Young adult men (n = 15) and women (n = 15), all with normal hearing, participated. P1-N1-P2 components were evoked with the following stimuli: 723-Hz tone bursts; naturally produced male and female /a/ tokens; synthetic male and female /a/ tokens; an /a/ token self-produced by each participant; and the same /a/ token produced by the participant but with a shiftin frequency. In general, P1-N1-P2 component latencies were significantly shorter when evoked with the tonal stimulus versus speech stimuli and natural versus synthetic speech (p <.05). Women had significantly shorter latencies for only the P2 component (p <.05). For the tonal versus speech stimuli, P1 amplitudes were significantly smaller, and N1 and P2 amplitudes were significantly larger (p <.05). There was no significant effect of gender on the P1, N1, or P2 amplitude (p >.05). These findings are consistent with the notion that spectrotemporal characteristics of nonspeech and speech stimuli affect P1-N1-P2 latency and amplitude components.

Purpose: The effects of type of stimuli (i.e., nonspeech vs. speech), speech (i.e., natural vs. synthetic), gender of speaker and listener, speaker (i.e., self vs. other), and frequency alteration in self-produced speech on the late auditory cortical evoked potential were examined.

Method: Young adult men (n = 15) and women (n = 15), all with normal hearing, participated. P1-N1-P2 components were evoked with the following stimuli: 723-Hz tone bursts; naturally produced male and female /a/ tokens; synthetic male and female /a/ tokens; an /a/ token self-produced by each participant; and the same /a/ token produced by the participant but with a shiftin frequency.

Results: In general, P1-N1-P2 component latencies were significantly shorter when evoked with the tonal stimulus versus speech stimuli and natural versus synthetic speech (p <.05). Women had significantly shorter latencies for only the P2 component (p <.05). For the tonal versus speech stimuli, P1 amplitudes were significantly smaller, and N1 and P2 amplitudes were significantly larger (p <.05). There was no significant effect of gender on the P1, N1, or P2 amplitude (p >.05).

Conclusion: These findings are consistent with the notion that spectrotemporal characteristics of nonspeech and speech stimuli affect P1-N1-P2 latency and amplitude components.

Key Words: late auditory cortical evoked potential, speech stimuli, hearing

P1-N1-P2 waveform components are late auditory cortical evoked potentials occurring between 40 ms and 250 ms (Martin &Stapells, 2005; Ponton, Eggermont, Kwong, &Don, 2000; Sharma, Marsh, &Dorman, 2000). The

P1-N1-P2 complex is considered to be a sensory evoked potential where waveform components are predominantly controlled by stimulus characteristics. That is, the response is thought to reflect stimulus representation or sensory encoding in the central auditory system, particularly when the listener is not actively attending (Martin, Sigal, Kurtzberg, &Stapells, 1997; Näätänen &Picton, 1987; Ostroff, Martin, &Boothroyd, 1998; Sharma &Dorman, 1999, 2000; Whiting, Martin, &Stapells, 1998). The P1 component does not appear to be affected by selective attention of the listener, whereas the N1 component exhibits an increase in amplitude (e.g., Näätänen, Gaillard, &Mäntysalo, 1978; Picton &Hillyard, 1974). In contrast, the P2 complex is diminished with selective attention (e.g., Alho, Sams, Paavilainen, &Näätänen, 1986; Näätänen &Picton, 1987). This is due in part to the superimposition of the Nd (processing negativity) and N1 components in the latency region of the P2. The P1-N1-P2 complex can be evoked to tonal stimuli and both natural and synthetic speech stimuli, including vowels (Agung, Purdy, McMahon, &Newall, 2006; Diesch, Eulitz, Hampson, &Ross, 1996; Eulitz, Diesch, Pantev, Hampson, &Elbert, 1995; Gunji, Hoshiyama, &Kakigi, 2000; Tremblay, Friesen, Martin, &Wright, 2003) and syllables (Cunningham, Nicol, Zecker, &Kraus, 2000; Ostroffet al., 1998).

Given that the P1-N1-P2 complex is sensitive to acoustic cues, one would expect responses to be different when elicited with tonal versus speech stimuli. Several differences in the P1-N1-P2 responses recorded via tonal stimuli and speech stimuli have been reported. In general, responses recorded to tonal stimuli have shorter P1-N1-P2 latencies with equivocal findings with respect to amplitude differences. For example, Eulitz et al. (1995) investigated late auditory evoked responses to five synthetic German vowels of two different durations (i.e., 600 ms and 45 ms) and a 1000-Hz tone (600 ms) presented at 60 dB SL to 11 adults with normal hearing (four women) aged 24-41 years. N1 peak latencies were significantly longer for the speech stimuli. No significant differences were found with N1 amplitudes between speech and tonal stimuli.

Tiitinen, Sivonen, Alku, Virtanen, and Näätänen (1999) also recorded late auditory cortical evoked potentials (i.e., N1-P2 responses) to both tonal and vowel stimuli. In order to match the tonal stimuli and speech stimuli in terms of frequency and intensity, Tiitinen et al. used a 535-Hz tone and two synthetic Finnish vowels (i.e., a "soft" /a/ and a "pressed" /A/). All stimuli had durations of 200 ms. N1-P2 response amplitudes were significantly larger for the vowel stimuli versus the pure-tone stimulus.N1 latency was significantly longer for the /a/ vowel versus the tonal stimulus; however, there was no significant difference between the tonal stimulus and the /A/ vowel. Further, it was reported that P2 latencies recorded with the pure tone were significantly shorter than both vowel stimuli.

Ceponiene et al. (2001) recorded P1, N250, and N450 wave components to synthetic vowel tokens, acoustically matched complex tones, and tone bursts from 8- to 10-year-old children to investigate stimulus effects. The authors found that P100 and N250 amplitudes were larger when recorded with complex tonal stimulus compared with the "sinusoidal tones." The N250 component amplitude was also smaller when recorded using the vowel token relative to the complex tones, but the N450 component amplitude was larger when recorded with the vowel token compared with the complex tones.With respect to latency differences, P100 latencies were statistically shorter for the complex tones compared with the vowel token. No P100 latency differences were found between the vowel and the sinusoidal tones conditions. N250 latencies were shorter for the sinusoidal tones compared with the vowels but not between the complex tones and the vowel tokens. No significant N450 latency differences were reported between any of the conditions. In a follow-up study, Ceponiene, Alku, Westerfield, Torki, and Townsend (2005) extended the findings to consonant-vowel syllable and nonphonetic stimuli (i.e., a composition of five tones) matched on acoustic complexity with children and adults. Consistent with the previous study, the N1 in adults and the P2 in both groups were enhanced by the nonphonetic stimuli, whereas the N2 and N4 peaks were enhanced by the syllables.

Late auditory cortical potentials evoked to speech stimuli are gaining increased interest due, in part, to their potential clinical application (Martin, Tremblay, &Korczak, 2008). However, there are differing opinions on whether to use naturally produced or synthetic speech. For example, Picton, Alain, Otten, Ritter, and Achim

(2000) suggest that naturally produced speech should be used in electrophysiological testing so that the results can be related to everyday listening experiences. Conversely, some argue that synthesized speech tokens allow for the manipulation of distinct acoustical cues (e.g., Digeser,Wohlberedt,& Hoppe, 2009). In addition, there are perceptual/comprehension/identification differences between natural and synthetic speech. That is, listeners generally perceive synthetic speech less successfully than natural speech (e.g., Brungart, Iyer, &Simpson, 2006; Papadopoulos, Katemidou, Koutsoklenis, &Mouratidou, 2010; Reynolds, Isaacs-Duvall,& Haddox, 2002; Roring, Hines, &Charness, 2007). It is unknown whether there are differences in speech-evoked auditory event-related potentials to natural or synthetic speech stimuli. To the best of our knowledge, there have been no studies in which researchers have examined late auditory cortical evoked potentials in a group of participants who listened to both naturally produced and synthetic speech.

The purpose of this study was to further examine P1-N1-P2 waveform components of late auditory cortical evoked potentials in female and male participants who listened to both tonal and speech stimuli. It was of interest to examine previously unexplored responses to stimulus manipulations in the same listeners. These included type of stimuli (i.e., nonspeech vs. speech), speech (i.e., natural vs. synthetic), gender of speaker, speaker (i.e., self-produced vs. others), and frequency alteration in self-produced speech. Specifically, P1-N1-P2 components were evoked to the following stimuli: tone bursts, naturally produced male and female /a/ tokens, synthetic male and female /a/ tokens, an /a/ token self-produced by each participant, and the same /a/ token produced by the participant but with a shiftin frequency. We chose a short duration (i.e., <100 ms) tonal stimulus, which is typically used in clinical evaluation, because it is optimal for evoking late auditory cortical evoked potentials (Hall, 2007). As noted above, in previous studies, researchers have not explored responses to synthetic and natural speech tokens in the same cohort of listeners, nor have they examined the speaker's gender in synthetic and natural speech tokens. Our interest in examining responses to self-produced speech tokens stems from a renewed interest in the link between speech production and speech perception (Guenther, Ghosh, &Tourville, 2006) where contemporary models of speech production give more credence to the involvement of the auditory system. Historically, auditory contributions to speech production have been discounted. For example, Borden (1979) asserted that the auditory system is too slow for online monitoring of speech production. Contemporary theorists posit that speech production and speech perception are intimately linked via feedforward and feedback control subsystems working in concert. These feedforward and feedback control systems facilitate communication and, of particular importance, allow for the monitoring of internal and external vocalizations (e.g., Guenther, 2006; Jeannerod, 1998; Numminen, Salmelin, &Hari, 1999). With this line of reasoning, one must ask "Is there a difference in response to a self-produced speech token and the same speech token externally generated by another speaker?" We were interested in evaluating responses to selfproduced frequency-shifted speech tokens. Researchers have demonstrated that alterations in frequency of one's voice affect speech production (e.g., Burnett, Freeland, Larson, &Hain, 1998; Chen, Liu, Xu, &Larson, 2007; Elman, 1981; Larson, Burnett, Kiran, &Hain, 2000) and reading comprehension (Carter, Rastatter, Walker, &O'Brien, 2009; Rastatter, Barrow, &Stuart, 2007). The auditory representation of self-produced nonaltered and frequency-altered speech has not previously been undertaken. We also wanted to examine the effect of listener gender. Although a significant effect of gender has been evidenced in essentially all dimensions of auditory function in adults, there is a paucity of investigations examining gender effects on the P1-N1-P2 waveform components of the late auditory cortical evoked potential in young adults. Onishi and Davis (1968) reported that female participants "tended to give responses of larger amplitude" (p. 588) for the N1-P2 complex to binaurally presented tonal stimulus. However, they did not report the effect of gender on peak amplitude values. Hoffman and Polich (1999) also found smaller amplitude responses in female participants (i.e., P2 in response to binaurally presented tonal stimulus). In contrast, Gölgeli et al. (1999) found no differences in N1 and P2 component amplitude or latency between genders to binaurally presented tonal stimuli.

To the best of our knowledge, no other study has performed such a comprehensive investigation of stimulus effects across a multitude of speech tokens in female and male listeners. It was hypothesized that P1-N1-P2 component latencies and amplitudes would differ between tonal and speech stimuli and would differ among the various speech stimuli due to temporal-spectral differences. Namely, responses that were recorded via tone bursts would have shorter P1-N1-P2 latencies and smaller amplitudes than those that were elicited via speech stimuli (Ceponiene et al., 2001, 2005; Tiitinen et al., 1999). Owing to the similarity among all speech tokens, we hypothesized that there would not be any significant latency or amplitude differences across speech stimuli conditions (i.e., natural vs. synthetic speech, female vs. male speaker, self-produced vs. other speakers, self-produced nonaltered vs. self-produced frequencyshifted speech). Finally, it was hypothesized that there would be no differences in P1-N1-P2 component latencies and amplitudes between female and male listeners across stimuli (Gölgeli et al., 1999).

Method

Participants

Participants included 30 White, English-speaking young adults: Fifteen were male (M = 24.1 years; SD = 3.5), and 15 were female (M = 24.1 years; SD = 3.4). All participants presented with normal-hearing sensitivity, which was defined as pure-tone thresholds at octave frequencies from 250 Hz to 8000 Hz ≤25 dB HL (American National Standards Institute [ANSI], 1996) and normal middle-ear function (Roup, Wiley, Safady, &Stoppenbach, 1998). Participants were recruited on a volunteer basis from the East Carolina University student body. The University and Medical Center Institutional Review Board of East Carolina University approved this research; all participants provided informed consent prior to testing. All participants were demographically similar, with no reported history of neurological disorders, head injuries, otological disorders, learning disabilities, or speech and language impairments as assessed with a self-report questionnaire. To assess cognitive function, we administered the Mini Mental State (Folstein, Folstein, &McHugh, 1975) to all participants. All participants demonstrated scores within normal limits (M = 29.9; SD = 0.4). The Edinburgh Handedness Inventory (Oldfield, 1971) was also administered to all participants to assess handedness. Laterality Quotient scores of 40 or greater are considered to represent right-handedness. All participants who were included in the study demonstrated righthand dominance with Laterality Quotient scores >40 (M = 72.1; SD = 20.8).

Apparatus

For all experimental listening conditions, participants were seated in a comfortable reclining chair placed inside a double-walled sound-treated audiometric suite (Industrial Acoustics Corporation). This audiometric suite met specifications for permissible ambient noise (ANSI, 1999).We performed data acquisition using Compumedics NeuroScan SCAN software (Version 4.4), SynAmps2 Model 8050 electroencephalography (EEG) amplifier, and Stim2 software. We used a 64-channel Ag/Ag/Cl Compumedics NeuroScan Quik-Cap to record ongoing EEG activity. All stimuli were presented via NeuroScan ER-3A insert earphones.

Male and female natural vowel tokens. Naturally produced male and female vowel tokens were recorded from a White young adult woman and a White young adult man, both of whom had a general American dialect and spoke with a normal vocal effort. Both the man and the woman generated 10 /a/ vowel tokens that were recorded at a sampling rate of 44100 Hz. Single /a / tokens of approximately 400 ms were selected. Duration was defined as the total length of the vowel, beginning at the point of initial phonation and ending when phonation ceased. The appropriate duration for these vowels was determined on the basis of results from a pilot study that was performed in order to determine the approximate duration of the vowel /a/ produced in isolation from speakers in the dialectical region. The selected vowel tokens were normalized through the use of Peak 4 software and were saved as a .wav file.

Male and female synthetic vowel tokens. We created synthetic male and female speech tokens using an Internet-based Klatt Synthesizer Interface (www.asel. udel.edu/ speech/tutorials/synthesis) at a sampling rate of

10000 Hz. The male /a/ was created through use of the following formant (F) frequencies and bandwidths (BWs; all in Hz): F0 = 132, F1 = 710, F2 = 1150, F3 = 2700, F4 = 3300, F5 = 3700, F6 = 4900, BW1 = 40, BW2 = 43, BW3 = 105, BW4 = 400, BW5 = 500, and BW6 = 1000. These stimulus parameters were chosen on the basis of parameters used by Hawks and Miller (1995). Bandwidths 4-6 were based on default settings within the Klatt Synthesizer program. The synthetic female /a/ was created with the following Fs and BWs (all in Hz): F0 = 208, F1 = 688, F2 = 1273, F3 = 2966, F4 = 3300, F5 = 5400, F6 = 6000, BW1 = 90, BW2 = 110, BW3 = 170, BW4 = 250, BW5 = 300, and BW6 = 450. These stimulus parameters were chosen on the basis of parameters used by Assmann and Katz (2000) and Hawks and Miller (1995). Bandwidths 4-6 were based on default settings within the Klatt Synthesizer program. The F0 was varied across the duration of the vowel from 190 Hz to 208 Hz to increase naturalness of the vowel token (Assmann &Katz, 2000). In order to remain consistent, the duration of these tokens was 400 ms.

Recorded self-produced vowel tokens. Prior to collection, participants were asked to produce the vowel /a/ 10 times into a Logitech (Model 980186-0403) desktop microphone. These tokens were recorded using Bias Sound Creative Peak 4.13 running on a Macintosh PowerPC G4 at a sampling rate of 44100 Hz. Participants were asked to produce the vowel tokens using a normal vocal effort and speech rate. The duration of each vowel was then measured. To remain consistent with the other vowel tokens presented in this study, the self-produced token closest to 400 ms was selected from the sample of 10 tokens. The average duration of the self-produced male and female tokens was 388 ms (SD = 17.5) and 386 (SD = 26.8), respectively. The participants' self-produced tokens were then frequencyshifted down one-half octave through the use of Bias Sound Creative Peak software (Version 4.13) and were presented as a frequency-shifted token. All speech tokens were amplitude normalized and were saved as .wav files.

Tonal stimulus. The center frequency of the tone burst was selected based on methodology presented by Tiitinen et al. (1999). In this study, the center frequency of the tonal stimulus was generated to match the mean center frequency of the highest peak observed in vowels /a/ and /A/. Following this rationale, male and female synthetic /a/ tokens were analyzed using SpectraPRO-FFT Spectral Analysis System software (Version 3.32) on a Dell Inspiron laptop. The center of the highest harmonic of both the synthetic male and female tokens was 722.66 Hz. Accordingly, the tone burst was generated with a center frequency of 723 Hz through the use of a Dell Optiplex GX620 computer (Intel Pentium 4 CPU, 2.99 GHz, 1.00 GB RAM, with a 16-bit integrated Creative SB Audigy 4 WDM sound card operating on a MicrosoftWindows XP operating system) and Compumedics NeuroScan Stim2 Sound Editor software (Version 2) at a sampling rate of 48000 Hz. A Blackman window was employed with a 10.5-ms ramp and a 49-ms plateau. The total duration was 70 ms.

Acoustical analysis and calibration. The amplitude time waveforms for all speech stimuli are presented Figure 1. Waveforms were generated using SpectraPROFFT Spectral Analysis System software (Version 3.32). Fast Fourier transforms (FFTs) were performed on these tokens through the use of the SpectraPRO-FFT Spectral Analysis System (see Figure 2). FFTs of both male and female natural vowel tokens were generated through the use of a Hanning window with a sampling rate of 44100 Hz, an FFT size of 2048, and a decimation ratio of 1. FFTs of the synthetic male and female vowel tokens were generated through the use of a Hanning window, a 10000-Hz sampling rate, an FFT size of 1024, and a decimation ratio of 1.

All stimulus presentation levels were calibrated to 75 dB pSPL using a Brüel &Kjæ r precision soundlevel meter (Type 2231) with a Brüel &Kjæ r octave band filter (Type 1625) attached to a Brüel &Kjæ r (Type 4144) pressure microphone. In order to keep calibration parameters consistent across all tokens, we performed calibration using pSPL measurements. All stimuli were presented via the Sound Editor Module through an insert earphone (NeuroScan ER-3A) coupled to a 2 cm3 (Brüel&Kjæ r TypeDB0138) coupler attached to the sound-level meter.

Procedure

Stimuli presentations were counterbalanced according to a digram-balance Latin squares design (Wagenaar,

1969) and were presented to the listener via NeuroScan ER-3A insert earphones. We used deep insert earphone placement (Dean &Martin, 2000). All stimuli were presented bilaterally at a rate of 1.1/s. Participants were asked to sit quietly and silently count the number of presented tokens. After each condition, participants were asked to write the number of tokens they counted on the sheets provided. They were also asked to remain alert and minimize movements, especially head and neck movements, while the stimuli were presented.

EEG activity was recorded from 11 electrode sites placed about the participant's head (i.e., F3, Fz, F4, C3, Cz, C4, T4, T3, Pz, M1, and M2). The nasion served as the reference, and Fpz served as the common ground. We monitored vertical eye movements using electrodes placed vertically above and below the lefteye. Electrode impedances were maintained at or below 5000 W. EEG activity was amplified 3,000 times and was analog filtered (i.e., 1-30 Hz). Analog-to-digital conversion at a rate of 500/s for all channels was performed with a PCbased NeuroScan system and SynAmps2 24-bit amplifier. All EEG activity was saved as continuous files for offline averaging and digital filtering.

All continuous files were epoched in a time-locked window from -100 ms to +500 ms relative to stimulus onset. We selected this response window to provide an adequate time window for visualization of all pertinent waveformcomponents (Martin&Stapells, 2005; Sharma et al., 2000). A prestimulus interval of -100 was used as the baseline correction for all recording channels. Epochs were then digitally filtered (i.e., 1-30 Hz, 24 dB/octave) and were re-referenced offline to linked mastoids (M1 and M2). Ocular movement artifacts were reduced from the epochs utilizing the Compumedics NeuroScan SCAN software (Version 4.4) Ocular Artifact Reduction algorithm (Semlitsch, Anderer, Schuster, &Presslich, 1986). Epochs containing artifacts exceeding ±50 mV were rejected from averaging. We averaged 150 samples, and we replicated this for all trials. Replication was defined as two or more waveforms with identifiable P1-N1 and/or P2 peaks within 25 ms (O'Brien &Stuart, 2001). We then averaged both replications, creating seven waveforms for each individual participant.

Electrophysiological waveform analyses. Waveform components P1-N1-P2 were evaluated in terms of latency and amplitude measures. P1 was defined as the largest positive peak following stimulus onset between 40 ms and 150 ms. N1 was defined as the largest negative deflection following P1 between 75 ms and 210 ms, and P2 was defined as the following positive peak between N1 and 300 ms. Amplitudes were measured from baseline to component peak. Waveform components were also considered to be present if greater responses were visualized at the frontocentral electrode sites (i.e., Fz and Cz) in comparison to the parietal electrode (i.e., Pz). We also used polarity inversion at the mastoid sites to determine response presence (Vaughan &Ritter, 1970). However, the response was not deemed absent if a polarity inversion did not occur (Martin &Stapells, 2005; Tremblay, Piskosz, &Souza, 2003).

Results

We measured grand average N1-P2 complex amplitudes at all electrode sites to determine the electrode location where the most robust response was recorded. For all conditions, the N1-P2 complex amplitude was greatest at the Cz electrode site; therefore, all data presented in the current investigation were collected from the Cz electrode site only. Grand average of amplitude and time waveforms recorded from Cz are presented for each experimental condition in Figure 3.

P1-N1-P2 Latency

Mean latencies and SDs for the P1, N1, and P2 waveform components, as a function of condition and gender, are presented in Table 1. We conducted three separate two-factor mixed (between and repeated factors) analyses of variance (ANOVAs) to examine the effect of stimulus condition and gender on P1,N1, andP2 latencies. The results of those analyses are shown in Table 2. A significant main effect of condition was found for each latency component.We performed five post hoc mutually orthogonal single-df contrasts (Keppel&Wickens, 2004) of interest to investigate the source of main effect of stimulus condition: tonal versus speech stimuli (i.e., tone bursts vs. naturally produced male and female speech, synthetic male and female

speech, and self-produced nonaltered and frequency-shifted speech); synthetic versus natural speech stimuli (i.e., natural male and female vs. synthetic male and female); female versus male speech (i.e., natural and synthetic female vs. natural and synthetic male); self-produced versus other speech (i.e., self-produced nonaltered and frequency-shifted speech vs. natural and synthetic male and female speech); and nonaltered self-produced speech versus frequencyshifted self-produced speech.1 For P1 latencies, significantly shorter latencies occurred for the tonal stimulus versus the speech stimuli (p <.0001, h2 = .35), for natural versus synthetic speech tokens (p = .029, h2 = .15), and for male tokens versus female tokens (p = .042, h2 = .14). For N1 latencies, significantly shorter N1 latencies occurred for the tonal stimulus versus the speech stimuli (p <.0001, h2 = .62), natural versus synthetic speech tokens (p <.0001, h2 = .40), and self-produced versus other speech (p = .043, h2 = .13). For P2 latencies, significantly shorter P2 latencies occurred for the tonal stimulus versus the speech stimuli and for natural versus synthetic speech tokens (p <.0001, h2 = .62). In addition, female participants had significantly shorter latencies than male participants (p = .007).

P1-N1-P2 Amplitude

Mean amplitudes and SDs for the P1, N1, and P2 waveform components, as a function of condition and gender, are presented in Table 3. We conducted three separate two-factor mixed ANOVAs to examine the effect of stimulus condition and gender on P1, N1, and P2 amplitudes. The results of those analyses are shown in Table 4. A significant main effect of condition was found for each amplitude component. To investigate the source of this main effect, we performed the same five orthogonal single-df contrasts described above. The only significant amplitude differences were between responses for tonal stimulus versus the speech stimuli: P1 amplitudes were significantly smaller (p <.001, h2 = .32), yet N1 (p <.001, h2 = .32) and P2 amplitudes (p <.0001, h2 = .59) were significantly larger for the tonal stimulus.

Discussion

To better understand the effect of stimulus and listener gender on auditory late cortical evoked potentials, we explored manipulations of type of stimuli (i.e., nonspeech vs. speech), type of speech (i.e., natural vs. synthetic), gender of speaker, speaker (i.e., self vs. other), and frequency alteration in self-produced speech. P1-N1-P2 components of the late auditory cortical evoked potential were generated with a tonal stimulus and six speech tokens. Initially, it was of interest to evaluate the effect on component latencies and amplitudes when elicited via the tonal stimulus compared with the speech tokens (i.e., nonspeech vs. speech). We hypothesized that responses evoked with the nonspeech token would differ from those recorded via the speech tokens. Specifically, component latencies would be shorter and amplitudes would be smaller (Ceponiene et al., 2001; Tiitinen et al., 1999) when evoked with tonal compared to speech stimuli. Consistent with the proposed experimental predictions, P1-N1-P2 component latencies were significantly shorter when evoked via the tonal stimulus versus speech stimuli. The findings with respect to P1-N1-P2 component amplitudes were equivocal: P1 components were significantly smaller for the tonal stimulus compared with the speech stimuli, whereas N1 and P2 components were significantly larger for the tonal stimulus compared with the speech stimuli.

It is well established that stimulus characteristics such as duration, rise time, intensity, and frequency affect P1-N1-P2 responses. With regard to stimulus characteristics, the most notable difference between the tonal stimulus and the speech tokens was token duration. The duration of the tone burst was 70 ms, and the duration of all speech tokens was held constant at approximately 400 ms. Investigators have shown differences in component latencies as a function of duration (Davis &Zerlin, 1966; Eddins &Peterson, 1999; Onishi &Davis, 1968; Skinner&Jones, 1968). If the duration of the tonal stimulus is greater than 30 ms with a fixed rise time, there is minimal effect on P1 and N1 latency and amplitude. That is, "the amplitude of N1-P2 is apparently determined within about 30 msec after the onset" (Onishi &Davis, 1968, p. 584). In this experiment, the effect of stimulus duration should be minimal given that all stimuli were longer than 30 ms.That is, differences in stimulus durations may not contribute significantly to the latency differences found in this experiment.

Differences in token rise time also affect component latency and amplitude. With respect to stimulus onset, the

P1-N1-P2 complex-specifically, the N1 component-is an onset response and, therefore, is greatly affected by the "onset" characteristics of the token (i.e., the initial 100 ms; Elfner, Gustafson, &Williams, 1976; Skinner &Jones, 1968). Thus, manipulating the onset of the stimulus (i.e., the rise time) can affect component latency and amplitude. Milner (1969) found that as stimulus rise time increased, component amplitude decreased. Onishi and Davis (1968) found that rise times shorter than 50 ms did not significantly affect N1-P2 amplitude; however, as rise time increased beyond 50 ms, N1-P2 amplitude decreased. Thomson, Goswami, and Baldeweg (2009) reported that N1 component amplitudes decreased as stimuli rise time increased. For component latency, Hyde (1997) reported that as stimulus rise time increased, component latency increased. In this experiment, the rise time for the nonspeech token was 10 ms. The rise time of the speech stimuli was not controlled across tokens so that the parameters of these tokens would remain as close to naturally occurring as possible. This was especially true for the participant self-produced tokens, where preserving naturalness of the token was essential. Rise times2 were 54 ms, 37 ms, 174 ms, 26 ms, 76 ms, 65 ms, 16 ms, and 54 ms for the natural male, natural female, synthetic male, synthetic female, male self-produced, male frequency-shifted self-produced, female self-produced, and female frequency-shifted self-produced tokens, respectively (see Figure 1). Rise time measurements, however, are not presented for all participant self-produced tokens. It is possible that P1-N1-P2 latency and amplitude differences found here were wholly related to stimuli rise time differences, given that the onset of the nonspeech tone was comparatively shorter and more rapid than the onset of the speech tokens.

Two additional factors may have contributed to the differences on responses between the tonal and speech stimuli. Although the frequency of the tone was constructed based on the center frequency of the synthetic vowel tokens, the difference between the responses may be related to the spectral characteristics of the tokens and the complexity of the tokens (Uppenkamp, Johnsrude, Norris, Marslen-Wilson, &Patterson, 2006). Second, interstimulus interval has been shown to affect auditory late cortical evoked potentials. Increasing the interstimulus interval serves to enhance N1 and P2 amplitudes (Budd, Barry, Gordon, Rennie, &Michie, 1998; Davis, Mast, Yoshie, &Zerlin, 1966; Fruhstorfer, Soveri,&Järvilehto, 1970; Hari, Kaila, Katila, Tuomisto, &Varpula, 1982; Woods &Elmasian, 1986). This has been attributed to reflect refractory effects of the late cortical potential generators. Given that the stimulus presentation rate was kept constant at 1.1/s, but the duration of the tones were 70 ms and the duration of the speech tokens were 400 ms, there were differences in the interstimulus interval between tone and speech tokens. That is, the shorter interstimulus interval difference for the tonal stimulus may have enhanced response amplitude.

In addition to evaluating the effect of tonal stimuli compared to speech stimuli, this experiment was conducted to investigate latency and amplitude effects across the six speech conditions (i.e., natural tokens compared to synthetic tokens; self-produced token compared to the other tokens, and male synthetic and natural tokens compared to female synthetic and natural tokens).We hypothesized that there would not be any significant latency or amplitude differences across speech stimuli conditions. With respect to the natural token versus synthetic token conditions, P1-N1-P2 component latencies were significantly shorter when recorded via the natural speech tokens compared to those recorded via the synthetic speech tokens. There were no significant differences found for P1-N1-P2 amplitudes. As with the tonal stimulus compared to the speech stimuli, spectro-temporal characteristics of the stimuli (Agung et al., 2006; Digeser et al., 2009), specifically differences in the initial onset of the tokens, may account for these experimental findings. Further, it has been speculated that natural speech and synthetic speech are processed differently. Supporting evidence for this notion is equivocal. Uppenkamp et al. (2006), via functional magnetic resonance imaging, demonstrated that natural tokens and synthetic tokens produced an identical pattern of auditory cortical activation. Benson et al. (2001), however, also used functional magnetic resonance imaging and found differing cortical activations for natural speech versus synthetic speech. Tremblay, Friesen, et al. (2003) also suggested that cortical processing for natural tokens and synthetic tokens may differ, based on responses from two studies, one eliciting waveform components using

natural speech and the other using synthetic speech.

In general, significant differences were not seen across all P1-N1-P2 latency or amplitude components elicited via male voiced tokens (i.e., natural and synthetic male) compared to female voiced tokens (i.e., natural and synthetic). The only significant finding was statistically shorter P1 latencies for male tokens compared to female tokens. Again, this finding may be related to the spectral differences between the eliciting tokens. Specifically, the lower frequency content of the male tokens compared to the higher frequency content of the female tokens. P1-N1-P2 components are sensitive to stimulus frequency as responses recorded using lower frequency stimuli demonstrate shorter component latencies compared to responses recorded with higher frequency stimuli (Agung et al., 2006; Alain, Woods, &Covarrubias, 1997; Antinoro, Skinner, &Jones, 1969; Jacobson et al., 1992; Sugg &Polich, 1995).

Two of the speech tokens that were employed to elicit the evoked potentials were self-produced by each participant (i.e., participant-produced /a/ tokens with that same /a/ pitch-shifted downward). Responses to these tokens were recorded to examine the effect on component latencies and amplitudes in comparison with the other speech tokens. No significant differences between self-produced tokens and the other speech tokens were found for P1 latency, P2 latency, or P1-N1-P2 amplitude. These findings were consistent with those reported in previous investigations (Heinks-Maldonado et al., 2007; Houde, Nagarajan, Sekihara, &Merzenich, 2002). Significantly shorter N1 latencies were found for responses recorded using self-produced vowels compared to the other speech tokens. This finding was inconsistent with previous findings (Heinks-Maldonado, Mathalon, Gray, &Ford, 2005).

The finding of significantly shorter N1 latencies for self-produced speech was, however, unexpected. It is likely related to the differences in spectral characteristics of the tokens. One self-produced token was passively presented without an alteration and the other token was pitch-shifted downward, thus shifting the spectral content into a lower frequency range. Researchers have reported that N1 amplitudes are larger and latencies shorter when evoked with lower frequency stimuli (Agung et al., 2006; Alain et al., 1997; Antinoro et al., 1969; Jacobson et al., 1992; Sugg &Polich, 1995). When considering the effect of this frequency shift, our finding of shorter N1 latencies for the self-produced speech tokens compared to the other tokens is plausible.

This investigation was also designed to examine differences between responses from male and female participants. In separating males from females, stimulus or condition effects can be evaluated without the influence of gender (Kudo et al., 2004). Gender differences have been demonstrated across various electrophysiological indices (e.g., early potentials; Beagley &Sheldrake, 1978; Bergholtz, 1981; Chan et al., 1988; Dehan &Jerger, 1990; Don, Ponton, Eggermont, &Masuda, 1993; Sabo, Durrant, Curtin, Boston, &Rood, 1992), however, findings for late evoked potentials have been equivocal (Gölgeli et al., 1999; Hoffman &Polich, 1999; Onishi &Davis, 1968). P2 latencies were significantly shorter when recorded from females than from males. No other significant gender differences were found for P1 or N1 latencies or component amplitudes.

In conclusion, it was demonstrated that differences were found in the P1-N1-P2 components of the auditory late cortical evoked potential elicited with different tonal, natural, and synthetic speech stimuli. P1-N1-P2 component latencies were significantly shorter when evoked with the tonal stimulus versus speech stimuli and natural versus synthetic speech. P1 amplitudes were significantly smaller and N1 and P2 amplitudes were significantly larger for the tonal versus speech stimuli ($p < .05$). There were little differences between male and female listeners. Females had significantly shorter latencies for only the P2 component ($p < .05$). There was no significant effect of gender on the P1, N1, or P2 amplitude ($p > .05$). It can be suggested that spectro-temporal characteristics of nonspeech and speech tokens affect P1-N1-P2 latency and amplitude components.

Acknowledgments

This article was presented in part at the 2010 American Speech-Language-Hearing Association Annual Convention, Philadelphia, PA.

Footnote

1An a of .5 was adopted as the criterion for significance. Corrections for familywise error are suggested only when the number of single-df planned comparisons exceeds the number of degrees of freedom associated with the treatment source of variance (dfa; Keppel &Wickens, 2004). In this case five single-df planned comparisons were made relative to six dfa.

2Rise times were calculated from the amplitude time waveforms of the speech tokens presented in Figure 1. Rise time was operationally defined as the time from the onset of the acoustic waves to the maximum amplitude.

Abstract: Although poorer understanding of speech in noise by listeners who are hearing-impaired (HI) is known not to be directly related to audiometric hearing threshold, HT (f), grouping HI listeners with HT (f) is widely practiced. In this article, the relationship between consonant recognition and HT (f) is considered over a range of signal-to-noise ratios (SNRs). Confusionmatrices (CMs) from25 HI ears were generated in response to 16 consonant-vowel syllables presented at 6 different SNRs. Individual differences scaling (INDSCAL) was applied to both feature-based matrices and CMs in order to evaluate the relationship between HT (f) and consonant recognition among HI listeners. The results showed no predictive relationship between the percent error scores (Pe) and HT (f) across SNRs. The multiple regression models showed that the HT (f) accounted for 39% of the total variance of the slopes of the Pe. Feature-based INDSCAL analysis showed consistent grouping of listeners across SNRs, but not in terms of HT (f). Systematic relationship between measures was also not defined by CM-based INDSCAL analysis across SNRs. HT (f) did not account for the majority of the variance (39%) in consonant recognition in noise when the complete body of the CM was considered.

Purpose: Although poorer understanding of speech in noise by listeners who are hearing-impaired (HI) is known not to be directly related to audiometric hearing threshold, HT (f), grouping HI listeners with HT (f) is widely practiced. In this article, the relationship between consonant recognition and HT (f) is considered over a

range of signal-to-noise ratios (SNRs).
Method: Confusionmatrices (CMs) from25 HI ears were generated in response to 16 consonant-vowel syllables presented at 6 different SNRs. Individual differences scaling (INDSCAL) was applied to both feature-based matrices and CMs in order to evaluate the relationship between HT (f) and consonant recognition among HI listeners.
Results: The results showed no predictive relationship between the percent error scores (Pe) and HT (f) across SNRs. The multiple regression models showed that the HT (f) accounted for 39% of the total variance of the slopes of the Pe. Feature-based INDSCAL analysis showed consistent grouping of listeners across SNRs, but not in terms of HT (f). Systematic relationship between measures was also not defined by CM-based INDSCAL analysis across SNRs.
Conclusions: HT (f) did not account for the majority of the variance (39%) in consonant recognition in noise when the complete body of the CM was considered.
Key Words: consonant confusions, audiometric hearing threshold, signal-to-noise ratio
Pure-tone audiometry is a well-established component of the audiometric test battery that measures behavioral hearing threshold to tones of different frequencies. For clinical and research purposes, many attempts have been made to test the correlation between speech recognition performance for hearing-impaired (HI) listeners and hearing thresholds. The results of such comparisons have generally shown little predictive value, particularly when speech recognition is measured in background noise (Festen &Plomp, 1983; Plomp, 1978; Smoorenburg, de Latt, &Plomp, 1982). Evidence of a poor predictive relationship between hearing threshold and sentence recognition performance in noise is well documented (Bentler &Duve, 2000; Killion, 2004a, 2004b; Lyregaard, 1982; Smoorenburg et al., 1982; Smoorenburg, 1992; Tschopp &Zust, 1994). The lack of correlation between the measures may be related to differences in the simple acoustic signals used for pure-tone audiometry and the complex nature of speech recognition even though frequency-specific audibility deficits are known to affect speech perception (Bamford,Wilson, Atkinson, &Bench, 1981; Carhart &Porter, 1971). Perception of running discourse may take advantage of increased information from complex signals and contextual and linguistic properties of speech as well as the linguistic experience of the listener.
In contrast to using meaningful sentences, some studies have investigated the relationship between speech recognition and hearing threshold using nonsense syllables (Bilger &Wang, 1976; Danhauer &Lawarre, 1979; Dubno, Dirks, &Langhofer, 1982; Gordon-Salant, 1987; Reed, 1975;Walden&Montgomery, 1975;Walden, Montgomery, Prosek, &Schwartz, 1980; Wang, Reed, &Bilger, 1978). Using nonsense syllables is essential if investigators are interested in reducing the influence of contextual and linguistic factors so that recognition relies more on the use of acoustic features (Allen, 2005; Boothroyd &Nittrouer, 1988).
Previous studies have reported an inconsistent association between audiometric pure-tone thresholds and nonsense syllable recognition under different experimental methodologies. Four studies (Bilger &Wang, 1976; Dubno et al., 1982; Reed, 1975; Wang et al., 1978) showed a systematic relationship associating better performance with lower thresholds, but another four studies (Danhauer &Lawarre, 1979; Gordon-Salant, 1987; Walden &Montgomery, 1975; Walden et al., 1980) supported no such relationship. A number of different approaches to analysis were applied across the studies.
In three studies that showed a systematic relationship with pure-tone threshold (Bilger &Wang, 1976; Reed, 1975; Wang et al., 1978), the relationship was evaluated with the results of a sequential information analysis (SINFA). SINFA provides the information for perceptual features embedded in confusion matrices (CMs) and determines the proportion of the information transmitted that is attributed to a given set of phonological features (Wang &Bilger, 1973). The procedure for constructing a (dis)similarity matrix for each subject can be summarized as follows. The results of a single SINFA were coded as a weighted vector for each of the stimulus features. The feature identified in the first iteration received the highest weight, the feature identified in the last iteration received the lowest weight, and the features not identified in the analysis received zero weight.

Whenever the number of features identified exceeded the maximum weight, the lowest ranking features were all assigned weights of one. The similarity between any two subjects was defined as the sum of the products of corresponding feature weights. Finally the similarity matrices were submitted to Johnson's (1973) pairwise multidimensional scaling procedure to represent the similarities among subjects spatially. Using this SINFAbased approach, the three studies showed a systematic relationship between phoneme recognition and configuration of the pure-tone threshold, distinguishing listeners with normal thresholds, those with a flat hearing loss, and thosewith hearing loss with sloping audiometric configurations (Bilger&Wang, 1976; Reed, 1975;Wang et al., 1978).

Unlike the SINFA-based approach, a similarity judgment task was applied in another three studies in which no systematic relationship between performance and audiometric thresholds was reported (Danhauer &Lawarre, 1979; Walden &Montgomery, 1975; Walden et al., 1980). In the similarity judgment task the subject was asked to rate the similarity between a pair of syllables using equal interval scaling (i.e., 1 being very similar, 7 being very dissimilar). Similarity judgment allows the listener to consider perceptual qualities of the phonemes being compared in addition to recognition. For example, a HI listener can judge different speech sounds to be perceptually similar because they were correctly recognized as different phonemes but judged to be perceptually similar, or because they were incorrectly recognized and judged to be the same speech sound. The results of the similarity judgment were used as input for the individual difference scaling (INDSCAL) model, a multidimensional scaling technique (Carrol &Chang, 1970). Using the similarity judgment the three studies showed no unique association between measures (Danhauer &Lawarre, 1979; Walden &Montgomery, 1975; Walden et al., 1980). It should be noted that even though Walden and Montgomery (1975) reported a systematic relationship between measures, the INDSCAL analysis with three-dimensional solutions revealed ambiguous subject space, particularly between sibilant and sonorant dimensions (see Walden &Montgomery, 1975, their Figure 2, p. 451).

Two studies analyzed phoneme recognition performance using raw CMs and compared the results with audiometric thresholds (Dubno et al., 1982; Gordon- Salant, 1987). Dubno et al. (1982) assessed consonant confusions at a fixed +20 dB signal-to-noise ratio (SNR; in cafeteria noise) in 38 HI listeners. A systematic relationship between consonant confusions and hearing threshold existed when the same consonant was given in error, most commonly for a given target across all three HI listener groups but with differences in error probability. That is, given a target /sa/, /qa/ was confused with the target at an error rate of 28.6% by the steeply sloping group, 10.4% by the gradually sloping group, and 4.2% by the flat group. However, the greatest percentage of errors was not consistently associated with a particular group. Moreover, the three HI groups were not completely separable when the complete CM was taken into account for acoustic feature (manner and place) analyses. Gordon-Salant (1987) measured CMs for consonant identification at +6 dB SNR (12 talkers babble) for three groups of elderly listeners (10 NH, 10 gradual sloping, and 10 steep sloping listeners). The INDSCAL analysis of these rawCMsrevealed no unique relationship between consonant confusions and the audiometric characteristics.

In summary, the results of four studies (Bilger &Wang, 1976; Dubno et al., 1982; Reed, 1975; Wang et al., 1978) lead to the conclusion that consonant confusions are systematically related to audiometric hearing threshold. Another four studies (Danhauer &Lawarre, 1979; Gordon-Salant, 1987; Walden &Montgomery, 1975; Walden et al., 1980) support the opposite conclusion.

An important distinction between the studies discussed above is the use of different input structures to the INDSCAL model. If SINFA-based (dis)similarity matrices (Bilger &Wang, 1976; Reed, 1975; Wang et al., 1978) or partial raw CMs (Dubno et al., 1982) were used for the INDSCAL, a systematic relationship between syllable perception and pure-tone audiometric threshold was obtained. In contrast, when similarity judgmentmeasures (Danhauer&Lawarre, 1979;Walden &Montgomery, 1975; Walden et al., 1980) or complete raw CMs (Gordon-Salant, 1987) were used as input to the INDSCAL, no systematic relationship was observed. Similarity judgment

measures are directly used as input for the INDSCAL. In contrast, SINFA-based measures should be carefully derived from raw CMs, and phonological features should be preselected by experimenters as input to the model. Consequently it is unclear how perceptual confusions embedded in CMs are reflected in SINFA-based (dis)similarity matrices. It is also unclear how the relationship between phoneme recognition and hearing threshold is impacted by these different input structures for the INDSCAL model.

Another issue in the previous studies is that CMs were measured in quiet (Bilger&Wang, 1976; Danhauer &Lawarre, 1979; Reed, 1975; Walden &Montgomery, 1975; Walden et al., 1980; Wang et al., 1978) or at +20 dB SNR (Dubno et al., 1982) and at +6 dB SNR (Gordon-Salant, 1987), which provided only partial information regarding the relationship between audiometric threshold and nonsense syllable recognition in noise. Finally, using nonsense syllables in noise provides the opportunity to evaluate performance with less use of contextual cues (e.g., meaning, grammar, prosody, etc.). These cues can increase speech understanding, particularly in noisy conditions, while not necessarily improving speech perception (Boothroyd &Nittrouer, 1988).

In the present study, we evaluate the relationship between audiometric threshold and nonsense syllable recognition with both SINFA- and CM-based INDSCAL analyses over a range of SNRs. The data evaluated here were previously studied for a separate analysis (Phatak, Yoon, Gooler,&Allen, 2009) that provided a new method to quantify the degree of consonant perception loss relative to normal hearing listeners over a range of SNRs. During the analyses, we found that consonant confusions were not hearing-threshold specific, which led to motivation for this study. In the present study, we evaluated the relationship between audiometric thresholds and syllable recognition in noise in (a) mean performanceintensity functions, (b) correlation and multiple regression models having hearing threshold as predictors, and (c) SINFA-based and CM-based similarity matrices applied as inputs to the INDSCAL model.

Method

Participants

The 22 paid participants had sensorineural hearing loss, were native speakers of American English, and were between the ages of 18 and 64 years. Three listeners had bilateral hearing loss; hence each ear was tested separately (leftand right ear identified as L and R), which resulted in a total of 25 ears tested. Descriptive information for listeners is given in Table 1.

Participants were recruited on the basis of screening preexisting audiograms obtained from the Department of Otolaryngology, Carle Clinic Association, Urbana, IL, and only those showing a three-frequency pure-tone average (0.5 kHz, 1 kHz, and 2 kHz) between 30 dB hearing level (HL) to 70 dB HLwere recruited. Listenerswhose hearing thresholdwas greater than 70 dBHL at f ≥2 kHz were not enrolled in the study because of high mean error rates in preliminary testing (see the Procedure section). The puretone audiograms of all participants were also measured for this study and are shown in the upper panel of Figure 1. All procedures were approved by both theUniversity of Illinois at Urban-Champaign Institutional Review Board and the Carle Medical Research Institutional Review Board.

Test Materials

Sixteen naturally spoken nonsense CV syllables composed of 16 American English consonants with the common vowel /a/ as in "father" were used as stimuli (Fousek, Svojanovsky, Grezl, &Hermansky, 2004). The 16 consonants presented were [/b/, /d/, /f/, /g/, /k/, /m/, /n/, /p/, /s/, /t/, /v/, /ð/, /ʔ/, /q/, /ʔ/, /z/]. Half of these syllables were spoken by five talkers and the remaining syllables spoken by another five talkers, resulting in 80 tokens [(5 talkers ×8 CVs) + (5 talkers ×8 CVs)] in total. The purpose of dividing syllables among talkers was to create a diversity of talkers and simultaneously shorten experiment time. The use of multiple utterances from several talkers also offers some assurance about the generality of the analyses beyond the experimental stimuli.

The CVs were presented in speech-weighted noise with no spectral correction (gain) as a function of SNR (-12 dB, -6 dB, 0 dB, 6 dB, 12 dB, and in quiet [Q]). Each token was level-normalized before presentation using VU-meter software (Lobdell& Allen, 2007). No filtering was applied to the stimuli. The masker was a steady-state

noise with an average speech-like power spectrum, identical to that used by Phatak and Allen (2007). For each CV, the RMS level of this noise was adjusted according to the level of the CVs to achieve the desired SNRs. Stimuli were computer-controlled and delivered via an external USB audio card (Mobile-Pre, M-Audio), and presented monaurally via an Etymotici ER-2 insert earphone. Sound levels were controlled by an attenuator and headphone buffer (TDT system 3) so that stimuli were presented at the most comfortable listening level (MCL) for each listener. The MCL was determined by each listener's self-rating with the Cox loudness rating scale (Cox, 1995) in response to 30 CVs with no error in quiet. System calibration estimates that CV presentation levels in the ear canal were between 75 and 85 dB SPL.

Procedure

The ear canal was inspected otoscopically and puretone audiometry was performed to measure hearing thresholds and to confirm type of hearing loss for each listener. Each participant was seated in a sound-treated room (Industrial Acoustics Company) for audiometry, practice, and experimental sessions. Stimuli were presented to a test ear via an insert earphone. Environmental sound to the other ear was attenuated using a foam earplug.

CV syllables were presented while participants viewed the graphical user interface that listed the 16 CVs with example words alphabetically. Participants were asked to select the button on the interface to identify the perceived CV.

A calibrate button was included so that the presentation level (MCL) could be determined by a subject's response to playing 30 CV syllables in quiet. In addition, pause and repeat buttons were available so that listeners could control the rate of stimulus presentation and could repeat the same stimulus without limit prior to responding. Our preliminary results with a few HI listeners showed no distinct influence of target repetition on performance.

Participants first performed a 30-min, two-practiceblock (120 trials per block) session on CV identification in quiet with feedback. The eligibility to participate was determined by requiring the average percent error to be less than 50% across two practice blocks in quiet. If percent error score (Pe [SNR]) was ≥50% on the two practice blocks, two additional blocks were given to further consider eligibility for participation. Listeners became eligible to participate if Pe (SNR) was ≤50% on the second pair of practice blocks, but they remained ineligible if Pe (SNR) continued to be ≥50%.

We administered the consonant identification test to measure confusion matrices for CVs in speech-weighted noise as a function of SNR. For each presentation, a CV and SNRwere selected and presentation randomized from the array of 16CVs and six SNRindices (includingQ).The set of individual stimuli [(8 CVs ×5 talkers) + (8 CVs ×5 talkers) ×6 SNRs = 480, named a set] was repeated six times (480 ×6 = 2880 trials in total), yielding 30 [2880 / (16 CV ×6 SNR)] repetitions of each CVat each SNR.

Each set (480 trials) was evenly distributed into four blocks (120 trials each), allowing participants to rest between blocks. No direct feedback about performance was provided for each CV presented. Percent correct feedback for each block was provided on the screen at the end of each block. The total number of trials and CVs already played were also provided on the screen.

Confusion matrices for each participant were plotted as a function of SNR. Any CV utterance produced by a particular talker that showed >20% error in quiet forNHlisteners was considered mispronounced and was removed from data analysis (Phatak &Allen, 2007). Total participation time to complete all protocols (puretone audiometry, CV practice, CV test, and break time) was about 6 hr and was performed in two visits.

Results

Audiometric Analysis and Pe (SNR)

The pure-tone audiograms were separated into one of two overall audiometric configurations to form a sloping group (n = 18; see Figure 1, top leftpanel) and flat group (n = 7; see Figure 1, top right panel). This classification was based on an historical scheme for describing the configuration of hearing threshold, HT (f), from the pure-

tone audiogram (Bamford et al., 1981; Clark, 1981; Goodman, 1965; Margolis &Saly, 2007; Yoshioka &Thornton, 1980). This classification scheme suggests that audiogram profiles can be classified by threshold configuration such as normal, flat, and sloping curves. In some studies the sloping curve is further divided into two subgroups, for example, sloping curves with a slope ≤20 dB/octave or ≥30 dB/octave for 1 kHz ≤f ≤4 kHz (Clark, 1981; Goodman, 1965). Similarly, the flat curve could further be divided into two subgroups, flat curves with a slope ≤15 dB/octave or ≥25 dB/octave for 1 kHz ≤f ≤4 kHz (Margolis &Saly, 2007; Yoshioka &Thornton, 1980). In our sloping group, only two out of 18 ears (denoted by the dotted line in Figure 1, top leftpanel) showed audiogram configurations with a slope ≥30 dB/octave for 1 kHz ≤f ≤4 kHz; therefore, subgroups were not defined. However, any trends indicated by the data points for these two listeners will be noted. For the flat group, all seven listeners fell into a group having slopes ≤15 dB for 1 kHz ≤f ≤4 kHz. The mean hearing thresholds (denoted as thick lines in the upper panels of Figure 1) differed significantly between the sloping and flat configuration groups, $F(1, 23) = 6.7$, $p < .05$. At frequencies <2 kHz, HT (f) for listeners with sloping hearing loss was approximately 20 dB better than for listeners with flat configuration, whereas at frequencies >3 kHz, HT (f) for the flat group is 15 dB better than for the sloping group.

A comparison of the Pe (SNR) between the two audiometric groups demonstrates a strong overlap in CV recognition performance with the range of Pe (SNR) exceeding 35% at each SNR. The lower panel of Figure 1 shows the Pe (SNR) across 16 CVs for individual listeners, coded according to the corresponding theHT (f). The mean Pe (SNR) for each group is shown by a thick line. A two-way repeated-measure analysis of variance showed no significant difference between the mean Pe (SNR) of the two groups, $F(1, 23) = 0.2$, $p > .05$. The main effect of SNR was significant, $F(5, 115) = 505$, $p < .001$. The error scores for the two listeners with slopes ≥30 dB/octave for 1 kHz ≤f ≤4 kHz generally showed poorest performance among the listeners with sloping hearing loss.

In summary, we conclude that the audiogram-based listener grouping is poorly associated with the mean Pe (SNR) for nonsense CV recognition in noise. The results shown in Figure 1 indicate that the likelihood of demonstrating representative and distinctive descriptions of speech-recognition performance across a range of HI listeners would be low if built upon the audiogrambased listener grouping.

Regression Model

To better understand the contribution of frequencydependent audibility to CV recognition, we investigated the extent to which thresholds of individual audiometric frequencies are associated with overall recognition of nonsense CVs in noise. Specifically, we determined the extent to which listener's hearing thresholds account for the variance in Pe (SNR). To study this question, a multiple regression model was tested with the slopes of Pe (SNR) forming the dependent variable and with the HT (f) at standard audiometric frequencies, as the independent variable. These slopes were computed for each listener, based on a sigmoid fit without transformation.

The HT (f) at standard audiometric octave frequencies, namely, x1 through x6 for 0.25 kHz to 8 kHz, were used as predictors. The best model was determined by testing all combinations of the 6 predictors. The search for the best combination of the predictors was finalized by finding the smallest sum of least square errors and the highest adjusted R2 values. As a result, HT (f) at 0.25 kHz, 2 kHz, and 4 kHz were included in the model as predictors. In the case of using multiple predictors, it is possible the predictors do not operate independently, but reveal multicollinearity, preventing an indication of the influence of individual predictors. Multicollinearity is >0.1 for all six predictors, which indicates no violation of the assumption that predictors operated independently (Tabachnick& Fidell, 1989). Other important assumptions were addressed appropriately.1

The final linear regression model showed an insignificant relationship between the three predictors, HT (f) and the slopes of the Pe (SNR), $F(6, 18) = 1.93$, $p > .05$. This model explained 39% of the total variance, suggesting that the balance of the variance is associated with other unmeasured variables. Based on weights (b coefficients) for the model, the order of effects on the slope of Pe (SNR) from greatest to least is for thresholds

at 2 kHz, 4 kHz, and 0.25 kHz.

INDSCAL Analysis

In this section, we attempt to use listeners' perceptual errors to identify the relationship between audiometric threshold and consonant confusions in noise. To display this relationship across subjects, we use the INDSCAL model (Carrol &Chang, 1970). The INDSCAL model takes each listener's (dis)similarity matrix (measured in a CM or similarity judgment) as its input, transforms each CM into Euclidean distances, and iterates a process of estimating individual subject differences by applying individual sets of weights to the dimensions of a common group space. In the subject space, each listener is represented as a point, and the location of a listener in the subject space is adjusted by that subject's weights, indicating the particular salience to each of the dimensions of the space. In the present study, two-dimensional solutions were retained for both SINFA-based similarity matrices and raw CMs for each subject and for each SNR. A scree plot, a graph presenting a lack-of-fit INDSCAL model relative to dimensions, supports three-dimensional solutions as the optimal number of dimensions, but a squared correlation index, the proportion of variance of the optimally scaled data, with two-dimensional solutions is also acceptable (Takane, Young, &de Leeuw, 1977). Another reason for choosing two-dimensional solutions is to avoid the complexity of interpreting stimulus features across additional dimensions. The squared correlation index for the two-dimensional solutions revealed that the model accounts for a variance of 72% to 97% over the SNRs tested.

SINFA-Based INDSCAL Model

Subject space. Evaluation of subject weight in twodimensional space, derived from the SINFA-based INDSCAL analysis, demonstrated no systematic relationship between stimulus features across SNRs and pure-tone threshold groups (see Figure 2). This result differs from that of Bilger and Wang (1976) despite obtaining (dis)similarity matrices using the same approach. However, two clear subject groups were identified, particularly by dimension (Dim.) 1. For example, seven subjects with flat hearing loss (ID is given) are consistently separated into two groups across SNRs except SNR = -12 dB; 3R and 117R were separated from other five subjects (4L, 4R, 76L, 113R, and 216L) by Dim. 1. The two listeners whose audiograms showed a slope ≥30 dB/octave for 1 kHz ≤f ≤4 kHz from the sloping group were also consistently classified in the same group across SNRs. This SINFA-based INDSCAL analysis revealed consistent groups of listeners across SNRs, but grouping was not consistent with the flat and sloping audiometric configurations.

To assess the consistency of these groups across SNRs, a retaining rate, the percentage of listeners remaining in the same group across SNRs, was computed, and the results are shown in top portion of Table 2. Overall retaining rate is constant across SNRs except -12 dB SNR. The retaining rates are given in each cell with the number of listeners in parentheses. Percentages oriented diagonally along the bottomof each column indicate the retaining rate between adjacent SNRs. For example, 23 listeners (92%) out of 25 maintained their groups between Q and 12 dB SNR and 16 (64%) out of 25 listeners were retained by their groups between -6 dB to -12 dB SNRs. Other cells indicate retaining rates for composite SNRs. For instance, 92% of listeners in the Q row remained in the same groups between Q and 12 dB SNR, but the retaining rate decreased to 68% when groups were considered over 12 dB, 6 dB, -6 dB, and -12 dB SNRs. The retaining rate decreases considerably at -12 dB SNR.

Two of the three subjects whose performance was measured separately for the right and leftears (4L/R in the flat group; 200L/R in the sloping group) were consistently categorized in the same group across SNRs (results were shown only for 4L/R in Figures 2 and 4). The third subject who was tested bilaterally (2L/R in the sloping group) was categorized in the same group at -12 dB and 0 dB SNRs, but not at other SNRs.

CM-based INDSCAL Model

Stimulus space. The group stimulus space illustrated in Figure 3 provides a graphical representation of the stimulus coordinates derived by CM-based INDSCAL. This group stimulus space depicts the perceptual proximities of the stimuli presumed to underlie all listeners' confusions. The dimensions are interpreted as the

consonant features that can best account for the arrangement of the stimuli along each axis.

The stimuli appear to be arranged in two clusters along Dim. 1: the duration consonants (/s/, /?/, /?/, and /z /) are distinguished from the other 12 CVs at three lower SNRs (see Figure 3, top panels), whereas the fricative consonants (/f/, /s/, /v/, /ð/, /?/, /?/ and /z/) best define clusters at higher SNRs (see Figure 3, bottom panels). The feature labeled as duration is adapted from Miller and Nicely (1955) to distinguish four fricative consonants that are characterized by long duration and intense, high-frequency noise. The presence of a long frication noise appears to be the important feature for defining Dim. 1 at lower SNRs.

Dim. 2 shows that the nasals (/m/ and /n/) are separated from the other 14 CVs at the four higher SNRs (see Figure 3). A misplacement of /?/ is observed for Dim. 2 at +12 dB SNR. At -6 dB and -12 dB SNRs, the consonants on Dim. 2 are arranged in a single cluster,which precludes defining that dimensionwith an interpretable feature. For Dim. 2, the manner of articulation clearly serves as the common perceptual dimension at the four higher SNRs.

Subject space. The subject weights on twodimensional solutions of the CM-based INDSCAL process with 25 HI ears are shown in Figure 4. A dimension weight reflects the strength of the dimensional property in accounting for the confusions made by each subject at each SNR. That is, the weights reflect the types of confusions made by subjects at each SNR. For example, if the confusions are mainly between stimuli that share stimulus features specified by a dimension, then subject weights will be relatively high for that dimension. Where the confusions are mainly between stimuli that do not share stimulus features described by the dimension, the subject weights for that dimension are relatively low.

The result of the CM-based INDSCAL analysis shows no discernible categorization of listeners between the two audiometric groups at any SNR, including the quiet condition (see Figure 4). At each SNR, listeners were grouped (A, B, and C), based on differences in weighted Euclidean distances, although actual subjects within each cluster vary according to SNR. This CMbased group seems to be mainly dependent on the SNR, suggesting that confusions are a function of SNR, not of audiometric configurations. One noticeable pattern in the subject space is that listenerswho had higher weights along Dim. 1 also had higher weights along Dim. 2. The variability of weights on both dimensions was noted for the two lowest SNRs. A distinct segregation of the two sloping group listeners with slopes ≥30 dB/octave for 1 kHz ≤f ≤4 kHz is demonstrated, particularly at 0 dB, 6 dB, and 12 dB SNRs, but any unique separation from other sloping group listeners across SNRs is not obvious. Because no consistency in HI grouping was found, plots of audiograms versus CM-based groups are not presented. In addition, the subjects with both ears tested (4L/R in the flat group; 2L/R and 200L/R in the sloping group) were consistently categorized in the same group at the four lower SNRs, but not for the two higher SNRs.

The retaining rate for CM-based listener grouping is shown in the bottom portion of Table 2. The retaining rate is proportional to SNR, that is, as a SNR decreases, the retaining rate also decreases, particularly at a SNR <0 dB. The rate is also largely poorer than that for the SINFA-based grouping. Out of 25 listeners, 13 (52%) maintained their groups between Q and 12 dB SNR and 11 (44%) were retained by their groups between -6 dB and -12 dB SNRs. Other cells indicate retaining rates for composite SNRs. For instance, 52% of listeners in Q row remained in the same groups between Q and 12 dB SNR, but the retaining rate decreased to 24% when groups were considered over 12 dB, 6 dB, and -6 dB SNRs. Finally only two listeners (8%) remained in the same groups over four SNRs from 12 dB to -12 dB. This retaining rate would vary with the SNR step size being compared. If equal step sizes are compared on the diagonals formed along the bottom of columns in Table 2, then a U-shaped function is more apparent with the best retention rate for comparisons at 0 dB SNR. Indeed, 0 dB SNR has the highest retention rate.

Discussion

The goal of the present study was to determine the extent to which audiometric hearing threshold is associated with nonsense CV recognition in noise. The results revealed that the Pe (SNR) does not seem to be directly

associated with the HT (f), as shown in Figure 1. However, in the quiet condition, the scores for the sloping hearing threshold group (20%) and for the flat hearing threshold group (25%) are similar to those reported by Dubno et al. (1982). Dubno et al. reported that errors among the listeners with sloping hearing loss were the lowest (22% error), whereas those with flat hearing loss were somewhat poorer (30% error), and those labeled steep hearing loss showed the highest error (50%) on CVor VC syllables in cafeteria noise at +20 dB SNR.

The multiple regression models revealed nonsignificant associations between the slopes of Pe (SNR) and HT (f). HT (f) contributed 39% of the total variances of the slope of Pe (SNR). The weights (b coefficients) for the model showed that effect on the slope of Pe (SNR) was the greatest for thresholds at 2 kHz. Carhart and Porter (1971) showed a similar finding for spondees: Adding a threshold at 1 kHz (except in the group with marked high-frequency loss) for the regression model was highly correlated with speech reception threshold (SRT), but adding threshold at 2 kHz to the model improved the prediction slightly. However, adding thresholds at 4 kHz and 0.25 kHz did not produce practical improvement in predictability for spondee SRT. Bamford et al. (1981) correlated pure-tone audiograms with the slope of sentence perception performance in quiet for 150 HI children. Poor correlation (r = 0.329) was reported. It was also reported that the correlation between measures was highly affected by the degree of hearing loss, particularly from severe to profound hearing loss.

SINFA-based listener grouping (see Figure 2) showed no unique relationship of audiometric characteristics with consonant confusions even though two distinct groups were consistently defined across SNRs. This poor relationship is related to two technical issues in the SINFA analysis.

First, the SINFA requires prior knowledge about unknown perceptual features embedded in CMs. In the SINFA procedure, phonological features are selected by the experimenter with some unknown assumption about the perceptual features. The analysis of SINFA-based INDSCAL provides only subject spaces without names of dimensions because experimenters select features for the model in advance. This is the reason that all studies that used SINFA never presented subject dimensions because the approach does not permit identification of that information. In addition, requirement of prior knowledge of perceptual features is a fundamental violation for INDSCAL model because the core concept of the INDSCAL model is to reveal unknown perceptual dimensions embedded in CMs or (dis)similarity matrices.

Another concern about using SINFA is related to the procedure for obtaining (dis)similarity matrices. As discussed in the introduction, the feature identified in the first iteration received the highest weight, the feature identified in the last iteration received the lowest weight, and the features not identified in the analysis received zero weight. Whenever the number of features identified exceeded the maximum weight, the lowest ranking features were all assigned weights of one. The similarity between any two subjects was defined as the sum of the products of corresponding feature weights. This means that a similarity matrix for one subject might be much like that of another subject even though their features were identified in very different orders. For example subject A has ratings from 6 to 1 for the same set of features, but subject B has ratings from 1 to 6. The sum of the products between subjects A and B is 56. Another two subjects, C and D, have two top ratings (6 and 5) in common, but ratings for other features are not in common. The sum of the products between subjects C and D is 61. It is highly likely that the SINFA-based INDSCAL model would consider these two pairs of subjects similar even though their feature perception is completely different.

As shown in the two-dimensional subject space derived from the CM-based INDSCAL (see Figure 4), no unique relationship between audiometric thresholds and perceptual confusions was evident across SNRs, including the quiet condition. This CM-based INDSCAL grouping seems to be a function of SNR, not of audiometric configuration.

Our CM-based INDSCAL solutions for perception in quiet are consistent with results of other studies (Danhauer &Lawarre, 1979; Danhauer &Singh, 1975; Walden et al., 1980) despite differences in some experimental conditions including (in their studies): a single talker, listener's demographics, stimulus context (CV-CV pairs), and response mode (similarity judgment using 7-point equal-appearing interval scaling). Danhauer and Singh

(1975) found that subject weights in the three-dimensional solutions generated by INDSCAL were neither obvious nor related to three different audiometric configurations. Danhauer and Lawarre (1979) also found that HI listeners represented in three-dimensional solutions could not be clustered into distinct subgroups according to three different configurations of hearing loss. Walden et al. (1980) also reported no consistent differences in feature weights between two HI listener groups represented by INDSCAL in four-dimensional solutions. This result is somewhat in disagreement with those of Walden and Montgomery (1975) who reported distinct HI listener groupings in three-dimensional subject space determined by the INDSCAL analysis. In contrast to a conclusion made by the authors, the INDSCAL analysis with threedimensional solutions revealed ambiguous subject space, particularly between sibilant and sonorant dimensions (see Walden &Montgomery, 1975, their Figure 2, p. 451). Compared with INDSCAL groupings from other studies, subject space in the study by Walden and Montgomery (1975) did not support distinct subject groups.

A study of CV perception in HI listeners by Bilger andWang (1976) provides a particularly important comparison with the current study because the complete body of information from both diagonal and off-diagonal cells in CMs was fully taken into account for the analysis. Whereas 14 CVs used by Bilger andWang were identical to those used in the current study, some details of the experimental conditions differed. For example, the number of talkers and vowels used differed (a single talker and three vowels [/i/, /a/, /u/] in Bilger andWang; 10 talkers and a single vowel /a/ in the current study). However, it has been demonstrated that differences in the vowel accompanying the consonant have little effect on the patterns of consonant confusions (Gordon-Salant, 1985; Phatak &Allen, 2007).

Grouping of pure-tone audiogram configurations as defined by SINFA-based INDSCAL of CV confusions in quiet revealed different patterns between the study by Bilger and Wang (1976, Figure 5, bottom panels) and the current study (Figure 5, top panels). Bilger and Wang found three distinct subgroups in two-dimensional space. Bilger andWang's data revealed differences in the average configuration of hearing thresholds that appear clearly discernible (Figure 5, bottom right panel). The NH/gradual group had a slope <20 dB for 1 kHz ≤f ≤4 kHz. For the same range of frequencies, the flat group had a slope <5 dB, and the steep group had a slope >30 dB. For the current study, the slopes of the average hearing thresholds showed great overlap across groups defined by SINFA-based INDSCAL (Figure 5, top right panel). For example, for 0.25 kHz ≤f ≤2 kHz, the slopes of group 1 and 2 are somewhat different (<15 dB), but for 2 kHz ≤f ≤4 kHz, the slopes of the two groups are similar (<10 dB). Listener grouping, defined by CM-based INDSCAL in the current study (Figure 5, middle panel) was different from that defined by SINFA-based INDSCAL in the current study and in Bilger andWang. For the current study, the slopes of the average hearing thresholds show great overlap across groups defined by CM-based INDSCAL (Figure 5, middle right panel). Specifically for 1 kHz ≤f ≤4 kHz, the slopes of groups A and B are similar (<20 dB), and the slope of group C is <30 dB.

The cause for the discrepancy in the results defined by SINFA-based INDSCAL between the current study and that of Bilger andWang (1976) might be talker variation. For the present study, 16 CVs were produced by 10 different talkers, whereas for the Bilger and Wang study, all CVs were produced by a single talker. It has been shown that perceptual confusions are clearly influenced by talker variation (Phatak, Lovitt, &Allen, 2008; Regnier&Allen, 2008). Phatak et al. (2008) showed that different utterances of the same consonant can produce a significant variability in performance scores and confusion patterns. The consonant most often confused with a given target consonant varied depending on the talker. The reason for using multiple talkers in the present study was to measure confusions under more realistic listening conditions. Such conditions may yield results that are more readily generalized but more complex in that the confusions are more distributed even for the same utterance. Thus, it is likely that talker variation is one of the variables that can spread the effect of the audiometric difference across subject space, resulting in inconsistent groupings for performance in quiet as shown in the current study.

The cause for the discrepancy in the results between CM-based INDSCAL in the current study and

SINFAbased INDSCAL in the study by Bilger and Wang (1976) appears to result from a difference in input structures for the INDSCAL model. In the study by Bilger and Wang, (dis)similarity matrices for the INDSCAL model were constructed from the indices of feature perception, determined by the SINFA (Wang &Bilger, 1973), whereas for the current study (dis)similarity matrices were normalized, raw CMs. Details of how (dis)similarity matrices for the INDSCAL model were constructed, based on the results of SINFA, appear in the Introduction above. The differences in the structure of (dis)similarity matrices directly alter the iteration process from an arbitrary initial configuration of subject space in the INDSCAL model, resulting in a different estimated configuration of subject spaces (Jones &Young, 1972; MacCallum, 1977; Takane et al., 1977). One of two conclusions made by Wang and Bilger (1973), about identifying distinct perceptual features for CVs from CMs measured in both in quiet and noise, is that similar information transmission for features does not guarantee similar consonant confusion patterns or vice versa. Thus, it is possible, based on the systematic differences between the present study and that of Bilger and Wang, that the dissimilarity matrices, constructed from information transmission for features (SINFA), are more reflective of audiometric threshold differences than of confusion matrices.

For both Bilger and Wang (1976) and the current studies, audibility might be one of the factors affecting internal structure of perceptual confusions. Bilger and Wang used a presentation level of 40 dB above the subject's SRT, and a MCL (75 dB È85 dB SPL) was used for the current study. Using data given in the study of Bilger and Wang, we computed the average presentation levels for each of the HI groups categorized by SINFAbase analyses as follows: 54.6 dB HL for theNH/gradual group (Figure 5, A panel), 67.6 dB HL for the flat group (Figure 5, B panel), and 67.0 dB HL for the steep group (Figure 5, C panel). For the current study, using the minimum audibility curve (ANSI S3.6-1996), the presentation levels of 75 and 85 dB SPL would be equivalent to 62.5 and 72.4 dB HL. The presentation levels in dB HL for both studies were comparable. However, an inspection of the audiograms given in Figure 5 for both studies indicates that sensation level is too low for some subjects. For example, in the study by Bilger andWang, three subjects in the NH/gradual group had sensation level less than 10 dB at frequencies >3 kHz; two and four subjects in the flat and steep groups showed the same results. In the current study, six subjects in the A group (Figure 5, middle panel) had sensation level of less than 10 dB at 3 kHz; this result was similarly evident in one and four subjects in the B and C groups, respectively (Figure 5, middle panel). Lower sensation level at high frequencies might affect perception of some consonants such as /sa/ and /?a/, but it is unclear how such a lack of audibility affects the confusion patterns. Consequently, it is difficult to predict how listener's groupings observed in both studies will be affected. It would be interesting to see how the relationship between consonant confusions and hearing threshold would be affected if a spectral compensation procedure such as NAL-R is applied to adjust frequency response based on the loudness equalization for each CV.

Another possible influence on the grouping observed in the current study is the characteristics of the noise masker (speech-shaped noise). That is, the presence of a noise stimulus might change the effective hearing loss configuration, making it more similar than different for persons with different losses. If this is the case, then the result of grouping in quiet for the current study should be different from that in noise. This was not the case for the results of the current study. For example, in Figure 2, seven subjects with flat hearing loss were consistently separated into two groups when syllables were presented in both noise and quiet. Regardless of presence of noise, the two listeners with steeply sloped hearing loss (threshold ≥30 dB/octave for 1 kHz ≤f ≤4 kHz) were also consistently classified in the same group. In addition, 3R and 117R in the sloping group were separated from five other subjects in the same group (4L, 4R, 76L, 113R, and 216L) across SNR including the quiet condition. Based on this evidence, it is unlikely that the presence of a noise stimulus changes the effective hearing loss configuration and makes persons with different losses more similar than different. The results of the present study might be useful for hearing aid fitting algorithm research.

For most current hearing aid fitting algorithms, the pure-tone audiogram is the primary input even though the

audiogram does not account for the majority of the variance in performance of speech perception in noise. Our results suggest that patients with similar audiometric configurations may require different hearing aid strategies.

Conclusions

A clear predictive relationship between the Pe (SNR) and HT (f), was not found for syllable recognition either in noise or in quiet. The result of a multiple regression model showed that 39% of total variance of the Pe (SNR) was contributed by the HT (f). The result of SINFAbased INDSCAL analysis revealed consistent grouping of listeners across SNRs, but groupings were not consistent with two configurations of pure-tone thresholds. The CM-based INDSCAL analysis showed no systematic relationship between the consonant confusions and the HT (f) at any SNRs, including the quiet condition. Thus, audiometric threshold does not account for the majority of the variance in performance of nonsensesyllable perception in noise when complete CMs were considered.

Acknowledgments

The data collection expenses were covered through research funding provided by Etymotic Research. We thank all members of the Human Speech Recognition group at the Beckman Institute, University of Illinois at Urbana-Champaign for their help. Our special thanks go to Feipeng Li and Sandeep Phatak for their careful reading and valuable suggestions. We thank Andrew Lovitt for writing the Matlab data collection code. We want to thank Justin Aronoff, associate researcher at House Ear Institute for his comments on MDS computation and interpretation of the results and thank Laurel Fisher for valuable comments on the regression analyses.

Footnote

1An assumption of normality of residual errors was tested by checking histograms for the residuals as well as normal probability plots. The linearity assumption between variables was verified by plotting bivariate scatter plots of the variables. In practice, these assumptions can never be fully confirmed; however in this case, linearity was read from these scatter plots.

Consequences of Broad Auditory Filters for Identification of Multichannel-Compressed Vowels

Author: Souza, Pamela; Wright, Richard; Bor, Stephanie

Publication info: Journal of Speech, Language and Hearing Research (Online) 55.2 (Apr 2012): 474-486.
ProQuest document link

Abstract: In view of previous findings (Bor, Souza, &Wright, 2008) that some listeners are more susceptible to spectral changes from multichannel compression (MCC) than others, this study addressed the extent to which differences in effects of MCC were related to differences in auditory filter width. Listeners were recruited in 3 groups: listeners with flat sensorineural loss, listeners with sloping sensorineural loss, and a control group of listeners with normal hearing. Individual auditory filter measurements were obtained at 500 and 2000 Hz. The filter widths were related to identification of vowels processed with 16-channel MCC and with a control (linear) condition. Listeners with flat loss had broader filters at 500 Hz but not at 2000 Hz compared with listeners with sloping loss. Vowel identification was poorer for MCC compared with linear amplification. Listeners with flat loss

made more errors than listeners with sloping loss, and there was a significant relationship between filter width and the effects of MCC. Broadened auditory filters can reduce the ability to process amplitude-compressed vowel spectra. This suggests that individual frequency selectivity is a factor that influences benefit of MCC when a high number of compression channels are used.

Purpose: In view of previous findings (Bor, Souza, &Wright, 2008) that some listeners are more susceptible to spectral changes from multichannel compression (MCC) than others, this study addressed the extent to which differences in effects of MCC were related to differences in auditory filter width.
Method: Listeners were recruited in 3 groups: listeners with flat sensorineural loss, listeners with sloping sensorineural loss, and a control group of listeners with normal hearing. Individual auditory filter measurements were obtained at 500 and 2000 Hz. The filter widths were related to identification of vowels processed with 16-channel MCC and with a control (linear) condition.
Results: Listeners with flat loss had broader filters at 500 Hz but not at 2000 Hz compared with listeners with sloping loss. Vowel identification was poorer for MCC compared with linear amplification. Listeners with flat loss made more errors than listeners with sloping loss, and there was a significant relationship between filter width and the effects of MCC.
Conclusions: Broadened auditory filters can reduce the ability to process amplitude-compressed vowel spectra. This suggests that individual frequency selectivity is a factor that influences benefit of MCC when a high number of compression channels are used.
Key Words: hearing aids, compression, multichannel, auditory filter, vowel
For many years, vowels were seen as "filler" between critical consonants that carried little information in themselves. Consider an example from popular culture: The voice of the "teacher" in animated Peanuts cartoons consisted of an unintelligible stream of vowel-like inflection without any consonants (actually created with a trombone). More recently, researchers have focused on the contributions of the vowel-to-speech recognition (e.g., Kewley-Port, Burkle, &Lee, 2007). Segmentally, both the static center of the vowel and the transitory onset/ offset boundaries carry useful information. For example, Rogers and Lopez (2008) found that speech recognition was impaired when the vowel center was removed, even though start and end formant transitions were intact. Vowels, then, deserve our attention for their contributions to speech recognition under different circumstances.
The most important identifying cues for a vowel are the frequency locations of the vowel formants (Hillenbrand, Houde, &Gayvert, 2006; Kewley-Port &Zheng, 1998; Klatt, 1982; Sommers &Kewley-Port, 1996; Syrdal &Gopal, 1986). Listeners can identify vowels given nothing but a sparse spectrum of tones at the formant frequencies (e.g., Molis, 2005).We can therefore view a vowel as a set of three to five spectral "peaks" separated by lower amplitude "valleys." We refer to the level difference between the peaks and valleys of the vowel spectra as spectral contrast.
To understand vowel identification, first consider representation of a vowel through a normal auditory system. With narrow auditory filters providing good frequency selectivity, the auditory system can easily resolve and distinguish the formant frequencies from the background, in which the background can be either the spectral valleys of the vowel or a masking noise. A high level of identification is achieved especially when formant information is combined with other cues, such as spectral shape and vowel duration.
Next, consider the same vowel, represented through an impaired system in which auditory filters are broader than normal (Dubno &Dirks, 1989; Glasberg &Moore, 1986). In such a system, closely spaced formants may fall within the same critical band so that the listener can no longer distinguish between vowels with similar formant frequencies. This is one reason why many listeners with sensorineural loss show degraded perception for

naturally produced vowels (e.g., Coughlin, Kewley-Port, &Humes, 1998; Liu &Kewley-Port, 2007; Richie, Kewley- Port, &Coughlin, 2003).

Even if vowel formants are resolved into separate critical bands, widened auditory filters may smear spectral detail. Consequently, listeners with hearing loss require a larger spectral contrast (i.e., peak-to-valley ratio) to achieve the same performance as listeners with normal hearing when listening to vowel-like synthetic stimuli (Leek, Dorman, &Summerfield, 1987; Turner &Holte, 1987). The individuals tested in Leek et al. (1987) needed a peak-to-valley ratio of about 6 dB (in contrast to 2 dB for listeners with normal hearing). Because naturally produced vowels have peak-to-valley ratios on the order of 5-30 dB, many vowels should still be identifiable despite the need for larger spectral contrast. However, accurate vowel identification will depend on the presented vowel, the listener's frequency selectivity, and whether alternative cues (such as vowel duration) are available.

The present study is concerned with effects of broadened auditory filters on vowel identification in combination with effects of digital amplification. Digital hearing aids invariably apply some form of wide dynamic range multichannel compression (MCC). Briefly, in MCC, the input signal is filtered into a number of channels. Gain is applied within each channel, with the goal of placing the output signal into the listener's dynamic range, and the channels are summed for the final output. Early researchers anticipated that a large number of compression channels might reduce spectral cues1 (Lippmann, Braida,&Durlach, 1981; Plomp, 1988). Although there was little empirical testing of this effect, poorer performance with MCC was assumed to be because of reduction of spectral cues (Woods, Van Tasell, Rickert, &Trine, 2006). However, loss of spectral detail was also presumed to be of minor consequence for speech recognition when considered in view of the other benefits of MCC (Yund &Buckles, 1995).

Studies of MCC have focused mainly on consonant or sentence recognition, in which spectral, temporal, and contextual cues all contain usable information. Spectral degradation fromMCCought to have the greatest consequence for vowel identification, which depends on spectral cues. Bor, Souza, and Wright (2008) undertook an acoustic analysis to quantify the acoustic and perceptual effects of MCC. Naturally produced vowels were processed with 1-16 compression channels, and a spectral contrast measure was developed to assess the effect of channel number. Most of the vowels showed significantly decreased spectral contrast, and reduced spectral contrast was associated with reduced vowel identification. It was of particular interest that recognition was reduced more for some listeners than others, even though they all had similar degrees of hearing loss.

To guide clinical choices, it would be useful to be able to determine which individuals might be most susceptible to such effects. It seems probable that the consequences of spectral change from MCC are magnified for individuals who have poorer representation of spectral detail because of broader auditory filters. Such a relationship has already been demonstrated, albeit for linearly amplified consonants (Preminger &Wiley, 1985). Given that vowels depend more heavily on spectral cues than do consonants (Xu &Pfingst, 2008; Xu, Thompson, &Pfingst, 2005), we expect a relationship between auditory filter width and perception of MCC vowels.

The present study builds upon our previous work (Bor et al., 2008) to further investigate the effects of MCC on vowel spectra and, in particular, to explore reasons for individual variability. The following goals were addressed: first, to describe auditory filter characteristics for listeners with sloping and flat loss; second, to determine whether those groups showed a difference in identification of multichannel compressed vowels; and third, to determine whether performance differences across groups were related to auditory filter width.

Method

Listeners

Twenty-eight adults2 participated in the study. The cohort included 13 listeners with sloping loss (53-88 years of age; mean age = 74 years) and 15 listeners with flat loss (44-88 years of age; mean age = 71 years). Listeners

were tested monaurally, and a loss that met the criteria in one ear was sufficient for inclusion. All listeners had sensorineural hearing loss, defined as no air-bone gap greater than 10 dB at octave frequencies ranging from 0.25 to 4 kHz and static admittance and tympanometric peak pressure within normal limits in the test ear according to Wiley et al. (1996). Each listener with sloping loss had normal hearing or a mild loss (≤ 35 dB HL)3 at 500 Hz, with 2000-Hz thresholds at least 20 dB worse than 500-Hz thresholds. Each listener with flat loss had a moderate loss (40-60 dB HL) at 500 Hz, with 500- and 2000-Hz thresholds within 10 dB of each other. Mean hearing thresholds for the two groups are shown in Table 1. Our primary interest was not audiometric configuration per se but rather the relationship between auditory filter width and identification of MCCvowels. The choice of listeners with flat and sloping loss was a convenient way to increase the probability that auditory filter patterns would vary across groups. Because pure-tone threshold and auditory filter width are moderately correlated (Carney &Nelson, 1983; Dubno &Dirks, 1989; Florentine, Buus, Scharf, &Zwicker, 1980; Stelmachowicz, Jesteadt, Gorga,&Mott, 1985), we expected that (a) low-frequency auditory filters would be wider for the listeners with flat than sloping loss, (b) high-frequency auditory filters would be similar across the two groups, and (c) there would be within-group variability.

There was no significant difference in age between groups, $t(26) = -0.68$, $p = .506$. Each listener completed the Mini-Mental State Exam (Folstein, Folstein, &McHugh, 1975) and had at least the minimum score of 26 (out of 30) considered to represent normal cognitive function. Group mean Mini-Mental State Exam scores were 29.5 points for the sloping group and 29.0 points for the flat group, with no significant difference between groups, $t(26) = 1.59$, $p = .454$.

Data were also collected for four listeners with normal hearing (26-33 years of age; mean age = 28 years). All of the listeners with normal hearing had pure-tone thresholds of 20 dB HL or better at octave frequencies ranging from 0.25 to 8 kHz. The normal-hearing data were used as a reference point for data interpretation.

English was the first or primary language for all listeners. All procedures were reviewed and approved by the local Institutional Review Board, and listeners were reimbursed for their time.

Auditory Filter Characteristics

Auditory filter characteristics were estimated with an adaptation of the procedure used by Leek and Summers (1996). Masked thresholds were determined for sinusoidal tones in the presence of notched-noise maskers. Tone frequencies were 0.5 or 2 kHz, on the basis of the auditory filters expected to be critical to the vowel identification task (first formant frequency [F1] M = 0.53 kHz, and second formant frequency [F2] M = 1.9 kHz across all vowels).

Stimuli. All signals were digitally generated in MATLAB at a 48.8-kHz sampling rate. The target tones were 360 ms in duration (including 25-ms cosinesquared rise and fall ramps). The tones were presented at 10 dB above the listener's hearing threshold at the tone frequency.4

The masker was 460 ms in duration (including 25-ms cosine-squared rise and fall ramps). Whenmasker and tone were presented together, the tone was temporally centered within the masker (i.e., the masker began 50 ms before and ended 50 ms after the tone). The masker was digitally generated in the frequency domain, resulting in two bands of noise located to either side of the target tone frequency. The maskers were placed either symmetrically or asymmetrically around the tone frequency, creating a variety of notch widths (see Table 2). Notch widths were chosen on the basis of recommended (abbreviated) parameters for estimating auditory filter widths (Stone, Glasberg, &Moore, 1992). The notch width was defined as the deviation of each edge of the central notch from the center frequency (fc), and was denoted as Df/fc. There were six notch widths: symmetrical widths of 0.0, 0.1, 0.2, and 0.4; plus two asymmetrical widths of 0.2 and 0.4 for the low and high band, and 0.4 and 0.2 for the low and high bands. The lower and upper edges for the notched noise were set at 0.8 ×fc (Baker &Rosen, 2002). Thus, the outer edges of the noise were 100 and 900 Hz for the 500-Hz tone and were 400 and 3600 Hz for the 2000-Hz tone.

Procedure. At each notch width, the tone level was fixed, and the masker level was varied adaptively to obtain

thresholds. The tone and masker were mixed and presented monaurally to the test ear via an ER2 insert earphone. The masked threshold was estimated for each notch width using a two-alternative forced-choice paradigm with feedback. In each trial, the masker was present in both intervals, and the tone was present in one of those intervals. Listeners were instructed to select the interval with the tone using a touch screen. In the first trial, signal-to-noise ratio was 0 dB. The masker increased in 5-dB steps after three consecutive correct responses and decreased in 5-dB steps after one incorrect response. The 5-dB step size decreased to 2 dB after four reversals and continued until 10 additional reversals occurred, at which point the threshold was calculated as the mean tone level of the last six reversals. A single threshold measurement was referred to as a block.

To familiarize the listener with the task, threshold was measured for each listener with the tone presented at 70 dB SPL using a symmetrical notch width of 0.2. Next, the probe level was fixed at 10 dB SL (re: audiometric threshold). For each listener, 24 thresholds (6 notch widths ×2 tone frequencies ×2 test blocks) were measured. Presentation order of the notch width and tone frequency was randomized.

Estimating the auditory filter. Auditory filter width was estimated using a roex (p, r) model, where p was the width of the filter's passband, and r was the dynamic range (Patterson, Nimmo-Smith, Weber, &Milroy, 1982). The Polyfit program (Rosen, Baker, &Darling, 1998) was used to calculate the auditory filter parameters and final equivalent rectangular bandwidth (ERB) values for this study. The model was specified to allow three polynomial terms for both the lower and upper slope of the filter, and the allowed shiftfor off-place listening was set at 0.2.

Unlike Leek and Summers (1996), we opted not to average discrepant data into the final value but rather to discard those points that, according to a quality check, did not represent a valid response to the stimuli. A data point was considered invalid if standard deviation within a block exceeded 5 dB. When invalid data points were noted during testing, the same condition was repeated in an attempt to obtain valid data. Ninetyseven percent of the data points passed the quality check and were retained. For those data, the betweenblocks difference was less than 1 dB averaged across all listeners, test tones, and notch widths. Correlation between the values for the first and second blocks was r = .89. In those cases, results for Block 1 and Block 2 were averaged together for the final notch-width result. Otherwise, results from a single block were used.

Although all listeners were able to complete the task, some estimated filters could not be fit. A modeled filter slope of zero indicated a poorly fit function. In the case of filter slope zero, each notched-noise condition was systematically removed from and/or added to the calculation to better model the filter function. In some cases, it was not possible to avoid a filter slope of zero by adding or subtracting conditions. The filter could not be modeled at 0.5 kHz for two listeners with flat loss and for one listener with sloping loss and at 2 kHz for six listeners with flat loss and for three listeners with sloping loss. Dubno and Dirks (1989) noted a similar issue, in which masked-threshold data for some listeners could not be appropriately fit by the two-parameter roex model, despite those listeners having similar hearing thresholds as the rest of the listener cohort.

Vowel Identification

Stimuli. Stimuli consisted of naturally produced vowels by six adult male and six adult female talkers. A detailed description of the vowel recording and selection can be found in Bor et al. (2008). Briefly, all vowels were recorded in an /hVd/ or /Vd/ context, including "heed" /i/, "hid" /I /, "aid" /e/, "head" /e/, "had" /æ /, "odd" /A/, "hood" /O/, and "who'd" /u/. The eight words were randomized and repeated five times, and words from equivalent positions in the set of repetitions were used to control for list effects on pronunciation. All talkers were instructed to read the list of words at a natural pace and vocal intensity. Vowels were recorded at 44.01 kHz or 22.05 kHz and were downsampled to 11.025 kHz.

One representative token of each vowel was selected for each talker on the basis of recording fidelity, clarity of each talker's voice, and similarity across vowels in the intonation. Linear predictive coding formant tracks overlaid on a wideband spectrogram and pitch tracks overlaid on a narrowband spectrogram were used to

ensure formant and pitch steady states at the vowel midpoint. The final set consisted of 96 words (12 talkers ×8 vowels). Table 3 lists means and standard errors of F1 and F2 for the vowel set. Peak amplitude was normalized across vowels. For these steady-state signals, final root-meansquare levels across vowels varied by less than 2 dB.

Compression. To create the MCC vowels, the 96 /hVd/ words were digitally filtered into 16 channels using 5-pole, Butterworth 1/3rd-octave band filters. The lower to upper range across all channels was set at 141 Hz and 5623 Hz, respectively. Division points between channels were based on equal-octave spacing (see Table 4). The channels were compressed separately using simulation software and then were summed to create the final MCC signals.

The compression parameters were the same in each channel and included a compression ratio of 3:1, an attack time of 3 ms, and a release time of 50 ms. Compression threshold was set at 30 dB below the peak level of the normalized vowel. Note that parameters suitable to test the experimental question took priority. For that reason, the compression parameters were deliberately not varied across individuals (or across channels), as would be done in the clinic. However, the compression parameters were within the range of those in clinical use. Output level of the vowels was dictated by the application of an individual frequency-gain response, described below.

To remove formant transitions and vowel duration cues, a 150-ms segment was extracted from the center of each vowel. The 150-ms duration was chosen after examining vowel duration among the entire set. Because all vowels were longer than 150 ms, the brief temporal overshoot of the attack time was removed. A 5-ms linear amplitude ramp was applied to the onset and offset of each segment.

A linear (uncompressed) condition was created using all process steps described here, except that the stimuli were bandpass filtered from 141 Hz to 5623 Hz, and there was no compression simulator.

To ensure sufficient audibility of all vowels for the listeners with hearing loss and to mimic a clinical scenario, amplification was added to the vowels prior to presentation. An individual frequency response was calculated for each listener using NAL-RP prescriptive values (Byrne &Dillon, 1986) and was used to create output targets (output as function of frequency) that were the same for the linear and MCC conditions. Output levels as a function of frequency were measured for each listener to ensure that targets were met and that there were no differences in audibility across conditions. An additional random attenuation of 1 or 2 dB was applied to prevent any unanticipated intensity biases.

Procedure. Listeners were seated in a double-walled sound booth. To familiarize the listener with the orthography of the vowel choices, each listener completed a training task at least twice or until performance was at least 88% correct. The task was to match the orthographic representation of the vowel sound to a set of three words that had the same vowel sound, using an eight-alternative forced-choice procedure. For example, /i/ was orthographically represented as "ee," and example words were cheese, meat, and leaf. There was no auditory signal during this task. Correct-answer feedback was given.

To measure vowel identification, stimuli were presented monaurally to the listeners via an ER3 insert earphone. The test ear for each listener was the same as the test ear for the notched-noise experiment.

A block consisted of 96 randomly ordered trials (8 vowels ×12 talkers). To account for learning effects (discussed in detail below), listeners completed four blocks in each condition (compressed or linear). Half the listeners heard the compressed blocks first, and half heard the linear blocks first. Listeners responded to each trial in an eight-alternative forced-choice paradigm using a touch screen. The location of response buttons on the touch screen was randomized for each block to prevent response bias.

Results

Auditory Filter Width

Figure 1 shows the auditory filter ERB for each listener group as a function of audiometric threshold. Larger ERB values indicate broader filters. Listeners with poorer thresholds tended to have wider auditory filters, but there was considerable variability.

At 500 Hz, there was a significant difference among groups, $F(2, 26) = 4.84$, $p = .017$. Post hoc analyses (Fisher's least significant difference) indicated that low-frequency (0.5-kHz) filters were wider for the listeners with flat loss than for listeners with normal hearing ($p = .007$) and were marginally wider for listeners with flat loss than those with sloping hearing loss ($p = .056$). There was no significant difference between listeners with sloping loss and with normal hearing ($p = .137$).

At 2000 Hz, there was a significant difference among groups, $F(2, 26) = 5.57$, $p = .011$. Between-groups post hoc comparisons showed no significant difference between listeners with flat and sloping loss ($p = .941$). The listeners with normal hearing had narrower filters than both the flat ($p = .008$) and sloping ($p = .004$) groups.

ERB values for 500 and 2000 Hz were correlated with each other ($r = .42$, $p = .017$). The significant but modest correlation reflects that although listeners with wide low-frequency filters tend to have wide highfrequency filters, having a wide high-frequency filter does not guarantee a widened low-frequency filter. That finding was consistent with a cohort that included listeners with sloping audiograms, for whom we would expect narrow low-frequency and wide high-frequency filters.

Vowel Identification

Learning on the task was minimal, with very similar scores across blocks. Within each condition (linear and MCC), mean scores improved by less than 5 percentage points on subsequent blocks, and performance stabilized (defined as a nonsignificant difference in scores, $p > .05$) between Blocks 2 and 3. Accordingly, scores for Blocks 2, 3, and 4 were averaged and used for all subsequent data analysis.

Scores for each group and amplification condition are summarized in Figure 2. There are several notable effects. First, the group mean performance is always poorer for theMCCthan for the linear condition, regardless of hearing status. In our paradigm, frequency-gain responses (and output levels) were the same for the linear and MCC vowels for each listener. Therefore, MCC did not provide any audibility or loudness comfort advantage, and the differences in scores between amplification conditions reflect the MCC processing.

Second, performance was better for listeners with sloping than with flat loss. Because both groups received appropriate audibility and were of similar age and cognitive status, it is likely that this effect is due to differences in cochlear processing. It is also notable that variability in the sloping loss group was quite small for linear amplification but increased with MCC. This suggests that listeners with sloping loss with similar audiograms and similar recognition of linearly processed speech may respond differently to processed signals.

The percent correct scores were converted to rationalized arcsine units (Studebaker, 1985), and a two-way repeated-measures analysis of variance was completed to compare across hearing loss group and amplification condition. Identification scores were worse for MCC than for linear speech, $F(1, 29) = 40.94$, $p < .005$, and for listeners with flat loss than for listeners with sloping loss, $F(2, 29) = 13.19$, $p < .005$. There was no interaction between hearing loss group and amplification condition, $F(2, 29) = 2.01$, $p = .153$.

Relationship Between Auditory Filter Width and Response to MCC

The analysis described above indicated that MCC had a similar (negative) effect on vowel identification for listeners with flat and sloping loss. However, the specific hypotheses motivating this work were that (a) frequency selectivity would vary within a hearing loss group and that (b) response to MCC would be influenced by frequency selectivity. The first hypothesis was supported by the data in Figure 1, in which not all listeners with a given audiometric configuration had similar frequency selectivity. The second hypothesis was tested with the following analysis.

First, the ERB values were converted to relative values by dividing each ERB (in Hz) by the test frequency. For example, an ERB of 200 Hz at an fc of 500 Hz converts to a relative ERB of 0.4, and an ERB of 200 Hz at an fc of 2000 Hz converts to a relative ERB of 0.1. Next, the relative ERB values at 500 and 2000 Hz were averaged to produce a single per-listener value that (roughly) represented the listener's frequency selectivity. Figure 3 shows vowel recognition as a function of average relativeERB for linear (filled circles) andMCC (open triangles) vowels. Best fit lines are shown for linear (solid line) andMCC (dashed line). Although there is considerable

variability, particularly for the MCC vowels, scores decreased at higher average relative ERBs.

A multiple regression model was used to determine the amount of variance in vowel identification that was accounted for by average relativeERBand type of amplification. In designing the regression model, we expected MCC to interact with auditory filter width. Consider the following example: the vowel /A/ spoken by a female talker with F1 about 800 Hz and F2 about 1200 Hz. In the compression algorithm used here, those formants would fall into Channels 8 and 10 (see Table 4). Even with reduced spectral contrast from MCC, a listener with narrow filter width may be able to resolve those closely spaced formants and correctly identify the vowel. However, for a listener with impaired frequency selectivity, the combination of reduced spectral contrast from MCC coupled with reduced spectral representation of the vowel because of loss of auditory tuning may result in an error. Accordingly, an interaction term representing the interaction between ERB and amplification type was also included in the model. Contributions of the main effect variables and the interaction were examined in a stepwise regression procedure using alphalevel criteria of .05 for probability of entry into the model and .10 for probability of removal from the model. The final model accounted for 85% of the variance in the score, $F(3, 63) = 113.57$, $p < .005$. Significant predictors were amplification type ($b = -0.16$, $t = 0.286$, $p < .005$), average ERB ($b = -1.18$, $t = -15.19$, $p < .005$), and the ERB ×Amplification interaction ($b = 1.07$, $t = 13.08$, $p < .005$). In other words, vowel identification is better for linear than MCC vowels, and it is better when the listener has good frequency selectivity. The significant interaction (illustrated by the solid and dashed fit lines in Figure 3) indicates that listeners with good frequency selectivity,whowouldotherwisebe able to resolve formant information, are more detrimentally affected by MCC than listeners with naturally poorer frequency selectivity.

Although not an experimental hypothesis, it is also of interest to examine the relationship between response to MCC and pure-tone threshold. Similar to the treatment of the relative ERB values, pure-tone thresholds (dB HL) at 500 and 2000 Hz were averaged to produce a single per-listener value that (roughly) represented the listener's hearing status. Table 5 shows pairwise correlation values (Pearson r) for average hearing threshold, average relative ERB, and vowel identification.

Vowel Error Patterns

Figure 4 shows the vowel error patterns, plotted as graphical confusion matrices. In each panel, presented (target) vowels (ordered by F1) are shown on the abscissa, and responses are shown on the ordinate. The size of each circle represents the number of responses for a particular presented vowel/responded vowel combination. Responses on the diagonal are correct, and those are noted by percent correct values. Responses offthe diagonal are incorrect. For example, for listeners with sloping loss listening through linear amplification, the vowel /i/ was correctly identified 96% of the time, and errors were about evenly distributed among the other vowels, with the exception of /e/, which was never chosen. For listeners with sloping loss listening through MCC amplification, the vowel /i/ was identified correctly only 62% of the time, and the most common errors were / I / and /?/. Qualitatively, the greater the "scatter" to either side of the diagonal, the more difficult the task. Mirroring the data from Figure 2, the largest number of errors occurred for listeners with flat loss presented with MCC vowels, and the smallest number of errors occurred for listeners with sloping loss presented with linear vowels.

Discussion

Considerations When Measuring Auditory Filter Width

Listeners with flat versus sloping loss are assumed to have different frequency resolution, particularly at low frequencies. In our data, listeners with flat loss had broader auditory filters than listeners with sloping loss at low frequencies, and they had similar filter widths at high frequencies. The exact width of the auditory filter varied among individuals even when they had similar hearing thresholds. Numerous investigators have demonstrated variability in frequency resolution (auditory filter width) among individuals (e.g., Carney &Nelson, 1983; Florentine et al., 1980; Hopkins &Moore, 2011; Stelmachowicz et al., 1985; Turner &Henn, 1989). Indeed, the pure-tone audiogram is now seen as a relatively coarse measure of hearing function, as demonstrated by

recent calls for more sensitive hearing assessment measures (Abel et al., 2009; Souza& Tremblay, 2006; Walden &Walden, 2004).

For the present data, average hearing threshold was at least as strongly related to vowel performance as the more specific filter measurements (see Table 5). Earlier work by Turner and Henn (1989) suggests that the hearing threshold-to-performance correlation is less related to audibility per se than to the relationship between auditory threshold and frequency selectivity. Listeners with better hearing thresholds tended to be those with good frequency selectivity, and they were also the listeners with the best vowel identification.

There are some practical problems with estimating auditory filters using the method reported here. Some listeners, particularly those with poorer thresholds, have auditory filter bandwidths that are too broad for precise mathematical modeling. In our data, more of these listeners were noted in the flat loss group and were excluded from data analysis. Some modeling errors can be avoided if test conditions include more repetitions at each notch width or if more notch-width conditions are included, but the amount of test time is already substantial. The average time required to obtain data for just two auditory filters was 2 hr per listener, rendering such testing inappropriate for clinical use. We have begun evaluating some "fast" auditory filter measurements that could be adapted for the clinic (Charaziak, Souza, &Siegel, 2011).

A related issue is choosing which auditory filters to measure. We selected auditory filters centered at 500 and 2000 Hz as representative of the frequency region for our vowel formants. Those frequencies were a reasonable, albeit sparse, description of across-frequency selectivity for each listener, but they are only a part of the abilities needed to perform well on the vowel task as a whole.We did not necessarily measure the auditory filter the listener would need to identify a specific formant for a specific vowel by a specific speaker. Also, identifying a formant is essential, but not sufficient, for vowel identification. The listener also needs to "reconstruct" the vowel across frequency-that is, to identify formants relative to other formants. Apoux and Healy (2009) estimated that 20 auditory filters are required for accurate vowel identification. In that sense, no single auditory filter measurement can predict vowel identification. Nonetheless, it is likely that listeners with broadened 0.5- and 2-kHz filters also have broadened filters at other frequencies and that listeners with poor frequency selectivity will have difficulty perceiving speech elements that rely on spectral contrast, such as vowels.

Influence of Auditory Filter Width on Identification of MCC Vowels

Vowel identification worsened with increasing auditory filter width and when MCC was used. There is evidence that both manipulations smooth the vowel spectra received by the listener.With regard to internal spectral representation, Leek and Summers (1996) tested listeners with hearing loss to determine how much spectral contrast was needed before they were able to separate out target components from background components. They assumed that the detectable difference in intensity between target peaks and background harmonics indicated how much contrast was preserved in the cochlear excitation pattern. Listeners with broader high-frequency auditory filters were less able to use F2 differences to make identification judgments and based their decision almost entirely on F1 peaks. Several authors (Leek &Summers, 1996; Turner &Henn, 1989) suggested that broader auditory filters create an altered internal representation (excitation pattern) of a vowel. Effectively, the output of each auditory filter results in a poorer signal-to-noise ratio than would be the case for a listener with a more sharply tuned auditory system. Animal models also support loss of frequency selectivity in a damaged cochlea (Miller, Calhoun, &Young, 1999).

Bor et al. (2008) demonstrated that increasing number of compression channels causes greater alteration to vowel spectra. They argued that overuse of MCC (i.e., using a large number of compression channels coupled with moderate to high compression ratios) could smooth vowel spectra in a manner akin to that of broadened auditory filters. After decades in which hearing aids were marketed with ever larger numbers of compression channels, there is growing acknowledgment that more is not always better, or at least that the level of acoustic manipulation should be customized for the listener (e.g., Edwards, 2007; Souza, 2011; Woods et al., 2006). The

interaction between auditory filter width and amplification type seen in the present data suggests that the spectral smoothing resulting from MCC has a relatively greater effect on a listener with narrower auditory filters, who would otherwise be able to resolve vowel formant peaks.

When MCC is needed for other reasons, such as loudness comfort or audibility across frequency, it might be possible to counteract the effects of spectral smoothing with additional processing. Spectral sharpening has been suggested for use in hearing devices (DiGiovanni, Nelson, &Schlauch, 2005; Oxenham, Simonson, Turicchia, &Sarpeshkar, 2007).However, Franck, van Kreveld-Bos, Dreschler, and Verschuure (1999) noted that vowel perception was poorer when eight-channel MCC was combined with spectral sharpening than with spectral sharpening alone. In contrast, combining single-channel compression with spectral sharpening had no effect compared with spectral sharpening alone. Although MCC alone (without sharpening) was not tested, the negative effects of MCC demonstrated by Franck et al. were consistent with the present data.

Relating Current Data to Clinical Use of MCC

To what extent will the data presented here generalize to wearable hearing aids in everyday listening situations? We know that listeners with hearing loss rely more heavily on vowel spectra than on dynamic formant transitions (e.g., Lentz, 2006), so the signals used in this study should have captured the effect of distortion on essential acoustic cues. However, our signals were more strictly controlled than would be the case in everyday listening. Under more realistic conditions, vowels amplified through hearing aids would contain other cues, such as vowel duration and formant transitions, and would also have lexical and contextual information from the word or phrase in which the vowel is embedded. We deliberately controlled for temporal confounds, such as vowel duration. The postcompression processing used here also eliminated any attack time overshoots. Accordingly, the data should be applicable to any compressor where compressor speed is sufficiently fast as to engage the compressor through the duration of the vowel. In a very slow-acting MCC system where some or all of the vowel is linearly amplified, performance might be more similar to the linear vowel scores presented here. Finally, although the spectrally flattened vowels used in this study were created with MCC parameters that were clinically feasible, an individual listener might receive more or less spectral contrast than represented here depending on the prescriptive procedure, compression parameters, cross-over frequencies, signal input level, and presence or absence of background noise. Crain and Yund (1995) noted that MCC affected vowel identification with some, but not all, compression parameters and recommended that individual adjustments be made for each listener.

The present study compared MCC and linearly amplified speech, in which the control (linear) condition was more similar to a single-channel aid with frequency shaping than to a digital hearing aid designed to function as a multichannel compressor but set to linear (i.e., compression ratio of 1:1 in each compression channel). Specifically, a digital hearing aid set to linear would filter the speech into channels (without compression) then would mix the output of the filters. Given the experimental focus on spectral cues, we chose a Butterworth filter that minimized spectral distortion within and outside the passband. Such a filter can introduce a delay in the temporal domain, particularly for very narrow filters. Spectral analysis of our filtered signals preand postcompression indicates that such distortion was minimal, in part because there was little energy present in the input signal for the narrowest (lowest frequency) filters. Moreover, even much greater amounts of temporal distortion are not expected to impact recognition of stationary-formant vowels (see Assmann &Summerfield, 2004, p. 270, for discussion of this issue).

In summary, hearing technology has become increasingly complex. First-generation digital hearing aids had no more than two or three channels, whereas today's MCC hearing aids provide as many as 20 channels. More channels have been viewed as a positive aspect of processing in terms of providing better loudness comfort, precise gain adjustments, and the potential for better noise control and feedback reduction (Chung, 2004a, 2004b). However, beyond some therapeutic point, there may be diminishing returns. Audibility can be maximized with as few as four channels (Woods et al., 2006). Despite a long-standing industry trend toward

more sophisticated processing, the most appropriate solution for some listeners may be simpler processing that preserves signal features.

Acknowledgments

Work was supported by National Institutes of Health Grant R01 DC0060014. We thank Kathryn Arehart, Marjorie Leek, Michelle Molis, and Chris Stecker for sharing code and expertise for portions of this project, and Star Reed and James Dewey for help with data analysis. Andy Sabin and Jon Siegel provided helpful suggestions regarding filter measurements. We also thank Steve Armstrong and Gennum Corporation (Burlington, Ontario, Canada) for providing the software used to simulate hearing aid compression.

Footnote

1Compression amplification applies more gain for low-level inputs and applies less gain for high-level inputs.With single-channel compression, the specified gain will be applied across the entire frequency range, and spectral peaks and valleys will be maintained. With MCC, spectral valleys will receive more gain than spectral peaks. For a more detailed description of this effect, the reader is referred to Bor, Souza, and Wright (2008).

2Number of participants was based on 80% power to detect the main effect of interest (Bausell &Li, 2002).

3Threshold values are expressed in dB HL (recommended by the American National Standards Institute, 2004).

4The presentation level was increased to 13 dB SL for three listeners because the level of the noise could not be lowered far enough for those listeners to detect the tone.

Abstract: In this article, a new signal-processing algorithm is proposed and evaluated for the suppression of the combined effects of reverberation and noise. The proposed algorithm decomposes, on a short-term basis (every 20 ms), the reverberant stimuli into a number of channels and retains only a subset of the channels satisfying a signal-to-reverberant ratio (SRR) criterion. The construction of this criterion assumes access to a priori knowledge of the target (anechoic) signal, and the aim of this study was to assess the full potential of the proposed channel-selection algorithm, assuming that this criterion could be estimated accurately. Listening tests with normal-hearing listeners were conducted to assess the performance of the proposed algorithm in highly reverberant conditions (T60 = 1.0 s), which included additive noise at 0 and 5 dB signal-to-noise ratios (SNRs). A substantial gain in intelligibility was obtained in both reverberant and combined reverberant and noise conditions. The mean intelligibility scores improved by 44 and 33 percentage points at 0 and 5 dB SNR reverberation + noise conditions. Feature analysis of the consonant confusion matrices revealed that the transmission of voicing information was most negatively affected, followed by manner and place of articulation. The proposed algorithm produced substantial gains in intelligibility, and this benefit was attributed to the ability of the proposed SRR criterion to detect accurately voiced or unvoiced boundaries. It was postulated that detection of those boundaries is critical for better perception of voicing information and manner of articulation.

Purpose: In this article, a new signal-processing algorithm is proposed and evaluated for the suppression of the

combined effects of reverberation and noise.
Method: The proposed algorithm decomposes, on a short-term basis (every 20 ms), the reverberant stimuli into a number of channels and retains only a subset of the channels satisfying a signal-to-reverberant ratio (SRR) criterion. The construction of this criterion assumes access to a priori knowledge of the target (anechoic) signal, and the aim of this study was to assess the full potential of the proposed channel-selection algorithm, assuming that this criterion could be estimated accurately. Listening tests with normal-hearing listeners were conducted to assess the performance of the proposed algorithm in highly reverberant conditions (T60 = 1.0 s), which included additive noise at 0 and 5 dB signal-to-noise ratios (SNRs).
Results: A substantial gain in intelligibility was obtained in both reverberant and combined reverberant and noise conditions. The mean intelligibility scores improved by 44 and 33 percentage points at 0 and 5 dB SNR reverberation + noise conditions. Feature analysis of the consonant confusion matrices revealed that the transmission of voicing information was most negatively affected, followed by manner and place of articulation.
Conclusions: The proposed algorithm produced substantial gains in intelligibility, and this benefit was attributed to the ability of the proposed SRR criterion to detect accurately voiced or unvoiced boundaries. It was postulated that detection of those boundaries is critical for better perception of voicing information and manner of articulation.
Key Words: reverberation, noise, dereverberation algorithms
(ProQuest: ... denotes formulae omitted.)
Reverberation is present in most daily listening situations. Reverberation can cause significant changes in speech quality and can have a very negative impact on speech intelligibility as it blurs, for instance, temporal and spectral cues and flattens formant transitions (Nabelek, Letowski, &Tucker, 1989). Although moderate amounts of reverberation do not affect speech recognition performance by normal-hearing listeners, reverberation has a detrimental effect on speech intelligibility by listeners with hearing impairment and elderly listeners (Assmann &Summerfield, 2004; Nabelek, 1993) as well as by automatic speech recognition systems (Palomäki, Brown, &Parker, 2004). The negative effects of reverberation on intelligibility vary across age (Neuman &Hochberg, 1983; Neuman, Wroblewski, Hajicek, &Rubinstein, 2010) and between native and nonnative listeners (Nabelek &Donahue, 1984).
Nabelek and Letowski (1985) studied the effects of reverberation on vowel recognition by 10 elderly adults with binaural sensorineural hearing loss and found that themean vowel recognition score obtained in a reverberation time (T60) of 1.2 s was approximately 12 percentage points lower than the mean score obtained in the nonreverberant (anechoic) conditions. Compared with vowels, consonants are generally more affected by reverberation. The stop consonants, for instance, are more susceptible to reverberation distortion than other consonants, particularly in syllable-final position. This is because reverberation "fills in" the gaps present during stop closures. When noise is added to reverberation, listeners make different consonant confusions from those made in reverberation or in noise (Nabelek et al., 1989). That is, noise generally masks speech differently than reverberation. The combined effects of reverberation and noise are quite detrimental to intelligibility (Nabelek &Mason, 1981; Nabelek &Pickett, 1974a). In a recent study with normal-hearing children and adults, Neuman et al. (2010) assessed speech intelligibility in reverberation + noise conditions in terms of speech reception threshold (SRT). When comparing the results to SRT norms obtained by adults in anechoic conditions, Neuman et al. (2010) reported a signal-to-noise ratio (SNR) loss1 of 1.5-3 dB for adults and 7.5-9.5 dB for young children (age 6 years) when reverberation (T60 = 0.3-0.8 s) was added. The SNR loss decreased as a function of age.
Addressing the degradation in speech intelligibility and quality due to reverberation has given rise to several dereverberation algorithms (e.g., see Benesty, Sondhi,& Huang, 2007; Jin &Wang, 2009; Kollmeier &Koch, 1994; Naylor &Gaubitch, 2010). Dereverberation by means of inverse filtering-or passing a reverberant signal through a finite impulse response (FIR) filter that inverts the reverberation process-remains one of the most commonly used methods (Miyoshi &Kaneda, 1988). However, the main drawback of inverse filtering methods is

that the acoustic impulse response must be known in advance or, alternatively, needs to be "blindly" estimated. Such algorithms, however, have severe limitations because room impulse responses (RIRs), particularly in highly reverberant rooms, have thousands of filter taps, making their inversion a computationally expensive task. Furthermore, some RIRs exhibit nonminimum phase characteristics. Thus, techniques that do not rely on inversion of the RIR are more attractive and more practical.

An alternative technique based on channel selection is explored in this article. Such a technique is attractive because it does not rely on the inversion of the RIR. The proposed method is based on decomposing, in short time segments (every 20 ms), the reverberant signal into a number of channels (via a fast Fourier transform [FFT]) and retaining only a subset of channels at each segment. The proposed criterion for selecting the appropriate channels is based on instantaneous measurements of the signal-to-reverberant ratio (SRR). Envelopes (computed using the FFT magnitude spectrum of each 20-ms segment) corresponding to channels with SRR larger than a preset threshold are selected, whereas envelopes corresponding to channels with SRR smaller than the threshold are zeroed out. The SRR reflects the ratio of the energies of the signal originating from the early (and direct) reflections and the signal originating from the late reflections. Note that the resulting reverberant signal is composed of the superposition of these two aforementioned signals. Hence, the underlying motivation in using the proposed SRR criterion is to retain the signal components arising from the early reflections while discarding the signal components generated from late reflections.Early reflections are known to benefit speech intelligibility inbinaural hearing (e.g., see Litovsky, Colburn, Yost, &Guzman, 1999) for normal-hearing listeners, whereas late reflections are known to be detrimental to speech intelligibility as they are responsible predominantly for smearing the temporal envelopes and filling the gaps (e.g., closures) in unvoiced segments (e.g., stops) of the utterance.

The above SRR criterion for channel selection was used and evaluated in our prior study (Kokkinakis, Hazrati, &Loizou, 2011) with listeners who have cochlear implants. That study, however, only evaluated the effects of reverberation-that is, with no additive noise present. In the present study, we evaluated the proposed channel-selection criterion using normal-hearing listeners in conditions wherein additive noise as well as reverberation are present. Nonsense syllables were used for testing to avoid ceiling effects. The aim of this study was twofold: (a) to determine the effectiveness of the proposed channel-selection criterion in suppressing or minimizing the combined effects of reverberation and noise and (b) to determine which consonant feature (voicing, manner of articulation, or place of articulation) is affected the most in reverberation + noise conditions.

Method

Listeners

Eight normal-hearing listeners with pure-tone thresholds less than 25 dB HL (at frequencies of 250 Hz up to 8 kHz), all native speakers of American English, were recruited for the intelligibility tests. Their ages ranged from 18 to 26 years, and all subjects were paid for their participation. The majority of the subjects were undergraduate students from The University of Texas at Dallas.

Stimuli

Telephone band-limited (300-3400 Hz) syllables in /aCa/ context were used for testing. The consonant set included 16 consonants recorded in /aCa/ context, where C=/p, t, k, b, d, g,m, n, dh, l, f,v, s, z, sh, jh/. All consonants were produced by an American male speaker and were recorded in a soundproof booth using Tucker-Davis Technologies recording equipment. The consonants were originally sampled at 25 kHz and down-sampled to 8 kHz. To simulate the receiving frequency characteristics of telephone handsets, all clean and corrupted signals were filtered by the modified intermediate reference system(IRS) filters (ITU-T Recommendation P.48, 1996). Telephone band-limited consonants were used to avoid ceiling effects.

The reverberant signals were generated by convolving the clean signals with real RIRs, recorded by Van den Bogaert, Doclo, Wouters, and Moonen (2009), with average reverberation time of T60 = 1.0 s and directto-reverberant (DRR) ratio of -0.49 dB for a 5.50 m ×4.50 m× 3.10 m (length ×width ×height) room. The distance

between the single-source signal and the microphone was 1 m. Speech-shaped noise was added to the reverberant signals at 0 dB SNR and 5 dB SNR-that is, the reverberant speech signal served as the target signal in the SNR computation.

Proposed Algorithm Based on Channel Selection

The proposed algorithm, henceforth called the ideal channel-selection (ICS) algorithm, is depicted in Figure 1. It is termed ideal to indicate that a priori information about the target signal is used. First, the clean and corrupted signals are segmented into 20-ms frames (with 50% overlap between frames) using a Hanning window, and a discrete Fourier transform (DFT) is computed. Note that in the frequency domain, the DFT decomposes the signal into N frequency bins, or channels (alternatively, an M-channel filter bank could be used in place of the DFT), where N is the duration of the frame in samples. Of the N/2 available channels (due to the DFT symmetry), a subset is selected based on the SRR criterion,2 which is computed as follows:

... (1)

where t indicates the frame index, f indicates the channel or frequency bin index, and S(f,t) and R(f,t) denote the complex DFT spectra of the clean (anechoic) and corrupted (reverberant or reverberation + noise) signals, respectively. Envelopes (computed using the FFT magnitude spectrum of each 20-ms segment) corresponding to channels with SRR >T are selected, whereas envelopes corresponding to channels with SRR ≤T are discarded, where T denotes a preset threshold value. Mathematically, this can be expressed by applying a gating or binary gain (BG) function to the spectrum of the reverberant signal as follows:

... (2)

where

... (3)

and where Trepresents the threshold value expressed in dB. To reconstruct the enhanced (dereverberated) signal in the time domain, the inverse DFT of bS ðf ; tÞ is computed, and the signal is finally synthesized using the overlap-add (OLA) method (MATLAB implementation of the above ICS algorithm is available from our website3). It is important to stress that the above binary timefrequency gain function (Equation 3) is applied to the reverberant spectrum and does not explicitly "clean out" reverberation but, rather, selects the reverberant channels that satisfy the SRR criterion (Equation 3).

The above operation of (ideal) binary gating is also known in the literature as the ideal binary mask, or ideal time-frequency mask, and it has been used extensively in computational models of auditory scene analysis (see review inWang&Brown, 2006). The ideal binary mask uses as a channel-selection criterion the instantaneous SNR computed at each time-frequency unit and has been used in applications in which the objective is to segregate a target speaker from a mixture (see Brungart, Chang, Simpson, &Wang, 2006; Li &Loizou, 2008a). The SNR criterion is clearly not appropriate for the reverberation-alone conditions, considering there are no additive maskers present. Given these differences, we refer to our algorithm as the ideal channel-selection algorithm rather than as the ideal binary mask algorithm. Both algorithms select in each frame a subset of channels, but the selection is made using different criteria.

The choice of the threshold T in Equation 3 is important in the construction and application of the proposed channel-selection criterion. To illustrate this, we show in the Figure 2 example synthesized waveforms of the syllable /a p a/, with the threshold set to T = -8 dB (Panel [d]) and T = 0 dB (Panel [e]). As shown, the latter threshold (0 dB) is aggressive, considering that apart from discarding the corrupted unvoiced segments and associated gaps, it also eliminates speech in the voiced frames, which in turn leads to distortion of the processed signal. In contrast, the use of T = -8 dB seems to eliminate the overlap-masking effects caused by the overlapping of succeeding segments of speech (in our case, the stop /p/) by the preceding phonetic segments (vowel /a/ in this example). As shown in Figure 2, by appropriately thresholding the SRR function (shown in Panel [c]), we can reliably identify the vowel/consonant boundaries even in highly reverberant settings (T60 = 1.0 s).

Figure 3 shows example synthesizedwaveforms of the syllable /a s a/ corrupted by reverberation and additive noise at +5 dB SNR. Waveforms from a low-frequency channel (f = 500 Hz) are shown in the leftcolumn, and waveforms from a high-frequency channel (f = 3060 Hz) are shown in the right column. As can be seen in Panels (d) and (h), the retained (by the channel-selection process) waveforms are still corrupted by noise; however, the vowel/consonant boundaries are preserved. The gap in the /s/ spectrum, for instance, at t = 300-500 ms is maintained in the retained waveform (compare Panels [a] and [d]).

The motivation for choosing the SRR criterion to guide the channel-selection process is as follows. The SRR provides, approximately, a simple measure of the ratio of the signal energy conveyed by the early reflections (and the direct sound) to that contained in the late reflections. It seems reasonable, then, to select a given channel only when the signal energy produced by early reflections dominates the energy produced by late reflections originating from the preceding signal. This is demonstrated in Figures 2 and 3. In Figure 2, for instance, during the /p/ closure (t = 245-362 ms), the reverberant signal contains a significant amount of energy caused by leakage from the preceding vowel (overlap masking). This energy is introduced primarily by the late reflections. TheSRRtakes extremely low values (-10 to -40 dB) during that period of the /p/ closure, wherein the contributions from the late reflections dominate. Consequently, by discarding a channel when the SRR is extremely low, we are reducing (and, to some extent, minimizing) the overlap-masking effects. In contrast, a large SRR value suggests dominance of the energy from the direct signal (and early reflections), as is often the case during the voiced segments (e.g., vowels) of the utterance (overlap masking may occur during voiced segments due to the energy originating from the preceding consonant; however, its effect is minimal). Consequently, channels containing energy from early reflections are retained (see, for instance, the vowel segment from t = 450 ms to t = 738 ms).

In reality, the denominator in the SRR contains energy fromboth early and late reflections, but nonetheless, we assume that the contribution of the early reflections is small. This assumption holds for the most part during unvoiced phonetic segments containing spectral gaps (e.g., stop closures), particularly in the low frequencies where the vowel formants reside and overlap-masking effects dominate. Ideally, it would be desirable to decouple the contributions of the early and late reflections, but that is not straightforward or easy to do, particularly when the reverberation time (T60) is long. For that reason, the entire reverberant signal is used in the denominator of the SRR for practical purposes. Similarly, we assume that the energy produced from the early reflections is close to that produced by the direct path. The proposed experiments will test whether the above approximations and assumptions hold.

A number of alternative criteria to the SRR criterion have been proposed and evaluated by Mandel, Bressler, Shinn-Cunningham, and Ellis (2010). However, these criteria were evaluated in the context of improving the performance of automatic speech recognition systems rather than as a means for improving speech intelligibility. In addition, most of the criteria proposed by Mandel et al. (2010) required access to the RIR. Hence, estimating such criteria poses great challenges. In contrast, the construction of the SRR criterion does not require access to the RIR.

As mentioned earlier, we denote the proposed algorithm as the ideal channel-selection (ICS) algorithm, where the term ideal is used to indicate that a priori knowledge is used to construct the SRR. In practice, the SRR needs to be estimated from the reverberant signal alone. The aim of the proposed experiments is to assess the full potential of the SRR criterion in terms of intelligibility benefit. If a large benefit is observed, that would suggest that significant efforts need to be devoted to developing techniques for accurately estimating the SRR. The resulting data from the proposed experiments will provide the upper bound in performance that can be obtained when the SRR criterion is estimated accurately.

Procedure. The listeners participated in 15 conditions, which included clean anechoic stimuli, reverberant stimuli, stimuli corrupted by noise alone (at 2 SNRs), and reverberation + noise (at 2 SNRs) stimuli. Six additional conditions involved ICS-processed stimuli (reverberant and reverberant + noise) using two different

threshold values (T = -8 dB and 0 dB). We denote the reverberant stimuli as R, the stimuli corrupted by noise alone as N, and the reverberation + noise stimuli as R + N. Three other conditions were included for comparative purposes based on a commonly used spectral subtractive (Wu &Wang, 2006) algorithm for suppressing reverberation. This algorithmwas applied to the reverberant and R + N stimuli. The spectral subtraction algorithm has been found to be effective in removing the impact of late reverberation (Wu &Wang, 2006) and was used in this study as an additional control condition.4

The consonants were presented to the listeners in random order. Six repetitions per condition were used. The presentation order of the various conditions was randomized across subjects. A practice session, in which the clean (anechoic) consonants were presented to the listeners, preceded the actual test. To collect responses, a graphical user interface (GUI) was used that allowed the subjects to identify the consonants they heard by clicking on the corresponding button on the GUI. All listening experiments were performed in a soundproof room (Acoustic Systems, Inc.) using a PC connected to a Tucker-Davis System3. Stimuli were presented to the listeners monaurally through Sennheiser HD 250 Linear II circumaural headphones at a comfortable listening level. The test session lasted for approximately 2 hr. A short break was given to the subjects every 30 min to minimize listener fatigue.

Results and Discussion

Consonant Identification in Reverberation and Noise

The results, expressed in terms of the mean percentage of consonants identified correctly, are shown in Figure 4. The bar labeled "clean" represents the mean score obtained in anechoic conditions. A two-way, repeated measures analysis of variance (ANOVA)5 indicated significant effect of SNR, $F(2, 14) = 63.2$, $p < .0005$; a significant effect of ICS threshold, $F(2, 14) = 257.1$, $p < .0005$; and a significant interaction, $F(4, 28) = 44.8$, $p < .0005$. As shown in Figure 4, the ICS algorithm improved speech intelligibility in all conditions, including the reverberation-alone (i.e., with no additive noise) condition. The choice of ICS threshold affected performance in the two noisy conditions but had little effect in quiet conditions because of ceiling effects. For that reason, an interaction was observed between the SNR level and ICS threshold.

ICS improved intelligibility in all conditions tested. Post hoc tests, according to Tukey's honestly significant difference, were conducted to assess the differences in scores between conditions. The intelligibility scores obtained in the reverberation-alone condition improved by more than 7 percentage points when the ICS algorithm was used. This difference was found to be statistically significant ($p = .003$). Larger improvements with the ICS algorithm were noted in the R + N conditions. Recognition scores improved from 61.7% correct to 94.5% correct at 5 dB SNR, and from 51.4% to 95.2% at 0 dB SNR. In all cases, the intelligibility improvement (relative to that with unprocessed stimuli) by the proposed ICS algorithm was found to be statistically significant ($p < .005$) when implemented with either threshold value (T = -8 dB or 0 dB). In the 0-dBR+Ncondition, the score obtained with the ICS threshold set to T = -8 dB was found to be significantly ($p < .0005$) higher than the score obtained with the ICS threshold set to T = 0 dB. In the 5-dB R + N condition, the score obtained with the ICS threshold set to T = -8 dB was not found to be significantly ($p > .05$) higher than the score obtained with the ICS threshold set to T = 0 dB. High performance was consistently obtained across all conditions tested when the ICS threshold was set to T = -8 dB. In all conditions tested, performance with the ICS was near that obtained by listeners in anechoic conditions-that is, near 96% correct.

Figure 4 also shows performance obtained in the condition wherein the stimuli were corrupted only by noise (no reverberation). The intelligibility scores were 86.59%and 73.05% atSNRsof 5 dBand 0 dB, respectively. These scores decreased to 62% and 51%, respectively, after adding reverberation. In both noise conditions (0 dB SNR and 5 dB SNR), scores were reduced by 30% after reverberation was added. Noise and reverberation degrade intelligibility in a complementary fashion. That is, regions in the spectrum that were not originally corrupted by reverberation are affected or masked by noise, leading to a severe degradation in intelligibility (30% reduction in our study). As reported by others, the combined effects of noise and reverberation are greater than the sum of

both effects taken separately (Nabelek &Mason, 1981; Nabelek&Pickett, 1974b). This was also confirmed with the data in our study. Table 1 shows the effects of reverberation, noise, and combined effects of reverberation and noise for individual subjects. These effects were computed by assessing the decrement in performance relative to the performance obtained in anechoic conditions. The combined effect was computed, for instance, as the difference between the scores obtained in the R + N condition and the scores in the anechoic condition. For nearly all subjects (except S6) and for both SNRs tested, the combined effects were greater than the sum of the reverberation and noise effects.

As can be seen from Figure 4, the performance of the spectral-subtractive dereverberation algorithm (Wu &Wang, 2006) was not satisfactory. The scores obtained using the spectral-subtraction algorithm in the reverberation-alone condition were significantly ($p < .005$) lower than the scores obtained using the unprocessed reverberant stimuli. This is partly because applying spectral subtraction may introduce signal distortion and may, therefore, produce a drop in the consonant identification scores. Second, the reverberant conditions examined in this study were quite challenging (this algorithm was originally tested in shorter reverberation times [T60 = 0.2-0.4 s] byWu &Wang [2006]). Performance in R + N conditions was even less satisfactory. We believe that it was because the SS algorithm was not originally developed to cope with low SNR conditions, as it had been originally tested at a high SNR (20 dB).

In brief, the proposed ICS algorithm was found to produce substantial gains in intelligibility in both reverberation-alone conditions and in conditions involving additive noise (see Figure 4). This outcome was consistent with the benefit observed by listeners with cochlear implants in our prior study (Kokkinakis et al., 2011). We attribute the intelligibility benefit to the ability of the SRR criterion to detect accurately voiced/unvoiced boundaries (see Figure 2). In continuous speech, reliable access to these vowel/consonant boundaries has been found to be critical for lexical segmentation and word retrieval (Li &Loizou, 2008b; Stevens, 2002).

Analysis of Consonant Errors

The consonant confusion matrices were analyzed in terms of percentage of transmitted information as per Miller and Nicely (1955), and the mean feature scores for place of articulation, manner of articulation, and voicing features are presented in Figure 5. A two-way repeated measures ANOVA indicated a significant effect of SNR, $F(1, 7) = 8.6$, $p = .022$; a significant effect of feature error, $F(2, 14) = 13.3$, $p = .001$; and a nonsignificant interaction,$F(2, 14) = 0.649$, $p = .538$. As can be seen from Figure 5, all three features, especially the voicing feature, were significantly affected, $F(2, 14) = 13.3$, $p = .001$, in the R + N conditions. In the presence of reverberation, place-of-articulation scores were generally higher than the manner and voicing scores.

Overall, on the basis of Figure 5, we can conclude that the transmission of voicing information is mostly affected in the R + N conditions. We attribute this to overlap-masking effects, which are largely responsible for filling the gaps (e.g., stop closures) that are present in some consonants (e.g., stops), making it difficult to distinguish between, for instance, the unvoiced stops (e.g., /t/) and the voiced stops (e.g., /d/). The filled gaps (by reverberation and noise) clearly affect the perception of voice onset time, and it is well known that in intervocalic stops, the duration of voice onset time as well as the duration of aspiration are effective cues signaling voicing contrast (Borden, Harris, &Raphael, 1994). These cues are severely corrupted by the combined effects of reverberation and noise.

All feature errors in place, manner, and voicing were compensated by the use of the ICS algorithm. An average improvement of about 8 percentage points in amount of transmitted information was achieved in the reverberation-alone condition. A larger improvement was noted at 0 dBSNRand 5 dB SNR, respectively, and that amounted to approximately 64 and 43 percentage points (respectively) for place, 43 and 36 points (respectively) for manner, and 65 and 54 points (respectively) for voicing in R + N conditions (on average, only 4%, 2%, and 6% below the scores obtained for place, manner, and voicing features, respectively, in the anechoic quiet conditions).

Predicting the Intelligibility of R + N Speech

The speech-transmission index (STI) has been shown in a number of studies to predict reliably the intelligibility of speech in reverberation, in noise, or in both (Houtgast &Steeneken, 1985). Aside from the STI, not many intelligibility measures exist that can predict the combined effects of reverberation and noise. In this study, we evaluated the performance of a speech-based STI that has been found previously to correlate highly with the intelligibility of noisemasked and noise-suppressed speech (Chen &Loizou, 2010; Ma, Hu, &Loizou, 2009). More precisely, we selected the normalized covariance measure (NCM), which is similar to the STI in that it computes the STI as a weighted sum of transmission index values determined from the envelopes of the probe and response signals in each frequency band (Goldsworthy &Greenberg, 2004). Unlike the traditional STI, however, which quantifies the change in modulation depth between the probe and response envelopes using the modulation transfer function, the NCM is based on the covariance between the probe (input) and response (output) envelope signals. The NCM has not been evaluated previously in situations where noise is present along with reverberation. Figure 6 shows the scatter plot of the mean consonant intelligibility scores obtained in all conditions (except the control conditions) against the corresponding mean NCM values. A linear fit is shown, but alternatively, a sigmoidal-shaped function could be used to fit the data (the computed correlation coefficient was found to be the same with either fitting function). The resulting Pearson's correlation coefficient was found to be quite high, r = .98. These data clearly show that the NCM is an effective measure for predicting not only speech intelligibility in noise (Ma et al., 2009) but also speech intelligibility corrupted by both reverberation and noise.

Conclusions

The combined effects of reverberation and noise have been found in this study to be quite detrimental to consonant recognition, an outcome consistent with prior studies (Nabelek &Mason, 1981; Nabelek &Pickett, 1974b). A signal-processing algorithm was proposed for the suppression of combined reverberation and noise. This algorithm is based on the decomposition of the reverberant stimuli into a number of frequency channels and the selection of channels with SRR exceeding a preset threshold (-8 dB). Channels with SRR values falling below the threshold were discarded. Hence, in the proposed algorithm, neither reverberation nor noise was explicitly suppressed or attenuated in any way because the channel-selection process was applied directly to the R +Nstimuli. When presented to normal-hearing listeners, the synthesized stimuli have been found to yield substantial gains in consonant identification. This outcome suggests that the combined effects of reverberation and noise do not completely mask important speech information. The channel-selection process, as guided by the SRR criterion, is a powerful process that can uncover quite effectively important speech information from the corrupted (by reverberation and noise) stimuli. Analysis of the consonant confusion errors indicated that the proposed algorithm significantly improved the transmission of voicing information, along with manner and place of articulation. Much of the intelligibility benefit was attributed to the ability of the SRR channelselection criterion to accurately detect and preserve voiced/unvoiced boundaries, often smeared in the presence of reverberation.

Footnote

1SNR loss reflects the increase in SNR required to attain 50% correct performance due to reverberation. This is relative to the SNR required by normal-hearing adults in anechoic, noise-alone conditions (SRT).

2Note that there are two major differences between our definition of SRR and the conventional SRR definition (Naylor &Gaubitch, 2010, Chapter 2). First, we do not use the direct-path signal, and second, the SRR given in this article is defined in the frequency domain for each T-F unit and is computed for each frame of the stimulus data.

4A two-stage algorithm was originally proposed in Wu and Wang (2006). In the first stage, an inverse filtering

algorithm was adopted for reducing coloration effects followed by a spectral-subtractive algorithm in the second stage for reducing late-reverberation effects. Note that the second stage was designed to subtract out the late reflections from the reverberated signal rather than subtract out additive noise. We were not able to obtain satisfactory performance via the inverse-filtering stage due to the long impulse response used in our study corresponding to a long reverberation time (T60 = 1.0 s). For that reason, we implemented only the second stage.

5We also ran the statistics using arcsine-transformed scores, but the results and conclusions remained the same.

Abstract: This study assessed selective listening for speech in individuals with and without unilateral hearing loss (UHL) and the potential relationship between spatial release from informational masking and localization ability in listeners with UHL. Twelve adults with UHL and 12 normal-hearing controls completed a series of monaural and binaural speech tasks that were designed to measure informational masking. They also completed a horizontal localization task. Monaural performance by participants with UHL was comparable to that of normal-hearing participants. Unlike the normal-hearing participants, the participants with UHL did not exhibit a true spatial release from informational masking. Rather, their performance could be predicted by head shadow effects. Performance among participants with UHL in the localization task was quite variable, with some showing near-normal abilities and others demonstrating no localization ability. Individuals with UHL did not show deficits in all listening situations but were at a significant disadvantage when listening to speech in environments where normal-hearing listeners benefit from spatial separation between target and masker. This inability to capitalize on spatial cues for selective listening does not appear to be related to localization ability.

Purpose: This study assessed selective listening for speech in individuals with and without unilateral hearing loss (UHL) and the potential relationship between spatial release from informational masking and localization ability in listeners with UHL.

Method: Twelve adults with UHL and 12 normal-hearing controls completed a series of monaural and binaural speech tasks that were designed to measure informational masking. They also completed a horizontal localization task.

Results: Monaural performance by participants with UHL was comparable to that of normal-hearing participants. Unlike the normal-hearing participants, the participants with UHL did not exhibit a true spatial release from informational masking. Rather, their performance could be predicted by head shadow effects. Performance among participants with UHL in the localization task was quite variable, with some showing near-normal abilities and others demonstrating no localization ability.

Conclusion: Individuals with UHL did not show deficits in all listening situations but were at a significant disadvantage when listening to speech in environments where normal-hearing listeners benefit from spatial separation between target and masker. This inability to capitalize on spatial cues for selective listening does not appear to be related to localization ability.

Key Words: unilateral hearing loss, informational masking, spatial release from masking, binaural, monaural, localization, selective listening

Most people listen to the world binaurally. Sounds are encoded in the auditory system via two auditory pathways, which produce an impression of an auditory scene. It is well established that binaural listening offers

significant communication advantages, particularly in complex auditory environments containing multiple sources (Bronkhorst &Plomp, 1989; Licklider, 1948; MacKeith &Coles, 1971). These advantages accrue because of the various ways that the auditory system processes interaural differences in the sounds reaching the two ears. For example, interaural differences allow listeners to localize and thus better segregate individual sound sources in the environment. Individuals with unilateral hearing loss (UHL) lose many of these advantages, because their auditory experience derives mainly from the sound present at one ear. Consequently, listeners with UHL have been shown to exhibit deficits on tasks that depend to some degree on binaural processing, namely, sound localization and speech understanding in noise (Bess, Tharpe, &Gibler, 1986; Bosman, Hol, Snik, Mylanus,& Cremers, 2003; Gatehouse &Cox, 1972; Linstrom, Silverman, &Yu, 2009; Ruscetta, Arjmand, &Pratt, 2005; Slattery &Middlebrooks, 1994). The current study was designed to expand our understanding of the deficits experienced by listeners with UHL in settings in which spatial cues would normally enhance speech recognition ability.

Speech Understanding by Normal-Hearing Listeners in Multisource Environments

Decades of research have examined how normalhearing listeners perceive speech in multisource environments. The earliest studies focused on listening conditions characterized by spectral and temporal overlap of the target and masker (French &Steinberg, 1947; Licklider, 1948), so-called energetic masking conditions. More recently, investigators have differentiated the effects of energetic masking from the effects of informational masking, which occur beyond what can be explained by overlapping excitation patterns between masker and target in the auditory periphery (Durlach et al., 2003). Informational masking occurs when the masker is qualitatively similar to the target or is characterized by uncertainty. Whereas energetic masking is thought to affect more peripheral auditory processes, informational masking is thought to affect cognitive-attentional processes (Brungart, 2001; Freyman, Helfer, McCall,&Clifton, 1999; Leek, Brown,&Dorman, 1991). Both energetic and informational masking are present in most real-world listening environments; however, one of the masker types is often dominant.

In environments dominated by energetic masking, normal-hearing listeners are known to take advantage of two binaural cues, namely, the head shadow effect and binaural interaction. The head shadow effect or better-ear effect occurs when spatial separation between the target and masker signals results in a better targetto- masker ratio in one of the ears, relative to the case where the target and masker are colocated. Thus, to the extent that a listener can attend to the ear with the better target-to-masker ratio, speech recognition is improved. This head shadow effect is between 3 dB and 8 dB, depending on the acoustical environment and the difference in azimuth between the speech target and masker (Bronkhorst &Plomp, 1988). The second binaural cue available in noisy environments to listeners with normal hearing is known as binaural interaction. Binaural interaction occurs when the target and interfering masker have different interaural timing delays (or phases), resulting in better speech detection or intelligibility than in conditions in which interaural timing delays of the target and masker are the same (Culling, Edmonds, &Hodder, 2006; Licklider, 1948). This effect is attributed to interaural differences in the absence of information that cues spatial location.A manifestation of the binaural interaction effect is the binaural intelligibility level difference (BILD). The BILD refers to the roughly 5-8 dB improvement in speech recognition threshold in noise under headphones produced by inverting the speech target in one ear with the masker presented diotically (Beutelmann, Brand, &Kollmeier, 2009; Goverts &Houtgast, 2010; Johansson &Arlinger, 2002; Levitt&Rabiner, 1967a, 1967b). Binaural interaction and head shadow effects can account for the advantages afforded by binaural hearing in most listening conditions that are dominated by energetic masking.

In settings in which informational masking is thought to play a major role, research has shown that listening performance is betterwhen the target and masker originate from different locations in auditory space than when they are colocated (Arbogast, Mason, &Kidd, 2002, 2005; Brungart &Simpson, 2007; Freyman, Balakrishnan, &Helfer, 2001; Freyman et al., 1999). This effect is called spatial release from masking, and although it occurs

with energetic maskers because of head shadow, the effect is considerably largerwhen themasker is primarily informational. The studies by Arbogast et al. (2002, 2005) employed digitally processed stimuli to maximize energetic or informational masking in various experimental conditions. The target sentences were presented simultaneously with same-band noise or sentence maskers (i.e., energetic maskers), a different-band noise masker, or a different-band sentence masker (i.e., an informational masker). The masker stimuli were presented in two spatial positions, colocated (i.e., target and masker both presented at 0° azimuth) and 90° to the right of the target (i.e., target presented at 0° and masker at +90° azimuth). In the colocated condition, listeners exhibited an average of 22 dB greater masking witha different-band speechmasker thanwith a differentband noise maker. Because the different-band noise masker and the different-band sentence masker did not contain significant spectral overlap with the target, the 22 dB poorer thresholds with the different-band sentence masker were attributed to the effects of informational masking, rather than energetic masking. In the conditions in which the different-band sentence masker stimuli were presented 90° to the right of the target, listeners received up to an 18 dB release from masking relative to the colocated condition. This is compared with a 6-7 dB spatial release that the listeners received when the same-band noise masker (i.e., an energetic masker) was separated from the target by 90° azimuth. Thus, the spatial benefits that listeners receive on informational masking tasks have been described as "perceptual" (Arbogast et al., 2002, p. 2097) and are much larger than the binaural advantages that listeners achieve by virtue of the head shadow and binaural interaction effects. Another study has shown that even compared with conditions where the better-ear signal is presented diotically, spatial separation provides a far greater release from informational masking (Best, Ozmeral, Gallun, Sen, &Shinn-Cunningham, 2005).

Speech Understanding by Listeners With UHL in Multisource Environments

Given the value of binaural cues for listening in complex auditory environments, it is not surprising that many individuals with UHL report communication difficulties in everyday listening situations. Studies conducted over the last several decades have confirmed that listeners with UHL exhibit speech understanding deficits relative to normal-hearing listeners in sound field environments having one or more sources of noise (Bess, Tharpe, &Gibler, 1986; Bovo et al., 1988; Linstrom et al., 2009; Ruscetta et al., 2005; Sargent, Herrmann, Hollenbeak, &Bankaitis, 2001; Tonning, 1971; Welsh, Welsh, Rosen, &Dragonette, 2004). Three of the more comprehensive studies examined children and revealed that children with UHL perform more poorly than their normal-hearing counterparts, even in the most favorable listening conditions where the speech was directed toward the listener's normal-hearing ear and the noisewas directed toward the impaired ear (Bess, Klee, &Culbertson, 1986; Bovo et al., 1988; Ruscetta et al., 2005). Studies examining the performance of adults with UHL have shown similar results (Linstrom et al., 2009; Sargent et al., 2001;Welsh et al., 2004). For example, Sargent et al. (2001) reported poor monosyllabic word recognition and sentence recognition in adults with UHL as compared with normal-hearing adults when the noise source was directed toward the good ear and when the noise source was directed toward both ears. In another study, Linstrom et al. (2009) compared sentence recognition of listeners with UHL who were fitted with bone-anchored hearing aids with that of normal-hearing controls. In this study, the Hearing in Noise Test (Nilsson, Soli, &Sullivan, 1994) was presented in various listening conditions in which the noise or speech was presented directly in front of the listener or 90° toward the listener's normal or impaired ear. Aided and unaided performance of the listeners with UHL was poorer than that of the normal-hearing controls across all listening conditions. These studies are consistent with others that offer anecdotal reports of listening difficulties in noise by adults with UHL (Colletti, Fiorino, Carner, &Rizzi, 1988; Giolas &Wark, 1967).

The previous studies of speech recognition in noise by individuals with UHL used paradigms in which the target speech was always presented from a different spatial location than the masker. In these conditions, normal-hearing listeners would be expected to capitalize on the binaural cues to improve recognition of the target message.We are not aware of any studies that have compared listening in noise by individuals with UHL with

that of normal-hearing individuals in listening conditions where the target and masker were colocated (i.e., in conditions in which spatial cues are minimal). Examining performance of listeners with UHL in colocated conditions is important because it would establish whether listeners with UHL have general deficits in speech understanding in noise or if their deficits are limited to listening conditions in which normal-hearing listeners take advantage of binaural cues afforded by spatial separation between the target and masker. Therefore, one of the objectives of the current study was to measure performance in both spatially separated and colocated conditions.

In environments dominated by energetic masking, one may predict performance of listeners with UHL from the relative target-to-masker ratio of the signals arriving at the listeners' normal-hearing ear. For example, in conditions in which the target is in front of the listener or on the side of the normal-hearing ear, and the masker is on the side of the impaired ear, the listener with UHL may receive some spatial benefit because the target-tomasker ratio at the normal-hearing ear would be better than if the target and masker were colocated. This benefit would be presumably limited to that afforded by the head shadow effect. In contrast, if the target is in front of the listener or on the side of the impaired ear, and the energetic masker is on the side of the normal-hearing ear, the target-to-masker ratio would be poorer at the normal-hearing ear than if the target and masker were colocated. The effect of the head shadow would put the UHL listener at a disadvantage in this condition.

It is more difficult to predict the effect of spatial separation on the performance of listeners with UHL in conditions characterized primarily by informational masking. In spatially separated conditions, listeners with normal hearing are thought to perceive the target and masker as coming from different locations and to use that information to direct their attention to the target talker and away from the other talker(s), resulting in spatial unmasking. For people with UHL, the availability of only one functioning ear precludes the comparison of auditory input from the two ears, which would presumably make determining the direction of the target and masker more difficult. Therefore, using the direction of the target and masker to achieve a spatial benefit for listening may be impossible for many listeners with UHL.

Localization in Listeners With and Without UHL

Although it is not known whether the processes by which listeners use binaural cues for localizing are the same as those they use for listening to speech in complex listening environments, it is reasonable to speculate that difficulties experienced by individuals with UHL in these tasks may be related to localization difficulties. For listeners with normal hearing, sound localization is dependent on two primary cues, interaural time difference and interaural level difference. An interaural time difference refers to the brief (less than 700 microseconds) time lag in the signal at the ear that is farther from the sound source relative to the ear that is closer to the sound source. An interaural level difference refers to the difference in intensity of the sound between the ear nearest to the sound source and the more distal ear. A large body of research on sound localization has focused on the relative salience of these two interaural difference cues, as well as other cues, such as the directionaldependent spectral shaping of input sounds by the pinnae.

Localization deficits in listeners with UHL are well documented in the literature (Agterberg et al., 2011; Bess, Tharpe, &Gibler, 1986; Bosman et al., 2003; Gatehouse &Cox, 1972; Humes, Allen, &Bess, 1980; Newton, 1983; Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2004; Viehweg &Campbell, 1960; Wazen, Ghossaini, Spitzer, &Kuller, 2005). These studies have reported that listeners with UHL demonstrate poor localization performance relative to their normal-hearing counterparts and that they tend to shift(or "bias") localization responses toward the side of the normal-hearing ear. These findings are generally consistent with those of studies that compared monaural and binaural localization in normal-hearing listeners by using test paradigms in which one ear was plugged for monaural conditions (Abel&Lam, 2008;Oldfield&Parker, 1986; Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2007; Wightman &Kistler, 1997).

Although many listeners with UHL show very limited or no ability to localize sounds on the horizontal plane, some listeners with UHL have shown reasonable localization performance (Agterberg et al., 2011; Gatehouse

&Cox, 1972; Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2004). Some investigators have concluded that the performance of listeners who demonstrate some ability to localize can be explained to a large extent by their reliance on intensity cues provided by head shadow (Van Wanrooij &Van Opstal, 2004). That is, on tests of localization in which the stimuli are kept at a fixed intensity, these listeners will capitalize on level cues by localizing low-intensity stimuli closer to the impaired ear and higher intensity sounds closer to the normal-hearing ear. Head shadow cues are arguably unreliable in real-world listening environments and can be effectively eliminated in localization tasks by roving (i.e., randomly varying) the intensity of the stimuli over trials. Still, a few listeners with UHL have shown surprisingly good performance on localization tasks even when roving intensity paradigms were employed, leading several investigators to suggest that these listeners have learned to localize sounds by using monaural spectral cues that arise fromdirection-dependent filtering by the pinna (Newton, 1983; Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2004).

The ability to use monaural spectral cues for localization is complicated by the fact that the sound present at the eardrum includes both the spectral features provided by the pinna and the spectral features in the source itself. Thus, the pinna filtering characteristics must be decoupled from the characteristics of the corresponding sound source (Wightman &Kistler, 1997). A few studies have suggested that learning to use monaural spectral cues for localization may take considerable time and practice. For example, Abel and Lam (2008) examined horizontal localization ability by normal-hearing listeners with a monaurally occluded ear and found that these listeners showed no improvement following mass practice over a period of a few days. This is consistent with animal studies that showed it took several months of practice for monaurally occluded ferrets to show improvement in localization performance (King et al., 2001). Findings from Slattery and Middlebrooks (1994) also suggested that monaural localization skills require time to acquire. In this study, the listeners with long-term UHL demonstrated better localization ability than the normal-hearing listeners who were tested with monaural occlusion. However, the conclusion that extensive monaural listening experience is a prerequisite for capitalizing on monaural spectral cues was disputed by Shub, Carr, Kong, and Colburn (2008). They used a testing paradigm that involved feedback and reference stimuli and found no differences between listeners with UHL and those with normal hearing on a monaural listening task. These investigators suggested that the testing paradigm has greater influence on monaural localization performance of participants than does monaural listening experience.

Relationship Between Localization and Speech Understanding in Multisource Environments

Binaural listening to speech in noise is thought to be facilitated, at least in part, by a listener's ability to separately localize a target speech sound and other distracting sounds. One explanation is that because the target and masker appear to be coming from different directions, listeners may make a conscious effort to attend in the perceived direction of the target talker and away from the perceived direction of the competing talker (Balakrishnan &Freyman, 2008; Freyman et al., 1999, 2001; Gallun, Mason, &Kidd, 2005; Ihlefeld &Shinn- Cunningham, 2008a; Kidd, Arbogast, Mason, &Gallun, 2005). In general, these studies have found that listeners receive greater benefit from spatial separation between masker and target when they have a priori knowledge of the target location than when the target location is uncertain. Thus, in environments characterized by considerable informational masking (e.g., "cocktail party" environments), directed attention appears to play an important role for listening. However, other studies dispute a possible role of sound localization in spatial release from masking (Culling, Hawley, &Litovsky, 2004; Drullman &Bronkhorst, 2000; Hawley, Litovsky, &Colburn, 1999). For example, Drullman and Bronkhorst (2000) tested speech recognition in both monaural and binaural conditions using virtual display in which the number and the location of competing talkers was varied. In addition, they measured the ability of the participants to localize the target talker among competing talkers using a closed-set, five-alternative forced-choice paradigm. Although target talker localization performance in the virtual condition was quite poor (i.e., 43%-57%), the ability to recognize the target talker's message in the virtual conditions was relatively good (i.e., approximately 70%-88%) in the various competing talker conditions.

These results suggest that the impact of spatial separation on speech recognition may not relate directly to the ability to localize the target talker.

Arecent study by Gallun et al. (2008) also casts some doubt on the speculation that listeners use perceived location as a cue to distinguish target and masker in complex listening environments. This study measured detection of a 500-Hz tone masked by noise (energetic masker) or random tones (informational masker) by using a variety of interaural manipulations of the target. Findings indicated that the perceived location of the target was not related to listeners' responses for either energetic or informational maskers. This study suggests that at least for tonal maskers, location may not be the salient cue that listeners use to achieve a spatial release from informational masking.

The Present Study

The current study was motivated by three related questions. The first was whether the speech understanding deficits exhibited by listeners with UHL arise primarily in conditions in which normal-hearing listeners are known to benefit from spatial cues or whether individuals with UHL exhibit more global listening deficits. The second was whether individuals with UHL demonstrate any spatial release from informational masking on a speech recognition task. We addressed these first two questions by measuring performance in a speech recognition task in which the target and masker were colocated (i.e., no binaural cues were provided) and in conditions in which the target and masker were spatially separated by 90° on the horizontal plane. The third question was whether there is a relationship between directional hearing and selective listening for speech in listeners with UHL. This question was studied via a sound localization task.

General Method

Individuals with UHL and with normal hearing were tested in three experiments, two of which were speech informational masking tasks either with or without spatial cues, whereas the third was a sound localization task. Participants with UHL and participants with normal hearing were recruited via local audiology clinics and Internet advertisements. Most of the individuals with UHL participated in all three experiments. Normal-hearing individuals in roughly the same age range served as controls in each of the experiments. All participants were native English speakers. Participants were paid $10 an hour. Testing sessions lasted 2 hr and were scheduled at the participants' convenience. The participants were offered breaks during the testing sessions, and most completed all the experimental testing in fewer than six sessions (10-12 hr). All aspects of this project were conducted under the approval of the Human Subjects Protection Program at the University of Louisville.

Participants With Unilateral Hearing Loss

Twelve individuals with UHL served as participants. Eleven were tested in all three experiments. One participant (UHL02) did not participate in Experiment 1. Table 1 presents demographic and audiologic information for each participant. Participants' ages ranged from 18 to 64 years, with a median age of 23.5 years. Their degree of unilateral impairment ranged from mild to profound. All participants had sensorineural hearing loss, with the exception of Participants UHL02 and UHL03, who had conductive hearing loss secondary to congenital aural atresia and congenital ossicular malformation, respectively. None of the participants reported current use of an amplification device, with the exception of ParticipantUHL11, who used an implantable bone anchored hearing device (i.e., a Baha). The Baha device was turned off, and the external portion was removed during testing. With one exception, all participants had thresholds of ≤25 dBHLat 250-8000 Hz in the ear with normal hearing. ParticipantUHL09 had borderline mild hearing loss in the midfrequency range (i.e., thresholds of 25- 30 dB at 1000-4000 Hz) in the better hearing ear.

Participants With Normal Hearing

For each of the three experiments, a group of 12 normalhearing adults was recruited. For purely logistical reasons, only a few normal-hearing listeners participated in more than one experiment. The participants ranged in age from 18.8 to 60.9 years (Mdn = 24.7 years) in Experiment 1, 18.9 to 60.9 years (Mdn = 24.6 years) in Experiment 2, and 19.6 to 61.9 years (Mdn = 30.1 years) in Experiment 3. Thus, the ages of the normal-hearing

participants were roughly comparable to the ages of the participants withUHL for Experiments 1 and 2 and slightly older than the participants with UHL for Experiment 3. All of the participants with normal hearing underwent a hearing screening, which demonstrated normal-hearing sensitivity, bilaterally, as defined by audiometric thresholds of≤25 dBHLat all octave frequencies 250-4000 Hz. One of the participantswith normal hearing had elevated thresholds, bilaterally at 4000 Hz, but her performance on the listening tasks was indistinguishable fromthe performance of the other normal-hearing participants.

Experiment 1: Speech Target and Masker Presented Monaurally

Experiment 1 was designed to compare monaural listening performance with headphones of participants with UHL with those with normal hearing. The purpose of this baseline comparison was to determine whether individuals with UHL (when listening with their normal ear) demonstrate performance comparable to that of normal-hearing individuals in monaural listening conditions containing primarily informational or energetic masking.

Method

Stimuli. Selective listening was measured via the Coordinate Response Measure (CRM) paradigm (Bolia, Nelson, Ericson, &Simpson, 2000), which has been shown to be a sensitive indicator of informational masking effects (Brungart, 2001; Brungart &Simpson, 2002, 2007; Brungart, Simpson, Ericson, &Scott, 2001; Wightman &Kistler, 2005). The CRM is a closed-set task that requires the listener to attend to a target phrase, while ignoring a highly similar masker phrase. For example, the listener is presented the target phrase "Ready Baron, go to green 5 now" with the simultaneously presented masker phrase "Ready Eagle, go to red 8 now." The CRM has been used in a number of studies examining energetic versus informational masking and the effects of spatial separation (Arbogast et al., 2002, 2005; Ihlefeld &Shinn-Cunningham, 2008a, 2008b; Kidd, Mason, Brughera, &Hartmann, 2005; Marrone, Mason, &Kidd, 2008). The advantages of the CRM are that the speech material carries very little linguistic context and that the sentences may be reused without memory influencing performance. Research by Brungart (2001) suggests that the single-talker masker in the CRMis primarily an informational masker, as evidenced by greater masking effects of speech maskers relative to spectrally and temporally comparable modulated noise maskers.

In one condition, both the speech target and speech maskers were selected from the corpus of sentences that form the basis of the CRM. Talker #0 served as the talker for all of the target sentences. The target sentences were drawn from those with the call sign "Baron." Each target sentence was paired with a masker sentence spoken by a random selection of one of the remaining three male talkers. The masker sentence contained random selections from the remaining seven call signs, three colors, and seven numbers. The target and masker sentences were time aligned, such that the word "Ready" of the target and masker sentences started at the same time. Because there were small variations in speaking rates among the talkers and small discrepancies in word length, the overall durations of the target and masker sentences were slightly different.

In a second condition, the masker was a speechspectrum noise that had the same long-term spectrum as the average CRM sentence. The amplitude of noise presented on each trial was modulated by the temporal envelope of a randomly selected (as in the first condition) CRM masker message. The envelopes were derived by full-wave rectifying theCRMsentence and then filtering the result with a sixth-order low-pass Butterworth filter with a 50-Hz cutofffrequency.

Targets and maskers were attenuated, mixed digitally, and converted to analog form on a Digital Audio Labs Card Deluxe 24-bit sound card at a 48-kHz sampling rate. Beyer DT990-Pro headphones were used to present the stimuli monaurally to the normal-hearing ear of the participants with UHL or to the right ear of the participants with normal hearing.

Procedure. Participants were seated in front of a computer screen either in a sound-isolated semi-anechoic room (T60 = 0.06 s) or in a double-walled sound-isolated room (IAC 1200). The screen displayed a start button and 32 response buttons organized in four color matrices (i.e., red, white, green, and blue), each containing

eight buttons (numbered 1-8). The participantswere instructed to attend only to the speech message containing the call sign "Baron" and to ignore any distracting stimulus. Using a computer mouse, the participants initiated each trial by clicking on the start button displayed in the middle of the screen and responded by clicking on the button corresponding to the heard color and number spoken by the talker with the call sign "Baron."

Prior to the experimental trial blocks, the participants completed 30 practice trials in a no-masker baseline condition in which the level of the target was varied over a 20 dB range. The baseline condition was administered to familiarize the participants with the task and to ensure perfect performance at each target level in the absence of a masker. During each 60-trial experimental block, the overall level (root-mean-square) of the masker was held constant at 60 dB SPL. From trial to trial, the level of the target was randomly assigned one of five levels, 5 dB apart, spanning a range of 20 dB. This procedure permitted estimation of a complete psychometric function, in which performance ranged from near chance (3%) to 100% correct as a function of target-to-masker ratio. For some participants, it was necessary to adjust the range of target levels following the first couple of trial blocks in order to capture a full range of performance. Each participant completed no fewer than five blocks of 60 trials. The first trial block in each condition was considered practice and was not included in the analyses. Thus, with some minor exceptions, each estimate of proportion correct was based on a minimum of 48 trials. Trial-by-trial feedback was not provided. Participants first received one block of trials in the modulated noise masker condition, followed by one block of trials in the speech masker condition. The conditions were then presented in an alternating manner until the participants completed five blocks in each condition.

Data analysis. Psychometric functions obtained with CRM speech targets and CRM speech maskers are often nonmonotonic (Brungart, 2001; Brungart &Simpson, 2002; Wightman &Kistler, 2005; Wightman, Kistler, &Brungart, 2006). This is thought to result from the notion that, for target/masker (T/M) ratios between -15 and 0 dB, some listeners can attend to the "softer" speech sound, thus using intensity as an additional cue for segregating target from masker. The use of this level cue results in a plateau in performance, between approximately -15 and 0 dB T/M ratios. For this reason, psychometric function data from this experiment were not fit with smooth curves in order to estimate threshold and slope. Instead, individual data and group means are plotted. For each participant, a mean proportion correct score was computed over T/M ratios from -15 to 0 dB for the speech masker condition and over T/M ratios from -15 to -5 dB for the modulated noise masker. These T/M ratios were chosen because each participant contributed at least 24 responses at each of these T/M ratios. Mann-Whitney U tests were then used to compare mean proportion correct scores over these T/M ratios between participants with UHL and participants with normal hearing.

Results

All participants demonstrated near-perfect performance (97%-100% correct) in the baseline condition (no masker), at all target levels. For all but one participant, target levels were between 30 dB SPL and 55 dB SPL. One participant had borderline mild hearing loss in the "normal" hearing ear and was tested with target levels between 45 dB SPL and 65 dB SPL. At these levels, she scored 97% correct.

Figure 1 (left-hand side) shows the results from the condition in which a speech masker was presented. Data from the participants with UHL are displayed in the top panel, and data from participants with normal hearing are displayed in the middle panel. The bottom panel shows the mean performance at each T/M ratio from both participant groups. As can be seen in Figure 1, there were large individual differences in performance from both participant groups in this condition. This is consistent with the results from previous studies of normal- hearing participants in comparable conditions (Wightman &Kistler, 2005; Wightman et al., 2006). Note that three of the participants with UHL and several of the normal-hearing participants exhibited a plateau in performance between -15 dB and 0 T/M ratios that has been ascribed to the use of intensity cues. As can be seen in the bottom panel of Figure 1, the mean performance of the participants with UHL resembles that of the participants with normal hearing. This is supported by the overlapping 95% confidence intervals of the group means at each

T/M ratio. A Mann-Whitney U test indicated no significant difference between groups in proportion correct scores computed across T/M ratios of -15 to 0 dB in the speech masker condition, U(n1 = 11, n2 = 12) = 70, p = .81. Thus, in this monaural listening condition, inwhich the target andmasker were presented to their normal-hearing ear, participants with UHL performed comparably to normal-hearing participants.

The right-hand side Figure 1 shows the results from the condition in which a modulated noise was used as the masker. There are two obvious differences between the results from the modulated noise masker condition and those from the speech masker condition. First, the psychometric functions from the modulated noise condition show none of the irregularities evident in the psychometric functions from the speech masker condition. Second, individual differences in performance with the noise masker are much smaller than with the speech masker. The data from both groups are comparable to data reported by Brungart (2001).

The most important result of the modulated noise condition is evident in the bottom right panel of Figure 1, which shows the mean data from both participant groups. Note that the performance of the participants with UHL is virtually identical to the performance of the normal-hearing participants who are listening monaurally. A Mann-Whitney U test indicated no significant difference between groups in proportion correct scores computed across T/M ratios from -15 to -5 dB in the modulated noise masker condition, U(n1 = 11, n2 = 12) = 63, p = .85. Thus, when listening with their normal-hearing ear, individuals with UHL appear to achieve normal levels of monaural speech understanding performance in the presence of either a purely energetic masker (modulated noise) or a primarily informational masker (speech).

Experiment 2: Speech Target and Masker Spatially Separated

Experiment 2 was designed to compare speech understanding performance in the sound field of participants with UHL with that of participants with normal hearing. In one of the conditions, the target and masker were colocated in front of the participant. The purpose of this condition was to measure performance when no spatial cues were present. In the other conditions, the target was in front of the participant, and the masker was spatially separated from the target by 90°. Comparison of performance in the colocated and spatially separated conditions provided an index of spatial release from masking.

Previous research has shown that normal-hearing listeners obtain greater benefit from spatial separation between target and masker when a primarily informational masker is used (Arbogast et al., 2002, 2005). Thus, in Experiment 2, we used a paradigm that is dominated by informational masking. This was accomplished by digitally processing the CRM stimuli to diminish spectral overlap between the target and masker messages, thus minimizing energetic masking. In addition, the processed stimuli minimized talker cues (i.e., the processing made it difficult to recognize and distinguish the target talker's voice from that of the masker talker), thus further isolating spatial separation as the cue under examination.

Method

Stimuli. The speech targets and maskers were the same CRM sentences used in Experiment 1. Speech targets and maskers were digitally processed to minimize spectral overlap between target and masker via the procedure described by Arbogast et al. (2002, 2005). The processing involved high-pass filtering with a firstorder Butterworth filter at 1200 Hz and passing the output through a filter bank that consisted of 15 nonoverlapping filters with equal bandwidths on a logfrequency scale. The bandpass filters were one-third octave, fourth-order Butterworth filters with center frequencies ranging from 215 Hz to 5461 Hz. The envelope of the output of each filter, extracted by half-wave rectification and low-pass filtering at 50 Hz, was used to modulate a sinusoid with a frequency equal to the center frequency of the band. The target sentence on each trial was constructed by summing a random selection of 8 of the 15 modulated sinusoids. The masker sentence was constructed by summing the remaining 7 sinusoids. Thus, the target and masker consisted of nonoverlapping modulated sinusoids. Figure 2 shows the magnitude spectra of a sample pair of a target sentence (gray) and a masker sentence (black). As seen in Figure 2, the target and masker do not overlap (except where they are more than 40 dB below peak levels). Thus, energetic masking was expected to be

minimized in the target-masker presentation. Stimuli were presented using a 48-kHz sampling rate from loudspeakers (Cambridge SoundWorks) positioned at an ear-level height, 1.2 m from the participant at angles of -90°, 0°, and +90° azimuth relative to the participant on the horizontal plane. The target sentences were always presented from the 0° loudspeaker. The masker sentences were presented either from the 0°, -90°, or +90° loudspeaker, depending on the experimental condition.

Procedure. Participants were seated in a semianechoic room (T60 = 0.06 s) and were asked to respond on each trial by verbally naming the color and the number that was spoken by the target talker using the call sign "Baron." The participant's voice was picked up by a microphone, and an experimenter outside the room recorded the responses for each trial on a computer. Trial-by-trial feedback was not given.

The level of the masker was held at a fixed intensity level of 55 dB. For a few participants, the masker level was adjusted by ±5 dB for a block of trials to capture a full range of performance (i.e., approximately 0%- 100%) while ensuring target audibility. For each block of trials, the level of the target was varied randomly from trial to trial over a 20 dB range in order to estimate the psychometric function relating performance to the T/M ratio. There was some variation in target levels across blocks of trials in order to obtain performance near chance at the lowest target level and near 100% at the highest target level.

Participants completed between 60 and 120 practice trials in the baseline condition before data were collected. The baseline condition was presented without a masker in order to familiarize the participants with the processed stimuli and to ensure perfect performance at each target level. The first 30 baseline trials involved listening and responding to unprocessed CRM stimuli. Then the participant completed 30 baseline trials with the processed stimuli. Additional practice trials with the processed CRM sentences were administered until the participant demonstrated perfect or near-perfect performance at all target levels. After completing the baseline condition, participants with UHL were tested in three experimental conditions:

1. Colocated: The target and masker were digitally attenuated and mixed and presented from a single speaker positioned at 0° azimuth.
2. Masker impaired: The target was presented at 0° azimuth, and the masker was presented at 90° azimuth on the side of the participant's impaired ear.
3. Masker normal: The target was presented at 0° azimuth, and the masker was presented at 90° azimuth on the side of the participant's normal-hearing ear.

The normal-hearing participants were tested in the colocated condition and in a condition in which the target was presented from the 0° loudspeaker and the masker from the -90° loudspeaker on the participant's leftside. Participants completed a minimum of 300 trials in each of the conditions. The conditions were presented in an alternating manner in blocks of 60 trials. The presentation order of the condition blocks was selected randomly. The first block in each condition was treated as a practice block. A minimum of 48 trials was used to estimate proportion correct at each of the T/M ratios tested.

Data analysis. The data from each condition (proportion correct at T/M ratios) were fitted with threeparameter (midpoint, slope, and upper asymptote) logistic functions in MATLAB using psignfit (Wichmann &Hill, 2001a, 2001b). Thresholds (i.e., T/Mratio corresponding to 51% correct) were estimated from the fitted functions for each participant in each of the experimental conditions. The 95% confidence intervals for threshold estimates were calculated using the bootstrapping procedure described by Wichmann and Hill (2001b).

Results

In this experiment, speech targets and maskers were processed into nonoverlapping modulated sinusoids to minimize energetic masking. Performance in the baseline condition (no masker) was nearly perfect (93%-100% correct) at all target levels tested (range: 30-55 dB SPL). As with Experiment 1, the participant with borderline mild hearing loss in the "normal" ear required a range of 45-65 dB to achieve near-perfect performance.

Figure 3 presents the raw data and the fitted psychometric functions for three representative participants with normal hearing. The error bars show the 95% confidence limits of the estimated thresholds (51% correct). As

suggested by the data shown in Figure 3, there was considerable variability across participants in the estimated thresholds. Nevertheless, all participants produced monotonic psychometric functions that spanned nearly the entire range of performance from chance (3% correct) to perfect (100% correct). Confidence intervals for the threshold estimates were approximately ±1.5 dB. Note that for the participants whose data are shown in Figure 3, spatially separating the target and masker resulted in a large improvement in performance (a leftward shiftof the psychometric function, toward lower T/Mratios). Such large improvements reflect spatial release from informational masking. For the participant whose data are shown in the middle panel, the spatial release was approximately 20 dB. Similar results from participants with normal hearing have been reported previously in several studies that used the CRM paradigm with processed stimuli (Arbogast et al., 2002, 2005). Spatial release has been shown to be greatest in experiments, such as the current one, in which the masker may be characterized as primarily informational. Spatial release from informationalmasking is usuallymuch larger than the performance improvement produced by the head shadow effect, which results in a slight improvement in T/Mratio at the shadowed ear when themasking stimulus is to one side (Bronkhorst &Plomp, 1989).

Figure 4 is comparable to Figure 3 except that the data are from three representative participants with UHL. Recall that the participants withUHL were tested in three conditions, one in which both the target and the masker were presented from the loudspeaker in front of the participant (colocated), one in which the target was in front and the masker was on the side of the impaired ear (masker impaired), and one in which the target was in front and the masker was on the side of the normalhearing ear (masker normal). For these three participants, presenting the masker on the side of the impaired ear produced a small improvement in performance, and presenting the masker on the side of the normal-hearing ear produced a small decrement in performance.

Tables 2 and 3 summarize the results from Experiment 2. The tables list estimated thresholds (and 95% confidence intervals) in each condition for both normalhearing participants and participants with UHL. Consider first the data obtained from the normal-hearing participants (Table 2). There are substantial individual differences in the thresholds in the colocated condition, ranging from -11.4 dB to -0.2 dB (T/M ratio), with a mean of -5.1 dB. Such large individual differences are not uncommon in tasks dominated by informational masking (Wightman &Kistler, 2005; Wightman et al., 2006). T/M thresholds in the condition in which targets and maskers were spatially separated ranged from -28.1 to -13.8 dB, with a mean of -20.5 dB. As seen in Table 2, spatial release (from informational masking) achieved by the participants with normal hearing ranged from 10 dB (NH06) to 27 dB (NH05), with a mean spatial release of about 15 dB. These findings are comparable to those of Arbogast et al. (2002, 2005), which also showed a mean spatial release of about 15-18 dB.

Next, consider the results from the participants with UHL (Table 3). Although the range of estimated thresholds from the colocated condition was about the same as for the participants with normal hearing, most of the threshold estimates were higher, indicating poorer performance in this group. The mean colocated threshold for the participants with UHL was -0.5, compared with a mean of -5.1 dB for the normal-hearing participants. This difference was significant, $t(22) = 2.97$, $p = .007$, $h2 = .21$. Table 3 also shows that all UHL participants achieved the best thresholds (lowest T/M ratio) in the masker impaired condition and the poorest threshold in the masker normal condition. Although the threshold differences across listening conditions in the UHL participant group were small, a repeated measures analysis of variance (ANOVA) showed that they were significant, $F(2, 22) = 76.4$, $MSE = 1.63$, $p <. 001$, $h2 = .87$. Post hoc comparisons using the Bonferroni adjustment indicated that thresholds were lower in the masker impaired condition than in the colocated condition ($p <.001$) and higher in the masker normal condition ($p = .003$) than in the colocated condition. The improvement in performance of the individuals with UHL produced by moving the masker from the front to the side of the impaired ear can be described as a "spatial advantage," but as will be argued in the Discussion, it is no greater than what would be expected given the change in T/M ratio at the normal-hearing ear (i.e., the head shadow effect) and as such does not imply a perceptual effect or processing of spatial cues by these participants. The decrement in performance in the masker normal condition as compared with the colocated

condition can be explained in a similar way.

Experiment 3: Localization of Noise on the Horizontal Plane

Experiment 3 examined the ability of participants with UHL and those with normal hearing to localize wideband noise bursts on the horizontal plane. The absence of the ability of the listeners with UHL to use spatial cues may be related to poor localization skills. Therefore, the objective of Experiment 3 was to measure localization performance.

Method

Stimuli. Stimuli for the localization task were 250-ms Gaussian white noise bursts, bandpass filtered between 200 Hz and 16 kHz and shaped by 20-ms cosinesquared on-offramps. The advantage of using a wideband noise in this experimentwas that it gave participants access to high-frequency pinna cues, which have been shown to be valuable formonaural localization (Wightman &Kistler, 1997). Independent noise samples were generated on each trial. The noise signals were output at a 48-kHz sampling rate with a Digital Audio Labs Card Deluxe 24-bit sound card. The level of the stimulus on each trial was random (uniform distribution) over a 10-dB range (i.e., ±5 dB), with a mean level of 65 dB SPL. The purpose of the intensity rove, which has been employed by previous studies examining monaural localization (Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2004, 2007; Wightman &Kistler, 1997), was to prevent the participantswithUHL fromusing the relative intensity of the stimuli at the normal-hearing ear as a localization cue. Single noise bursts were presented either to a single loudspeaker (Cambridge Sound Works) or, at half power, to two adjacent loudspeakers in order to simulate a position between the two loudspeakers. The frequency response of each loudspeakerwas digitally flattened with inverse filtering techniques.

Procedure. Localization testing was conducted in the same semi-anechoic room as was described in Experiment 2. Seven loudspeakers were positioned at ear level and were spaced 30° apart from -90° to +90° degree azimuth. Participants were seated in the center of the array of speakers, facing the speaker positioned at 0° azimuth, and were asked to maintain an upright and frontal orientation throughout testing. The speaker-head distance was 1.2 m. The seven loudspeakers were labeled with numbers in increments of 10, ranging from 0 to 60. On each trial, a brief 1000-Hz "warning" tone was presented from a loudspeaker located above the participant's head 1 s before the onset of the stimulus. The target noise was then presented randomly either from one of the seven loudspeakers or from one of the six simulated positions at the midpoint of two adjacent speakers. Following the presentation of the noise signals, the participant was asked to respond verbally with an integer between 0 and 60 that best identified the location where he or she perceived the noise to have originated. Responses were picked up by a microphone. Participants were told that the noise could originate from any position, either at the loudspeaker positions or anywhere in between. An experimenter in an adjacent room recorded responses and ensured that the participant maintained a frontal orientation during the presentation of the stimuli. A camera placed in the testing chamber allowed the examiner to monitor the orientation of the participant.

All participants were given at least 65 practice trials to familiarize them with the localization task. Following the practice trials, participants completed a minimum of 195 experimental trials (range: 195-585 trials). No feedback was given to participants regarding the accuracy of their responses.

Data analysis. Performance on the localization task was evaluated by examining stimulus-response plots and by calculating RMS error between the target and response angles. Mean signed error was also computed in order to evaluate response bias.

Results

Figure 5 illustrates the localization performance in the horizontal plane of each of the 12 participants with normal hearing, and Figure 6 shows the performance of the 12 participants with UHL. The panels in both figures are organized according to participant age (i.e., youngest to oldest). The scatter plots show the response angles as a function of target angle. Participants' judgments, which ranged from 0 to 60, were converted to angular

judgments for the purpose of analysis. Prior to graphing, the data points were "jittered" slightly by adding a uniform random deviate of ±2.5° to the coordinates to eliminate the overlap resulting from duplicate responses to a given target (Cleveland, 1993). The average RMS error between response and target angles is shown in the upper leftof each panel. As seen in Figure 5, the performance of the participants with normal hearing was quite good, as evidenced both by the small RMS errors and the cluster of responses around the major diagonal (response angle = target angle).

In contrast to the normal-hearing participants, there were large individual differences in performance among the participants with UHL, as seen in Figure 6, with RMS errors ranging from 16° to 68°. Some participants (UHL02 and UHL03) performed only slightly poorer than the normal-hearing individuals, whereas others (UHL09, UHL10, and UHL12) showed little or no ability to localize the stimuli. Table 4 displays mean signed error and RMS error of the participants with UHL on the side of the impaired ear and the side of the normal-hearing ear. As seen in the table, most participants showed better performance (and a response shiftor bias) on the side of their normal-hearing ear. One participant (UHL12) had better performance on the side of her impaired ear. Two participants (UHL02 and UHL10) showed equivalent performance on their impaired and normal-hearing sides.

One of the aims of the localization experiment was to compare the localization abilities of participants with UHL with their ability to receive spatial benefit on a speech task (Experiment 2). To this end, Pearson product-moment correlation coefficients were calculated between RMS error on the localization task (Experiment 3) and threshold differences from the speech task (Experiment 2). Threshold differences on the speech task were defined as the difference in thresholds between the colocated condition and the masker impaired condition (D0°-90° impaired) and the difference in thresholds between the colocated condition and the masker normal condition (D0°-90° normal). Localization performance (RMS error) was not significantly correlated with D0°-90° impaired ($r = .09$, $p = .781$) or D0°-90° normal ($r = .45$, $p = .151$), suggesting that there was no relationship between localization performance and the ability to use spatial cues on the speech task among the participants with UHL. It seems clear that even for those participants with UHL who demonstrated near-normal ability to localize (e.g., UHL02 and UHL03), spatial separation of the target and masker on the speech recognition task provided only a modest performance advantage (about 4 dB for both participants) over the colocated condition. In addition, the spatial advantages on the speech task obtained by these participants in the speech task were no greater than that obtained by participants who demonstrated no ability to localize.

Discussion

In multisource listening environments, individuals with normal hearing exploit binaural cues for understanding speech and localizing sound sources (e.g., Arbogast et al., 2002, 2005; Bronkhorst &Plomp, 1989; Freymanet al., 1999, 2001; Ihlefeld&Shinn-Cunningham, 2008a, 2008b). In contrast, individuals with UHL are not afforded such binaural benefits and consequently show perceptual deficits in environments in which normal-hearing listeners rely on spatial cues (e.g., Bess, Tharpe, &Gibler, 1986; Linstrom et al., 2009; Ruscetta et al., 2005; Sargent et al., 2001; Welsh et al., 2004). However, previous research has not systematically explored the listening performance of individuals with UHL in ways that can delineate the specific nature of their perceptual deficit. The current study sought to better define listening skills in individuals with UHL by evaluating performance on spatial and nonspatial listening tasks. Specifically, speech recognition on an informational masking task was measured under headphones in conditions in which the target and masker were presented monaurally, and in the sound field in conditions in which the target and masker were colocated or were presented with 90° of spatial separation between target and masker. In addition, localization performance was measured to investigate whether localization skills are related to the ability to achieve a spatial release from informational masking on a speech perception task in listeners with UHL.

Regarding monaural listening performance, our findings revealed no difference between the performance of normal-hearing adults and those with UHL. Specifically, when the target and masker were presented monaurally over headphones to the normal-hearing ear (Experiment 1), the performance of the participants withUHLwas

comparable to the monaural performance of normal-hearing participants who were assessed in the current study and in previous studies (Brungart, 2001; Wightman &Kistler, 2005; Wightman et al., 2006). This was true both when the masker was a single talker (informational masker) and when it was a modulated noise (energetic masker).

In contrast to monaural listening performance using headphones, performance in the sound field conditions (Experiment 2) revealed significant differences between listeners with and without UHL, even when there was no spatial separation between target and masker. Although the colocated condition of Experiment 2 should not offer any benefit from binaural listening, given that the target and the masker were not spatially separated (and thus do not produce different patterns of interaural differences), there was a significant difference of about 4.5 dB between the average threshold of participants with UHL and participants with normal hearing, favoring the performance of the normalhearing group. The source of this difference is unknown and will remain a topic for future study. However, this finding appears consistent with a handful of studies that have shown superior performance in diotic versus monaural listening conditions by normal-hearing listeners on comodulating masking release tasks (Schooneveldt &Moore, 1989), detection tasks (Langhans &Kohlrausch, 1992; Zwicker &Henning, 1985), and speech perception tasks (Bronkhorst &Plomp, 1988; Davis, Haggard, &Bell, 1990; Gallun et al., 2005). Some investigators attribute the superior diotic performance to a statistical advantage of having two independent observations versus a single observation of the stimuli (Schooneveldt &Moore, 1989; Zwicker &Henning, 1985), whereas other investigators have suggested that the monaural-diotic performance difference relates to efferent interaction between the right and leftauditory pathways (Langhans& Kohlrausch, 1992).

In the condition in which the target and masker were spatially separated in Experiment 2, the normalhearing participants used binaural spatial cues to attend selectively to the target and ignore the masker. The data (Figure 3 and Table 2) showed as much as a 27 dB release from masking in this condition. This result was consistent with several other studies of informational masking by showing large benefits in normal-hearing listeners from spatial separation between the target and masker that exceed the benefits that can be attributed to head shadow effects or binaural interaction (Arbogast et al., 2002, 2005; Kidd, Arbogast, et al., 2005; Shinn-Cunningham, Ihlefeld, Satyavarta, &Larson, 2005).

In contrast to the normal-hearing participants, participants with UHL did not demonstrate the use of spatial cues to achieve better performance when the target and masker were spatially separated. Compared with the colocated condition, when the masker was presented on the side of the impaired ear, participants with UHL showed an average threshold improvement of approximately 4 dB. When the masker was presented on the side of the normal-hearing ear, participants with UHL showed an average threshold decrement of approximately 2.5 dB compared with the colocated condition. These threshold changes are nearly identical to the those predicted by a model proposed by Zurek (1993) that takes into account the changes in T/Mratio and consequent changes in the Articulation Index (French &Steinberg, 1947; Kryter, 1962) at the normal-hearing ear. This model was designed to predict speech intelligibility in monaural and binaural conditions based on the directionality of a target and a single-source masker. Specifically, in monaural conditions using high-context speech material and a speech spectrum noise masker, Zurek's model predicts an improvement of about 4 dB when the noise is on the side of an occluded ear and a decrement of about 3 dB when the noise is on the side of the normal-hearing ear. These changes in performance reflect head shadow effects. Thus, the changes in performance (i.e., benefits and decrements) of the participants with UHL produced by spatial separation of target and informational masker appear to be predictable based on differences in T/M ratio at the normalhearing ear. This is in contrast to the large perceptual benefits of spatial separation in normal-hearing listeners that are commonly described as spatial release from informational masking. Even the participants with mild or moderate degrees of UHL appeared to be unable to achieve a true spatial release from informational masking.

The inability of listeners with UHL to achieve a spatial release from informational masking is consistent with results from a study of normal-hearing listeners by Marrone et al. (2008), who measured performance on the

CRM in binaural and monaurally occluded (i.e., plugged) conditions. In this study, the spatially separated conditions employed noise on both sides of the participant (i.e., at ±45° or ±90°); thus, there was no "better ear" in terms of T/Mratio. In the binaural condition, the participants achieved a sizable spatial release from informational masking, which was effectively eliminated in the monaural occluded condition. Thus, similar to results from the current study, this study suggested that monaural participants fail to exhibit spatial benefits when head shadow cues are discounted.

The fact that the participants with UHL in the current study did not show marked improvement in performance in what should have been the most advantageous condition for them(i.e., the condition inwhich themasker was on the side of their impaired ear) was consistent with a study by Best et al. (2005). This study measured participants' abilities to identify finch song amidst energetic and informational maskers. The participants achieved an average of 10 dB greater release from informational masking when the target and masker were spatially separated than when the better ear signal was presented diotically. Thus, in conditions characterized by considerable informational masking, normalhearing listeners receive binaural listening advantages that exceed those gains obtained simply by having access to the better ear signal. Arguably, normal-hearing listeners use central processes to obtain a release from informational masking by directing their attention toward a target signal and away from distracters. These same attentional processes used to obtain a spatial release from informational masking do not appear to be available to listeners with UHL.

The third objective of the current study was to measure localization performance in listeners with and without UHL and investigate whether spatial release from informational masking on a speech task was related to localization ability. Findings from the localization experiment (Experiment 3) were consistent with those of previous studies, in that there was considerable individual variability in performance among the participants with UHL, participants with UHL showed deficits in performance relative to participants with normal hearing, and participants with UHL tended to bias their responses toward the side of their normal-hearing ear (as seen in Table 4). Two participants (UHL02 and UHL03) in the current study were able to localize the sound sources with near-normal proficiency. However, these participants had only mild-to-moderate hearing loss in the impaired ear and thus had the greatest amount of residual hearing. Unlike the participants with severe-toprofound UHL, it is possible that these two individuals with milder degrees of UHL were able to use interaural difference cues to assist their localization. This is consistent with results from a recent study by Agterberg et al. (2011) of listeners with mild-to-severe UHL that suggested that their listeners who showed relatively proficient localization abilities were able to use their limited binaural difference cues to perform the localization task. A related finding was reported byWightman and Kistler (1997) in a study of the impact of artificial broadband interaural level differences on localization. Normalhearing listeners achieved surprisingly good localization performance, even with a 40 dB interaural level difference. In the current study, a few participants with profound UHL (i.e., UHK04 and UHL07) demonstrated localization performance that seemed better than what might be expected given their degree of UHL, but their performance was poorer than that of normal-hearing listeners.

As explained in the introduction, previous investigators have suggested that many listeners with UHL use intensity cues provided by the head shadow on localization tasks (Agterberg et al., 2011; Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2004). That is, these listeners tend to localize low-intensity stimuli closer to the impaired ear and higher intensity stimuli closer to the normal-hearing ear. Although these trialby- trial variations in level at the functioning ear can be valuable cues for localizing stimuli on laboratory tasks that employ fixed-intensity paradigms, such level cues are not accessible in real-world listening. In the current study, we attempted to reduce the participants' ability to rely on such intensity cues by roving the overall level of the stimuli over a 10 dB range. Although this level rove almost certainly lessened the participants' ability to utilize level cues on the localization task, it is possible that a 10 dB level rove was not large enough to prohibit some participants from using intensity cues to determine the approximate position of the sound source, as argued by Van Wanrooij and Van Opstal (2004).

Some listeners with UHL are thought to be able to capitalize on monaural spectral cues to localize sound sources (Newton, 1983; Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2004). Monaural spectral cues may assist in localization because the characteristics of pinna filtering change depending on the position of the sound source. The use of monaural spectral cues for localization relies on the listener's ability to extract pinna filtering characteristics from an incoming signal and associate those characteristics with the corresponding sound direction (Wightman &Kistler, 1997). Because the spectrum received at the ear is a combination of the source spectrum and the pinna characteristics, knowledge of the source spectrum is required in order to decode the pinna cues. However, some researchers suggest that after years of monaural listening experience, some individuals with UHL may learn to use monaural spectral cues to determine the direction of sound on the horizontal plane (Newton, 1983; Slattery &Middlebrooks, 1994; Van Wanrooij &Van Opstal, 2004). These studies and others (i.e., Abel &Lam, 2008; King et al., 2001) suggest that the ability to use monaural spectral cues is not learned immediately following unilateral deafness or monaural occlusion but that it is learned over a period of at least several months. However, another study by Shub et al. (2008) found no difference between listeners with UHL and those with normal hearing on a monaural localization task and suggested that the testing paradigm itself, rather than monaural listening experience, had greater influence on monaural performance of normal-hearing listeners. In the current study, all participants with UHL had their hearing loss for at least 4 years (most for over 10 years), and there did not appear to be a relationship between duration of unilateral impairment and localization ability.

Regarding a possible relationship between spatial release from informational masking and localization ability in listeners with UHL, findings from the current study suggest that there is none. Correlational analyses showed no significant relationships between the small spatial effects on the informational masking task and performance on the localization task in participants with UHL. Although there was considerable variability in the ability to localize by the participants with UHL, there was little variability on the spatial speech task in that none of the participants with UHL achieved a spatial release from informational masking beyond what would be predicted fromhead shadow effects. A few of the participants demonstrated localization performance that was nearly comparable to that of normal-hearing participants, but they did not show substantial improvements in speech understanding when the target and masker messages were spatially separated. This was despite the fact that participants were informed of the location of the target and masker sources prior to each block of trials. This finding seems to be in contrast with previous studies that have suggested that normalhearing listeners use differences in the perceived location of a target to obtain a spatial release from masking in complex listening situations and that "knowing where to listen" improves performance (Ericson,Brungart, &Simpson, 2004; Kidd, Arbogast, et al., 2005). However, findings from the current study are consistent with other studies that have cast doubt on the relationship between localization and spatial release from informational masking. For example, these studies have suggested that listeners do not appear to use perceived location to obtain binaural release from informational masking (Gallun et al., 2008) and that spatial release from masking is not well predicted by localization ability (Drullman &Bronkhorst, 2000; Hawley et al., 1999).

Conclusion

This study explored selective listening skills and localization abilities in individuals with UHL. Findings lend themselves to the following conclusions:

1. The monaural listening performance of individuals with UHL is comparable to that of individuals with normal hearing.
2. Speech understanding in noise deficits of listeners with UHL appears to be most pronounced in environments in which normal-hearing listeners are able to benefit fromspatial separation between the target andmasker. ListenerswithUHLappear to be unable to achieve spatial release from informational masking beyond what may be attributed to the head shadow effect. The inability to achieve a spatial release from informational masking by listeners with UHL appears to occur even in those who have mild degrees of UHL and/or proficient localization

abilities.

3. Listeners with UHL show great variability in localization skills. Some individuals with UHL exhibit localization ability that is nearly comparable to normal-hearing listeners, while others show little or no ability to localize sounds. Localization performance tends to be poorest on the side of the unilateral impairment.

Abstract: To determine the feasibility of using a virtual auditory test material to evaluate reverberation and noise effects on speech recognition of pediatric cochlear implant (CI) users and to compare their performance with that of children with normal hearing. Virtual test materials representing nonreverberant and reverberant environments were used to measure speech recognition of 7 children with CIs in quiet and in noise, and of 18 childrenwith normal hearing in the quiet condition. Performance of CI users in noise (signal-to-noise ratio resulting in 50% performance) was compared to normative data from a previous study (Neuman, Wroblewski, Hajicek, &Rubinstein, 2010). For CI users, stimuli were sent directly to the CI speech processor via auxiliary input, whereas children with normal hearing were tested using insert phones. The speech recognition of children with CIs decreased significantly in the reverberant condition. There were individual differences in susceptibility to reverberation. Children with CIs also required higher signal-to-noise ratios than children with normal hearing in the reverberant condition. Direct connect testing with reverberant test materials allows assessment of speech recognition under conditions typical of classrooms and could be useful in identifying children with CIs whose performance decreases significantly in the presence of reverberation and noise.

Purpose: To determine the feasibility of using a virtual auditory test material to evaluate reverberation and noise effects on speech recognition of pediatric cochlear implant (CI) users and to compare their performance with that of children with normal hearing.

Method: Virtual test materials representing nonreverberant and reverberant environments were used to measure speech recognition of 7 children with CIs in quiet and in noise, and of 18 childrenwith normal hearing in the quiet condition. Performance of CI users in noise (signal-to-noise ratio resulting in 50% performance) was compared to normative data from a previous study (Neuman, Wroblewski, Hajicek, &Rubinstein, 2010). For CI users, stimuli were sent directly to the CI speech processor via auxiliary input, whereas children with normal hearing were tested using insert phones.

Results: The speech recognition of children with CIs decreased significantly in the reverberant condition. There were individual differences in susceptibility to reverberation. Children with CIs also required higher signal-to-noise ratios than children with normal hearing in the reverberant condition.

Conclusion: Direct connect testing with reverberant test materials allows assessment of speech recognition under conditions typical of classrooms and could be useful in identifying children with CIs whose performance decreases significantly in the presence of reverberation and noise.

Key Words: cochlear implants, classroom acoustics, speech perception

Increasing numbers of elementary school-age children with cochlear implants (CIs) are being educated in

mainstream classes (Daya, Ashley, Gysin, &Papsin, 2000; Sorkin &Zwolan, 2004). It is of concern that the acoustic environments in these classrooms may interfere with their ability to hear and understand speech. The recently developed American National Standards Institute (ANSI; 2002) classroom acoustics standard recommends a maximum reverberation time of 0.6 s and background noise levels of 35 dBA in classrooms. However, a recent survey of elementary school classrooms revealed that poor acoustics are still likely in many schools (Knecht, Nelson, Whitelaw, &Feth, 2002). In Knecht et al.'s (2002) study, only one of 32 classrooms surveyed was in compliance with ANSI recommendations for reverberation time and background noise levels. Approximately half of the rooms exceeded the recommended reverberation time (reverberation times ranged from 0.4 to 1.2 s), and only four rooms had acceptable background noise levels (noise ranged from 28 to 67 dBA in the unoccupied classrooms). Of further concern are reports of very high noise levels in occupied classrooms leading to signal-to-noise ratios (SNRs) poorer than +10 dB (Crandell &Smaldino, 2000; Picard &Bradley, 2001).

Although pediatric CI users must function in classrooms with challenging acoustic environments, clinical evaluations of speech recognition are administered in sound-treated rooms with minimal reverberation. A recent study conducted by Iglehart (2009) suggested that reverberation and noise levels typical of classroom environments cause far greater speech recognition difficulties for children with CIs than for children with normal hearing. Iglehart compared speech recognition performance of 17 children with CIs (ages 7-16 years) and 20 children with normal hearing (ages 5-16 years). The assessment was carried out in a single classroom with reverberation time adjusted by hanging absorptive panels. Reverberation times (RT) were 0.3, 0.6 and 0.9 s (RTs shorter than, equal to, and longer than the RT recommended in the ANSI classroom acoustics standard). Mean recognition scores (words in sentences) of children with normal hearing approximated 100% at 9 dB SNR in all three RT conditions. In contrast, the mean performance of the children with CIs reached an asymptote at +21 dB SNR. For the children with CIs, mean scores were 92% in the 0.3-s condition, 80% in the 0.6-s condition, and 68% in the 0.9-s condition. Although the mean performance in the 0.3-s condition is good, such a short RT is not typical of classrooms (Knecht et al., 2002), and such a favorable SNR (+21 dB) is not likely to occur in an occupied classroom(e.g., Crandell &Smaldino, 2000; Larsen &Blair, 2008; Picard &Bradley, 2001). The significant decrease in performance in the 0.6-s condition is alarming because this is the RT recommended in the ANSI classroom acoustics standard. Although the 0.9-s condition exceeds that recommended in the ANSI standard, classrooms with similar, and even longer, RTs are still encountered (Knecht et al., 2002). These findings raise concerns about how classroom acousticsmay be affecting children with CIs in mainstream classrooms and support the need for a method of testing the effects of reverberation and noise on children with CIs in a manner that is feasible in the clinic.

Over thirty years ago, Nábelek and Robinette (1978) suggested that, as part of the clinical evaluation, it might be important to assess the effect of reverberation and noise on the speech perception performance of persons with hearing loss; however, it is difficult to test reverberation effects in audiometric test environments, and such clinical measures are still unavailable. In research studies that have evaluated the effect of classroom acoustics on the speech perception of children, testing has often been carried out in reverberant rooms (e.g., Finitzo-Hieber&Tillman, 1978; Iglehart, 2009; Nábelek& Pickett, 1974; Yacullo &Hawkins, 1987). This approach is not feasible in the clinic because a test room with reverberation typical of classroomenvironments is not available. An alternative means of testing involves headphone presentation of reverberant test materials recorded using microphones at the eardrum locations of an auditory research manikin (e.g., Johnson, 2000;Neuman&Hochberg, 1983).Athird approach, suggested by Koehnke and Besing (1996), is to use digital signal processing techniques to create virtual auditory test materials. To create a virtual reverberant speech recognition test material, the binaural room impulse response (BRIR) is recorded in one or more reverberant rooms using a pair of microphones mounted on a manikin. The BRIR is then convolved with standard speech recognition test materials. When the reverberant test material is played through headphones, the listener hears

the speech as if he or she were sitting at the location in the room where the BRIR was recorded. Koehnke and Besing demonstrated the feasibility of measuring spatial release from masking under headphones using virtual test materials that simulated an anechoic and a reverberant environment. The virtual auditory test approach is used in currently available tests of spatial release from masking, such as the Hearing In Noise Test Pro (Bio-Logic Systems Corp., 2006) or the Listening in Spatialized Noise-Sentences test (Cameron &Dillon, 2009).

A limitation to using virtual auditory test materials with CI users is the need to deliver the signals through headphones or insert phones in order to preserve the acoustic cues related to the test room and the position of the listener (and the listener's ears) relative to the test signal(s). Testing under headphones is not typically an option in assessing performance with CIs; however, direct delivery of the test material to the CI speech processor via auxiliary input provides a way to preserve the acoustic characteristics of a reverberant room in the virtual test stimuli while testing the listener's performance with a signal processed through the speech processor of the CI. Chan, Freed, Vermiglio, and Soli (2008) demonstrated comparable test results on sound localization and spatial release from masking measures from CI users in sound field or with what they called the "direct-connect assessment technique." Therefore, if virtual test materials developed using BRIRs recorded in a classroom are delivered to a child's CI using this direct-connect assessment technique, it will be possible to determinehowthe acoustics of the classroom will affect that child's speech recognition performance. Recently, Neuman, Wroblewski, Hajicek, and Rubinstein (2010) developed a virtual auditory test material to research the effects of reverberation and noise on the speech recognition of children and adults with normal hearing. This test material may be useful for assessing the performance of children by delivering the signal directly through the CI speech processor.

The purpose of the present study was twofold: to (a) determine the feasibility of using a virtual auditory test material (delivered to the CI via auxiliary input) to evaluate reverberation and noise effects on the speech recognition performance of pediatric CI users and (b) compare performance of the children with CIs with that of their peers with normal hearing.

Method

Participants

Children with CIs. Participants in the study included seven elementary school-age CI users (Nucleus 24 device, Freedom processor, ACE strategy). Six of the seven children used bilateral CIs (sequential implantation). All were experienced CI users (6-10 years with the first implant, 5months-5.5 yearswith the second device). Demographic information appears in Table 1.

equal to, and longer than the RT recommended in the ANSI classroom acoustics standard). Mean recognition scores (words in sentences) of children with normal hearing approximated 100% at 9 dB SNR in all three RT conditions. In contrast, the mean performance of the children with CIs reached an asymptote at +21 dB SNR. For the children with CIs, mean scores were 92% in the 0.3-s condition, 80% in the 0.6-s condition, and 68% in the 0.9-s condition. Although the mean performance in the 0.3-s condition is good, such a short RT is not typical of classrooms (Knecht et al., 2002), and such a favorable SNR (+21 dB) is not likely to occur in an occupied classroom(e.g., Crandell &Smaldino, 2000; Larsen &Blair, 2008; Picard &Bradley, 2001). The significant decrease in performance in the 0.6-s condition is alarming because this is the RT recommended in the ANSI classroom acoustics standard. Although the 0.9-s condition exceeds that recommended in the ANSI standard, classrooms with similar, and even longer, RTs are still encountered (Knecht et al., 2002). These findings raise concerns about how classroom acousticsmay be affecting children with CIs in mainstream classrooms and support the need for a method of testing the effects of reverberation and noise on children with CIs in a manner that is feasible in the clinic. Over thirty years ago, Nábelek and Robinette (1978) suggested that, as part of the clinical evaluation, it might be important to assess the effect of reverberation and noise on the speech perception performance of persons with hearing loss; however, it is difficult to test reverberation effects in audiometric test environments, and such clinical measures are still unavailable. In research studies that have

evaluated the effect of classroom acoustics on the speech perception of children, testing has often been carried out in reverberant rooms (e.g., Finitzo- Hieber&Tillman, 1978; Iglehart, 2009; Nábelek&Pickett, 1974; Yacullo &Hawkins, 1987). This approach is not feasible in the clinic because a test room with reverberation typical of classroomenvironments is not available. An alternative means of testing involves headphone presentation of reverberant test materials recorded using microphones at the eardrum locations of an auditory research manikin (e.g., Johnson, 2000;Neuman&Hochberg, 1983).Athird approach, suggested by Koehnke and Besing (1996), is to use digital signal processing techniques to create virtual auditory test materials. To create a virtual reverberant speech recognition test material, the binaural room impulse response (BRIR) is recorded in one or more reverberant rooms using a pair of microphones mounted on a manikin. The BRIR is then convolved with standard speech recognition test materials. When the reverberant test material is played through headphones, the listener hears the speech as if he or she were sitting at the location in the room where the BRIR was recorded. Koehnke and Besing demonstrated the feasibility of measuring spatial release from masking under headphones using virtual test materials that simulated an anechoic and a reverberant environment. The virtual auditory test approach is used in currently available tests of spatial release from masking, such as the Hearing In Noise Test Pro (Bio-Logic Systems Corp., 2006) or the Listening in Spatialized Noise-Sentences test (Cameron &Dillon, 2009). A limitation to using virtual auditory test materials with CI users is the need to deliver the signals through headphones or insert phones in order to preserve the acoustic cues related to the test room and the position of the listener (and the listener's ears) relative to the test signal(s). Testing under headphones is not typically an option in assessing performance with CIs; however, direct delivery of the test material to the CI speech processor via auxiliary input provides a way to preserve the acoustic characteristics of a reverberant room in the virtual test stimuli while testing the listener's performance with a signal processed through the speech processor of the CI. Chan, Freed, Vermiglio, and Soli (2008) demonstrated comparable test results on sound localization and spatial release from masking measures from CI users in sound field or with what they called the "direct-connect assessment technique." Therefore, if virtual test materials developed using BRIRs recorded in a classroom are delivered to a child's CI using this direct-connect assessment technique, it will be possible to determinehowthe acoustics of the classroom will affect that child's speech recognition performance. Recently, Neuman, Wroblewski, Hajicek, and Rubinstein (2010) developed a virtual auditory test material to research the effects of reverberation and noise on the speech recognition of children and adults with normal hearing. This test material may be useful for assessing the performance of children by delivering the signal directly through the CI speech processor. The purpose of the present study was twofold: to (a) determine the feasibility of using a virtual auditory test material (delivered to the CI via auxiliary input) to evaluate reverberation and noise effects on the speech recognition performance of pediatric CI users and (b) compare performance of the children with CIs with that of their peers with normal hearing. Six of the seven children used bilateral CIs (sequential implantation). All were experienced CI users (6-10 years with the first implant, 5months-5.5 yearswith the second device). Demographic information appears in Table 1. Neuman et al.: Virtual Test Approach 533 These children were recruited with the assistance of the New York University Cochlear Implant Center, as well as through local speech pathologists and audiologists who provide services to children with implants. Clinicians referred only those children whom they assessed as capable of performing the experimental task and of having good speech articulation and good speech recognition scores. Speech recognition scores obtained during the clinical evaluation preceding participation in the study appear in Table 2. Because testing required that children repeat sentence material, it was important to identify children whose speech production would not interfere with measurements of speech perception. Furthermore, in order to be able to demonstrate the effects of degradation of speech on performance without worrying about floor effects, it was necessary to recruit listeners who demonstrated good speech recognition performance in the nonreverberant condition. The participants in the

study functioned well with their CIs and were not chosen to be representative of all children with implants.
All children met the following five inclusion criteria: (a) diagnosed as prelingually deaf; (b) between the ages of 6 and 12 years (elementary school age), and received the first implant by age 3 years (to increase the likelihood that they would be in a mainstream educational setting, see Govaerts et al., 2002); (c) used English as their primary or only language; (d) demonstrated no errors in articulation, as evidenced by performance onthe Goldman-Fristoe Test of Articulation-2 (GFTA-2; Goldman &Fristoe, 2000); and (e) were identified by their speech therapists with no other disability or delay (including academic deficits, a learning disability, attention-deficit/hyperactivity disorder, cognitive disability, specific language impairment, etc.). One child who participated in the study received the first implant at age 3 years and one month.
Children with normal hearing. We assessed speech recognition in quiet (nonreverberant and reverberant conditions) in a control group of 18 children with normal hearing. Nine of the children were ages 6 through 7 years, and nine of the children were ages 9 through 12 years.The children with normal hearingwere typically developing American English speakers and had no history of recurrent middle ear disorders or insertion of ventilating tubes for treatment of recurrent otitismedia with effusion. All had hearing within normal limits, as established through audiometric screening (20 dB HL at 500, 1000, 2000, and 4000 Hz). None had been identified as having a language or learning disability, and none exhibited any speech articulation problems on the Goldman-Fristoe-2 Test of Articulation (Goldman &Fristoe, 2000).
Data for the listeners with normal hearing for the reverberant-noise condition were taken from Neuman et al.'s (2010) study. In that study, nine participants were in each age group (ages 6, 7, 8, 9, 10, 11, 12 years, and adult), and selection criteria for the children were identical to those described above.
This study was approved by the institutional review boards of the New York University School of Medicine and of Brooklyn College, City University of New York. Informed written consent was obtained from the parent of each child participating, and assent was obtained from each child prior to any testing.
Materials
We created a set of reverberant test materials by convolving BRIRs recorded in a classroom with recordings of the Bamford-Kowal-Bench Speech in Noise Test (Etymotic Research, 2005). A full description of the classroom, the method for recording the BRIRs, and the approach to creating test materials was reported by Neuman et al. (2010). In brief, the classroom had a volume of 228 m3 and a RT of 0.8 s. Absorptive panels were hung to record additional BRIRs to assess shorter reverberant conditions. Three sets of impulse responses were used in the current study: RTs were (a) 0.8 s, (b) 0.6 s, and (c) a nonreverberant test condition created by truncating the BRIR before the first reflection. Truncation of the BRIR yielded a test condition that maintained the Knowles Electronic Manikin for Acoustic Research (KEMAR) head-related transfer function but removed the reverberation characteristics of the room. For the quiet test conditions, the 0.8-s BRIR was convolved with the speech track (Bamford-Kowal-Bench sentences; Bench, Kowal, &Bamford, 1979) of the split-track recordings (List Pairs 9-12 and 14-18). This test condition represents an RT longer than recommended in the ANSI classroom standard, but it is still typical of many current classrooms (see Knecht et al., 2002). For the noise condition, the 0.6-s BRIR was convolved with the premixed speech in noise (List Pairs 1-7). The test materials for the 0.6-s condition are identical to those used in Neuman et al.'s study. Note that the RTs assessed in quiet and in noise differ. The original intent was to assess the 0.8-s condition in quiet and in noise; however, pilot data revealed that children with CIs found the task too difficult and frustrating when noise was combined with the longer RT. Therefore, the 0.6-s reverberant condition was used in the noise condition; this is the RT recommended by ANSI (2002).
We created test CDs with varying orders of both list and RT condition for ease of data collection.
Procedure
Testing was completed in a single test session. We first administered the GFTA-2 to determine eligibility to participate. The test protocol for children with CIs included speech recognition testing in quiet for the

nonreverberant and 0.8-s reverberant conditions as well as speech recognition testing in noise for the nonreverberant and 0.6-s reverberant conditions. Two list pairs were administered in each test condition, and key words were scored. For the test in quiet, we calculated a percentage correct score. The metric used to assess performance in noise was the signal-to-noise ratio resulting in 50% performance (SNR-50). SNR-50 was calculated as recommended in the Bamford-Kowal-Bench Speech in Noise Test manual (Bench et al., 1979). The order of testing was counterbalanced. The children with normal hearing were tested only in the quiet condition. Recall that the control group data in noise were from Neuman et al.'s (2010) study.

All children were tested in a quiet (background noise levels ≤35 dBA) or sound-treated test room. Test materials were administered using a portable Memorex CD player. The child's task was to repeat each sentence he or she heard. The examiner scored the test during the test session. The line output of the CD player was amplified and sent to monitor headphones to allow the examiner to hear the stimuli.

The only difference in instrumentation for testing the children with CIs and children with normal hearing was the transducer used to deliver the signal. When testing the children with normal hearing, we sent the CD player headphone output to a pair of Etymotic Research ER-6i isolator earphones with the volume control of the CD player set to achieve 71 dB SPL in a Zwislocki coupler. When testing children with CIs, we connected the headphone output of the CD player directly to the CI speech processor via the auxiliary input jack using the Nucleus Freedom TV/HiFi Cable (Part No. Z60829). The stimuli created from the right microphone impulse response were sent to the right ear, and the leftmicrophone stimuli were sent to the leftear (either via insert phone or speech processor). The child who used only one CI heard the recording from the microphone on the appropriate side.

The direct connection of the output of the CD player to the speech processor using the TV/hi-ficable bypasses the CI microphone. The pre-emphasis of the signal usually provided by themicrophone is incorporated into a filter that is part of the TV/ hi-ficable. When testing the children with CIs, we reduced themicrophone sensitivity setting to "5" in order to reduce the possibility of environmental noise interference, since in some cases testingwas not done in a sound-treated room. Thismicrophone sensitivity level allowed each participant to hear his or her own voice during testing but not any extraneous noises in the room. Adjusting the microphone sensitivity volume control does not affect the level of the sound from the TV/hi-ficable (Cochlear Americas, 2005). Testing was carried out at a comfortable listening level determined by the child. To find this level, the volume control of the TV/hi-ficable was set to the maximum setting, and the volume control of the CD player was manipulated by the examiner while the child listened to a practice list of the test material. The CD player volume control initially was set at the same point as was used for testing the children with normal hearing. The volume control was then systematically adjusted to determine the preferred listening level. The volume control was increased slowly until the child indicated that the sound was too loud, then was decreased until it was not loud enough, and finally increased to the level at which the speech was judged to be comfortable and clear. It is interesting to note that the children with CIs all selected a similar volume control setting. With this setting, the output of the cable (1000-Hz calibration signal from the test recordings) was approximately equivalent to the voltage that would be sent to the speech processor with a signal level of 65 dB SPL reaching the CI microphone (calibration information provided by the Cochlear Corporation, personal communication, July 10, 2009).

We used the same presentation level to test nonreverberant and reverberant conditions. Although it is true that reverberation will cause an increase in the level of the signal, for the purposes of this test material, we decided to equate speech levels in order to be able to estimate the effect of reverberation alone on speech recognition performance in quiet. Because the speech and noise are co-located, both speech and noise signal levels would be affected similarly by reverberation for the speech recognition in noise condition. The difference in SNR-50 between the nonreverberant and reverberant conditions yields information about the increase in SNR necessary to maintain a speech recognition score of 50% in the reverberant test condition. The speech recognition data collected for the children with normal hearing were also obtained with signal levels matched for the

nonreverberant and reverberant test conditions.

We used List Pair 9 as a practice list for all children. Children with CIs were tested in noise using List Pairs 1 through 8. List Pairs 10 to 18 were used for testing performance in quiet for all children. Two list pairs were administered to each child in each test condition. The test lists were distributed in an approximately balanced manner between the nonreverberant and reverberant test conditions across participants.Within each test session, each reverberation condition was assessed once in the first half of the session, and then again in the second half of the session, with a counterbalanced order of testing within the first and second half of a session. The order of testing quiet and noise conditions was counterbalanced among participants. No participant heard the same list more than once.

Results

Mean speech recognition scores in quiet in the nonreverberant and reverberant test condition are shown in Figure 1. The bars in the figure represent themean speech recognition performance for the children with CIs. Mean scores of younger (ages 6-7) and older (ages 9-12) children with normal hearing are plotted as line graphs. As can be seen, the performance of the children with CIs was quite good in the quiet, nonreverberant condition. These scores provide evidence that these CI users are capable of excellent speech recognition performance on this test material when the speech signal is not degraded by reverberation or by noise. Scores of the CI users ranged from 93% to 100% (M = 97.14%). Scores of the children with normal hearing ranged from 97% to 100% (M= 99.22%). Ceiling effects did not allow us to assess differences in performance between the children with CIs and those with normal hearing in this quiet, nonreverberant condition. In the quiet, reverberant condition, however, the mean speech recognition performance of the children with implants deteriorated dramatically, whereas the children with normal hearing still maintained good speech recognition performance. Some of the children with CIs showed large decreases in scores in the reverberant condition, and others showed only a small change. The speech recognition scores of the children with CIs ranged from 55% to 88% (M= 76.29%). The decrease in mean performance of children with CIs due to reverberation was statistically significant (Wilcoxon signed-rank test, W= 28, N = 7, $p < .01$, directional test). These data suggest that a reverberant condition typical of many classrooms can cause significant decreases in the speech recognition performance of children with CIs and that there are individual differences in the susceptibility to the effect of reverberation on speech.

The performance of the children with CIs was assessed in noise in both nonreverberant and reverberant conditions. The mean SNR-50s were 5.82 dB in the nonreverberant condition and 10.25 in the reverberant condition (a lower number is indicative of better performance). The increase in SNR required in the reverberant condition to maintain 50% performance was statistically significant (Wilcoxon signed-rank test, W = -28, N = 7, $p < .01$, directional test). In Figure 2, the performance of the children with CIs in the reverberant, noisy condition is compared with normative data obtained in Neuman et al.'s (2010) study. The mean SNR-50 for the children with CIs is shown on the far right. As one can see, on average the children with CIs require a much higher SNR for 50% performance than the children with normal hearing. Recall that the 0.6-s RT tested is typical of a classroom meeting the ANSI (2002) maximum recommended RT for an elementary school classroom.

In Figure 3, the SNR-50 of individual children with CIs is plotted in relation to mean data from children with normal hearing of similar age (data are from Neuman et al., 2010). The data for children with normal hearing show systematic decreases in the SNR required as a function of age. In contrast, a wide range of performance across the children with CIs is evident, and performance does not seem related to age (or years of experience with the CI). For example, one of the youngest children with bilateral CIs performed almost as well in noise as her peers with normal hearing, whereas one of the oldest children had the poorest performance in the noisy reverberant condition. This is the only child in our experimental group with a unilateral implant. Whether this might be a factor contributing to her need for a much higher SNR is not clear.

Discussion and Conclusions

The results of this study suggest that it is feasible to test the effect of reverberation and noise on the speech recognition performance of children with CIs using virtual auditory test materials delivered via auxiliary input to the speech processor and that the test material is sensitive to the deleterious effects of reverberation on the performance of children with CIs. Although the speech recognition performance of both children with normal hearing and children with CIs appears to be quite good in the nonreverberant, quiet test condition, the reverberant test condition clearly differentiated between the two groups of listeners. Whereas the performance of the children with normal hearing on the sentence test material was relatively unaffected in the reverberant test condition, the performance of the children with the CIs decreased significantly. This is of concern, because Knecht et al. (2002) reported that 10 of the 32 classrooms surveyed had RTs longer than the 0.8-s condition tested. The fact that all of the children with CIs scored higher than 90% on the nonreverberant test results and on the test materials administered in the clinic, but scored lower on the reverberant test material, suggests that the test results from a child's clinical evaluation will not necessarily predict performance when listening to speech degraded by reverberation and noise present in classroom environments.

When listening in the reverberant (0.6-s reverberation), noisy condition, on average, the children with CIs required a much higher SNR to obtain 50% speech recognition performance than children with normal hearing. The SNR-50s of individual children ranged from 6 dB to 14.5 dB. These findings are of concern when one considers reports of SNRs of <10 dB in occupied classrooms (Crandell &Smaldino, 2000; Larsen &Blair, 2008; Picard &Bradley, 2001); that the classrooms for the youngest children typically are among the noisiest (Picard &Bradley 2001); and that younger children require higher SNRs than older children or adults to obtain equivalent levels of performance in noisy, reverberant conditions (Neuman et al., 2010). It is clear that many of the children with CIs would have significant difficulty understanding speech in such noisy environments.

The results of this study suggest the need for a test that can identify children who are susceptible to degradations of the speech signal by reverberation, noise, and their combination. Current clinical measures of speech recognition performance of children with CIs are typically carried out in minimally reverberant, sound-treated test rooms. The test results obtained under these "optimal" listening conditions may mislead parents and educators into believing that a child with a CI will function as well as his or her normal hearing peers in the mainstream classroom. The results from this study suggest that reverberation has a very different effect on speech perception in children who use CIs than on children with normal hearing. In addition, there appears to be a range of performance in children with CIs indicating differences in susceptibility to the effects of reverberation and noise.

The direct-connect assessment approach using test materials that are representative of a range of classroom environments may make it possible to measure a child's functional listening ability in a reverberant environment. The results could be used to determine and provide documentation of a child's need for accommodation in the classroom and assist in developing a child's Individualized Education Plan.

Acknowledgments

The research reported in this article was supported by funding from the U.S. Department of Education, National Institute on Disability and Rehabilitation Research Grant H133E03006. The content of this article does not necessarily represent the policy of the U.S. Department of Education, and the reader should not assume endorsement by the U.S. federal government.

We thank Frank Iglehart of the Clarke School for the Deaf for providing access to the classroom and for advice on placement of the absorptive panels used during the recording process. Mario Svirsky and Chin-Tuan Tan provided technical guidance, and the Cochlear Corporation provided technical information required for implementing direct-connect testing. We are grateful to Susan Waltzman and William Shapiro of the New York University Cochlear Implant Center for facilitating the study and to the clinicians who helped recruit participants. Finally, we thank the children (and their parents) for participating in the study.

Etymotic Research provided ER-6i earphones and eartips for testing the children with normal hearing. The

Cochlear Corporation provided TV/hi-ficables for the study.

Full text: Headnote

You might think this kind of technology could have been around only a few years, but people have been investigating electrical stimulation of hearing for centuries. Find out more about cochlear implants and if they are right for you.

Hearing assistive technology for people with hearing loss falls into two basic categories: amplification and artificial hearing. Amplification adds intensity to incoming sound to overcome sensory or mechanical loss, but still relies on the natural hearing mechanisms to convert that sound energy to nerve impulses the brain can

interpret as meaningful sound.

When the severity of sensorineural hearing loss reaches a point where this is no longer feasible, natural hearing must be bypassed. A cochlear implant (CI) is an option for many people who are "beyond hearing aids."

Cochlear Implants 101

A cochlear implant is a device that converts sound into small electric pulses that the brain learns to interpret as speech, music and environmental sounds. While each product is slightly different in design, essentially they all work as follows:

Sound is picked up by a microphone mounted at or near the ear. The microphone converts the sound into a digital version; much like is done with current hearing aids. That digital "picture" of the sound is then sent to the speech processor. This small computer, either worn behind the ear or on the belt or collar, converts the digital sound picture into a set of instructions called a "map."

From the speech processor, the map is sent via a short cable to the external transmitter which is held in place by a magnet. The transmitter sends the map through the skin via radio waves to the internal receiver). This then decodes the map into a series of electrical pulses which travel down the electrode array to stimulate different areas of the cochlea.

After training, which may take months to years, the brain assigns meaning to these pulses and interprets them as sound.

Several factors affect how well someone will hear with a CI including how long their hearing has been impaired, the specific cause of the hearing loss, the specific anatomy of their cochleae and the availability and quality of aural habilitation services after implantation.

A Very Brief History of Cochlear Implants

In the late 18th century, Alessandro Volta connected a gang of batteries adding up to about 50 volts to two probes which he stuck inside his ears. He sensed a loud boom, followed by what he described as the sound of thick soup boiling. Not a good idea, but it was the beginning of our understanding that the brain could interpret external electrical stimulation as sound.

Several attempts were made throughout the next centuries, but it wasn't until the 1960s that we had anything close to clinical applications in humans.

In 1972, the House Ear Institute 3M single channel electrode and external speech processor was made commercially available and the race was on. Since then, rapid and significant advancements have been made in electronic hearing in people with severe to profound sensorineural hearing loss.

A Few Highlights

1981 Cochlear Corporation founded in Australia

1984 The U.S. FDA approves the House Ear Institute 3M Single Channel Cochlear Implant Clarke, et al., releases the Nucleus Multi-Channel Cochlear Implant in Australia

2000s Contoured electrodes, improved BTE processors, T-Mic, ongoing improved connectivity and usability with telecoils, FMs, remote controls

Process, Not Products

The CI market and product offerings continue to evolve at a rapid pace. Rather than try to name anything that is "new" now, but might be "old" in a few months, let's spend some time on the process of obtaining a CI. Since the majority of Hearing Loss Magazine readers are adults, I'm going to focus on adult CI recipients. Those

looking for information on CIs for kids, should contact the manufacturers listed at the end of this article, or their audiologist.

Candidacy

Technically, each new product approved by the FDA has its own specific candidacy, but in general, the criteria for adults are as follows:

* Moderate-to-profound sensorineural hearing loss in both ears
* Pre-operative HINT sentences recognition scores of 50 percent or less in the ear to be implanted and 60 percent or less in the opposite ear or binaurally
* Pre-linguistic or post-linguistic onset of severe-to-profound hearing loss
* No medical contraindications
* A desire to be part of the hearing world

Level of Hearing Loss

It is important to note that candidacy has recently opened up to include people with less hearing loss at the time of implantation. This is due to improvements in not only the implants themselves, but also in surgical techniques. If you investigated CIs even a few years ago and were told your hearing was "not bad enough yet" you may want to revisit them.

Speech Testing Scores

Depending on factors such as specific model and preferences of the evaluation team, the specific speech tests might vary. The important point is that it must be demonstrated that your ability to understand speech at amplified levels is poorer than average for people with your level of hearing loss. The HINT mentioned above is the Hearing In Noise Test. This test measures how well you understand speech in sentence form in quiet and with different amounts of noise. Cochlear implant research has shown that for the most part, those with HINT scores worse than these demonstrate significant improvement with cochlear implantation.

Pre-linguistic or post-linguistic onset of hearing loss - Back in the old days candidacy was reserved for those who lost their hearing after learning language. Again, improvements in products and more importantly, a better understanding of how folks born deaf will do allowed the FDA to authorize CIs for people meeting other criteria regardless of when they lost their hearing. Of course, they still need to have realistic expectations. We'll get to those shortly.

No medical contraindications - Since the cochlear implant's electrode array needs to slide inside the inner ear's snail-shaped cochlea, the physical structure of this organ is important. Some congenital disorders that cause hearing loss also deform the cochlea and make inserting the electrode array difficult or impossible. Disease processes like meningitis can cause bone to fill the cochlea. While neither of these is insurmountable, having atypical cochlear anatomy affects how well the electrode array sits near the hearing nerve, and therefore how well you'll hear after implantation. As part of the pre-implant evaluation, CT scans are done of both cochleae to assist in ruling out these issues.

Realistic Expectations

While not always listed as specific implantation criteria, these are critical. As with any other medical intervention, the results of cochlear implantation vary from complete failure to pretty amazing. The bulk of people fall in the middle, but the popular press tends only to report the "miracles." While the folks we see on TV and in the news "heard instantly" or could listen on the phone in a few weeks, for most people, hearing electronically takes months or years. The mapping process makes it possible for most people to hear quiet sounds as well as a person with a slight to mild hearing loss, however, since the CI uses microphones, there will still be limitations. Speech understanding in noise will be limited by room acoustics and signalto-noise ratio just like hearing aids. It is entirely appropriate for a CI recipient to expect to hear and understand the TV, small group conversations, music and the sounds of nature with their CI alone. It is not, however, probable that they will hear optimally in large rooms, noisy restaurants or theaters without the use of some kind of Hearing Assistive Technology (HAT).

The best advice I've heard when it comes to CIs and expectations is from a friend who has bilateral implants which she received many years apart: Low expectations, high hopes.

A Desire to Be Part of the Hearing World

This is tied to realistic expectations. If a person grows up using sign language and hearing aids, but desires more access to environmental sounds and music, they might find a cochlear implant desirable. Because they are not using their hearing for their primary communication input system, they will likely derive less "benefit" than someone who primarily uses their hearing and speech to communicate. This does not preclude them from getting implanted, but the CI team should counsel them to have different expectations than someone who has used hearing and speech all their lives, despite hearing loss.

Learning to Hear Again

When you got your first hearing aid(s), you had to reacquaint yourself with the sounds of the world. Remember the first time you flushed the toilet? YEOWZA! After getting hearing aids, it is recommended that you have a few weeks or so of auditory REhabilitation. (Learning to re-awaken the parts of your brain now connected to amplified and filtered sound traveling through your not-so-perfect hearing system.)

With cochlear implants, your brain is learning to make sense of electrical pulses in the place of sound for the first time ever. We call this auditory HABilitation. Fundamentally it is similar to auditory rehabilitation, but because we are building a new foundation rather than shoring up an old one, it takes a bit longer.

Unfortunately, as with hearing aids, the habilitation piece of adult cochlear implantation is highly variable from person to person. Some folks get some advice and instructions for self-paced home-based training. For some, this means listening to familiar unabridged recorded books along with the text, then gradually relying less on the text. Some CI manufacturers offer computerbased at-home programs. Depending on your insurance coverage and location, formalized group and individual aural habilitation classes are available. Which technique is "best" for you depends on many factors, but considering the significant emotional, time and financial commitment involved in cochlear implantation, it well behooves you to do more than just go home and start hearing.

Getting a CI

If you feel you have reached the end of the road with hearing aids, ask your hearing health care professional to refer you for an evaluation. If they aren't aware of a CI center near you, visit the websites listed on page 19 of this article. In addition to a physician and center locator, they all have very good information for prospective implant recipients. As you narrow your search, be aware that some surgeons and centers only offer certain products. If there are specific features you need in a different product, discuss this with the center, or consider another center that offers the brand with features you want and feel you need.

Once you decide on a center, you'll have a CI evaluation which includes several specialized hearing tests, a medical and surgical consult and probably a CT scan. The center and CI manufacturer will work with your insurance to assist with funding and let you know what your co-pay or cost share is.

An important part of this process is to communicate with as many recipients as possible. Each manufacturer has support networks, but there are also independent listservs and online communities including HLAA's own www.myhearingloss.org. The advantage of these is that you hear about the entire range of products and experiences out there.

Surgery and Recovery

Once you select a surgeon and center, and have been cleared for a CI, you'll have surgery. CI surgery today is much less invasive than in years past. Most people can have their surgery as an outpatient procedure. A short time after surgery, your wound will be checked by the surgeon, and then you'll wait three to four weeks before your CI is activated.

Activation

During activation, the audiologist will test the electrode array's ability to carry current (impedance) and then find the lowest amount of current needed for you to sense sound at each electrode (threshold). They'll also measure

how much current you can tolerate (tolerance). This creates your first map. The map then assigns sounds reaching the microphone at between 25 and 30 dB to your threshold. This means that any sounds in the environment hitting the microphone at 25 dB will be just barely audible. Also included in the map are a few other settings related to how the speech processor codes information (called a strategy). Finally, since your brain will be acclimating to new sounds and "wanting more," the audiologist will usually make two or three additional programs with increasing amounts of "hearing" for you to work through until your next mapping. It is not uncommon for people to have two days of mapping sessions at activation, and then wait a month for the next mapping.

Follow-up Mapping

After a month or so, you'll return for more impedance, threshold and tolerance testing. Typically the difference between threshold and tolerance (dynamic range) has increased, allowing the audiologist to map access to more sound. Often this will be the first post-implant hearing test as well. Ideally, you will have already begun some type of auditory habilitation and have gotten plugged into some kind of support system.

After this appointment, you'll generally be seen every six months for a year, then annually after that unless problems occur.

One or Two?

Initially, CIs were only prescribed in one ear. Data collected over the past several years has shown that two devices really are better than one, even if you have severe to profound hearing loss. For some, this means one CI and one hearing aid (bimodal). For an increasing number of people, this means a second CI (bilateral). Discuss the relative merits of bilateral implants with your CI center, including whether you want them both at the same time (simultaneous) or one at a time (sequential). For many the deciding factor is insurance coverage, but again, each manufacturer has a department specifically tasked with helping people with finding funding or reimbursement; so be sure to ask and investigate.

Ongoing Maintenance

Like any other electronic device, CIs need maintenance. The internal components should be trouble-free for many, many years; however the external parts will need to be replaced and cared for. The speech processors should be stored in a dehumidifier like the Dry &Store®. Wires from the processor to the external transmitter need to be checked. Savvy recipients will have a spare set of wires, and magnets at home since Murphy's Law applies here as well, and most CI centers are closed when you most need that wire! Let's not forget the batteries. Speech processors use either stacks of 675 button cells or proprietary lithium-ion rechargeable batteries. Having spare sets on hand is critical if you need to hear for long days.

Wrapping Up

If your hearing loss has pushed your hearing aids to their limit, the good news is that cochlear implants are better than they have ever been. The internal components used today are designed to be compatible with future speech processors, and surgical techniques are making the process of hearing electronically easier than ever. While very remarkable, CIs are still electronics with microphones and have limitations. Combining CIs with Hearing Assistive Technology like audio loops, infrareds and FMs can now allow those with even profound losses to rejoin the hearing world.

Finally, there are tremendous resources at your fingertips for support, encouragement and education through HLAA, the manufacturers and independent listservs.

So plug in, tune up and party on!

Selective Auditory Attention in Adults: Effects of Rhythmic Structure of the Competing Language

Author: Reel, Leigh Ann; Hicks, Candace Bourland

Publication info: Journal of Speech, Language and Hearing Research (Online) 55.1 (Feb 2012): 89-104.
ProQuest document link

Abstract: The authors assessed adult selective auditory attention to determine effects of (a) differences between the vocal/speaking characteristics of different mixed-gender pairs of masking talkers and (b) the rhythmic structure of the language of the competing speech. Reception thresholds for English sentences were measured for 50 monolingual English-speaking adults in conditions with 2-talker (male-female) competing speech spoken in a stress-based (English, German), syllable-based (Spanish, French), or mora-based (Japanese) language. Two different masking signals were created for each language (i.e., 2 different 2-talker pairs). All subjects were tested in 10 competing conditions (2 conditions for each of the 5 languages). A significant difference was noted between the 2 masking signals within each language. Across languages, significantly greater listening difficulty was observed in conditions where competing speech was spoken in English, German, or Japanese, as compared with Spanish or French. Results suggest that (a) for a particular language, masking effectiveness can vary between different male-female 2-talker maskers and (b) for stress-based vs. syllable-based languages, competing speech is more difficult to ignore when spoken in a language from the native rhythmic class as compared with a nonnative rhythmic class, regardless of whether the language is familiar or unfamiliar to the listener.

Purpose: The authors assessed adult selective auditory attention to determine effects of (a) differences between the vocal/speaking characteristics of different mixed-gender pairs of masking talkers and (b) the rhythmic structure of the language of the competing speech.

Method: Reception thresholds for English sentences were measured for 50 monolingual English-speaking adults in conditions with 2-talker (male-female) competing speech spoken in a stress-based (English, German), syllable-based (Spanish, French), or mora-based (Japanese) language. Two different masking signals were created for each language (i.e., 2 different 2-talker pairs). All subjects were tested in 10 competing conditions (2 conditions for each of the 5 languages).

Results: A significant difference was noted between the 2 masking signals within each language. Across languages, significantly greater listening difficulty was observed in conditions where competing speech was spoken in English, German, or Japanese, as compared with Spanish or French.

Conclusions: Results suggest that (a) for a particular language, masking effectiveness can vary between different male-female 2-talker maskers and (b) for stress-based vs. syllable-based languages, competing speech is more difficult to ignore when spoken in a language from the native rhythmic class as compared with a nonnative rhythmic class, regardless of whether the language is familiar or unfamiliar to the listener.

Key Words: selective auditory attention, competing speech, language rhythm

On a daily basis, humans are faced with the challenge of listening to speech in environments where other sounds are present. These competing sounds may include nonspeech noises and/or speech from other talkers. To accurately perceive speech in competing conditions, listeners must have adequate selective auditory attention skills so that they can select and attend to the relevant speech information (i.e., the target signal) while simultaneously ignoring any irrelevant auditory stimuli in the environment (i.e., the masking or competing signals; Medwetsky, 2002). Without these skills, listeners would be unable to function effectively in the complex acoustical conditions often present in home, work, school, and social environments.

Nonlinguistic Characteristics of Competing Speech Signals

Previous studies have shown that selective attention in competing speech conditions is affected by nonlinguistic factors, such as differences among the spatial location (e.g., Freyman, Balakrishnan, &Helfer, 2004), intensity (e.g., Cooke, Garcia Lecumberri, &Barker, 2008), number (e.g., Simpson &Cooke, 2005), gender (e.g., Brungart, 2001), and vocal /speaking characteristics (e.g., Freyman, Helfer, &Balakrishnan, 2007) of the target and masking talkers. However, isolating the individual effects of these factors is difficult because it has been shown that each nonlinguistic characteristic of a masking speech signal interacts with other nonlinguistic characteristics. For example, the effect of signalto- noise ratio (SNR) can vary depending on the gender of talkers in the primary and competing signal (e.g., Brungart, 2001; Brungart, Simpson, Ericson, &Scott, 2001). Despite these complex interactions, a common finding across most studies is that the degree of interference (i.e., masking effectiveness) provided by a competing speech signal declines and selective auditory attention performance improves as differences increase among the nonlinguistic characteristics of the target and masking speech signals. Presumably, this pattern occurs because differences among the spatial location, intensity, number, gender, and/or vocal/speaking characteristics of the target and masking talker(s) provide cues that help the listener separate the signals and selectively attend to only the target speech.

Linguistic Characteristics of Competing Speech Signals

In addition to nonlinguistic cues, listeners also may rely on differences among linguistic characteristics of the target and masking speech in order to selectively attend to a target speech signal in the presence of one or more masking speech signals. The majority of studies in this area have investigated effects of the semantic content (i.e., meaning) of masking speech using different forms of speech spoken in the listeners' native language, including meaningful forward sentences, nonmeaningful forward sentences, and reversed sentences (e.g., Chermak, 1975; Freyman et al., 2001). However, results of these studies failed to reveal a consistent

pattern regarding effects of the semantic content of masking speech signals. For example, Chermak (1975) found that adults experienced significantly greater difficulty ignoring masking speech that consisted of nonmeaningful/ grammatically correct sentences, as compared with sentences that were meaningful/grammatically correct or nonmeaningful/ungrammatical. Alone, these results appear to indicate that nonmeaningful speech is a more effective masking signal than meaningful speech. However, in contrast to this pattern, other studies have shown that sentences that are reversed (and, therefore, devoid of meaning) are easier for listeners to ignore than are forward, meaningful sentences (e.g., Freyman et al., 2001; Rhebergen, Versfeld, &Dreschler, 2005; Sperry, Wiley, &Chial, 1997). Adding to the inconsistency among findings in this area, results of other studies have revealed no significant differences between listeners' abilities to ignore masking speech consisting of meaningful forward speech, nonmeaningful forward speech, and/or reversed speech (e.g., Chermak, Vonhof, &Bendel, 1989; Johnstone &Litovsky, 2006). As such, many questions remain unanswered at this time regarding whether the linguistic characteristics of competing speech, including the semantic content of the signal(s), may influence listeners' selective auditory attention.

Given the inconsistencies between results obtained using different types of native language masking speech, a small number of studies have compared listeners' performance in conditions where competing speech is spoken in the native language versus an unfamiliar language. Speech in an unfamiliar language offers the advantage of having a more similar basic time envelope (i.e., rapid onsets and slow offsets) to the native language as compared with reversed speech (i.e., slow onsets and rapid offsets; Rhebergen et al., 2005). In addition, speech that is uttered in an unfamiliar language has no semantic content at the sentence or word level, unlike nonmeaningful, forward sentences in the native language, where individual words still carry meaning. Because of these characteristics, competing speech in an unfamiliar language may provide a better control condition than nonmeaningful forward or reversed native language sentences when testing effects of the semantic content of masking speech. Furthermore, comparison of results obtained when competing speech is spoken in different languages may reveal linguistic characteristics other than meaning that can influence the masking effectiveness of competing speech signals.

The small number of previous studies that used competing speech in an unfamiliar language can be divided into two groups based on the reported pattern of results. For example, Garcia Lecumberri and Cooke (2006) and Van Engen and Bradlow (2007) each found that listeners experienced greater difficulty selectively attending when the competing speech was spoken in the native language than when competing speech was spoken in an unfamiliar language. Together with evidence from the majority of studies that used reversed masking speech, findings from these two studies suggest that semantic content of the masking speech signal significantly affects selective auditory attention such that meaningful competing speech is more difficult to ignore than competing speech that lacks meaning. However, this explanation may be overly simplistic, given that two additional studies reported no significant differences between listeners' abilities to recognize a target speech signal when masking speech was spoken in the listeners' native language versus when it was spoken in an unfamiliar language (Freyman et al., 2001; Tun, O'Kane, &Wingfield, 2002).

The inconsistency between these two sets of results suggests that the masking effectiveness of a competing speech signal may be influenced by linguistic characteristics other than meaning. For example, languages vary in the degree to which they either share similarities or differ in areas such as lexical roots, consonant inventory, vowel inventory, syllable structure, stress patterns, and rhythmic structure (McLeod, 2007). Similarities among linguistic factors such as thesemay explain why Freyman et al. (2001) and Tun et al. (2002) each found no significant differences between monolingual listeners' abilities to recognize target speech in conditions where the masking speech was spoken in English (the native language) versus Dutch (an unfamiliar language). Previous research indicates that English and Dutch share linguistic characteristics, including use of variable stress patterns, Germanic lexical roots, a similar number of vowels, and a stress-based rhythmic structure (Sebastián-Gallés, Dupoux, Costa, &Mehler, 2000). As such, similarities between linguistic properties of English

and Dutch may have caused listeners in the studies by Freyman et al. (2001) and Tun et al. (2002) to experience an equal level of difficulty in separating target English speech from the masking speech signal, regardless of the language in which the masking speech was spoken.

In contrast, differences between linguistic characteristics of languagesmay explainwhy the studies byGarcia Lecumberri andCooke (2006) andVan Engen and Bradlow (2007) both found that monolingual English-speaking listeners experienced greater difficulty ignoring competing speech spoken in their native language (i.e., English) as compared with competing speech spoken in an unfamiliar language (i.e., Spanish in one study and Mandarin Chinese in the other). In both studies, the unfamiliar language differed considerably from the listeners' native language in areas such as lexical roots, number of vowels, and rhythmic structure of the language. Such differences may have made it easier for listeners to separate the target native language speech (i.e., English) from competing speech spoken in the unfamiliar language. However, when the target and competing speech signals were both spoken in English, overlap among linguistic characteristics of each signal may have increased the relative difficulty of the task.

Native Language Rhythmic Structure and Speech Processing

Overall, the previously described results suggest that the difficulty of a selective auditory attention task increases as nonlinguistic and/or linguistic similarities increase between the target and masking speech signals (e.g., Brungart, 2001; Freyman et al., 2004; Garcia Lecumberri &Cooke, 2006). Together, studies of this nature assist in answering the question of how characteristics of competing speech signals influence selective auditory attention. However, the ability to process a target speech signal in competing speech conditions may be also be affected by the listener's language background. One question of particular interest relates to how selective auditory attention in competing speech conditions may be affected by the rhythmic structure of the listener's native language.

With respect to spoken language, rhythm is a term used to refer to "the regularities which govern the grouping of elements in a language's phonological structure" (Murty, Otake, &Cutler, 2007, p. 78). Early researchers proposed that all languages could be classified into three rhythmic classes: stress-based, syllable-based, and mora-based. Languages such as English, Dutch, German, and Russian were classified as stress-based languages, whereas Spanish, French, and Italian were considered syllable-based languages (Abercrombie, 1967; Pike, 1945; both as cited in Nazzi, Jusczyk, &Johnson, 2000). Japanese, on the other hand, was considered to be the only member of the mora-based rhythmic category.

Studies comparing acoustic-phonetic characteristics of different languages provide evidence that at least some languages have rhythmic properties consistent with these three classes. For example, Ramus, Nespor, and Mehler (1999) analyzed speech samples from native speakers of eight languages (i.e., English, Polish, Dutch, French, Spanish, Italian, Catalan, and Japanese) and found that languages typically classified as belonging to different rhythmic classes differed significantly on two measures: the percentage of total sentence duration that involved vocalic intervals and the SD of duration measured for intervals of consonants/ clusters of consonants. No significant differences were seen between results for languages typically classified as belonging to the same rhythmic category. In a similar study, Grabe and Low (2002) measured the duration of vocalic intervals and intervocalic intervals for 18 languages. Results supported the classification of German, English, and Dutch into one rhythmic category (i.e., stress-based) and the classification of French and Spanish into a separate rhythmic category (i.e., syllablebased). However, results of the study failed to support the contention that Japanese has its own unique rhythmic structure, separate from that of stress-based and syllable-based languages. Results for the other 12 languages also failed to neatly align with one rhythmic category, suggesting that languages may vary in the degree to which they exhibit classic stress-based or syllablebased rhythm.

Despite questions as towhether all languages fall into three proposed rhythmic categories, existing acoustic-phonetic evidence indicates that at least some languages have rhythmic properties consistent with specific classes (e.g., English, German, Spanish, French). Evidence from behavioral studies suggests that as early as

infancy, listeners are able to detect rhythmic differences between languages (e.g., Grabe&Low, 2002; Nazzi, Bertoncini,& Mehler, 1998; Ramus et al., 1999), and it has been shown that these sensitivities to language rhythm play a critical role in how listeners process speech in quiet listening conditions. Specifically, studies of infants and adults indicate that native listeners of languages from the same rhythmic class tend to process speech in similar ways, whereas native listeners of languages from different rhythmic classes generally use different types of speech processing strategies (e.g., Cutler, Mehler, Norris, &Segui, 1983, 1986;Cutler&Otake, 1994;Houston, Jusczyk, Kuijpers, Coolen, &Cutler, 2000; Vroomen, van Zon, &de Gelder, 1996). These findings suggest that the rhythmic structure of the native language serves as a type of filter through which listeners process all incoming speech signals, regardless of the language in which the speech input is spoken (Sebastián-Gallés et al., 2000).

Goals

Overall, results from previous studies of selective auditory attention suggest that a competing speech signal provides a greater degree of masking as similarities increase between characteristics of the target and competing speech signals (e.g., Brungart, 2001; Freyman et al., 2004; Garcia Lecumberri &Cooke, 2006). Few studies have investigated how selective auditory attention performance is affected by (a) differences among vocal /speaking characteristics of masking talkers (i.e., variability between maskers within a language) and (b) the language in which the competing speech is spoken (i.e., variability across languages). A question of interest relates to whether-and how-the rhythmic structure of the language of a competing speech signal may affect a listener's ability to selectively attend to and process a target speech signal. In an attempt to answer this question, we compared monolingual Englishspeaking adult listeners' abilities to selectively attend to meaningful English sentences in conditions where competing speech was spoken in a stress-based language (English or German), a syllable-based language (Spanish or French), or a mora-based language (Japanese). The primary goals of the study were to determine how monolingual adult listeners' selective auditory attention performance was affected by (a) the semantic content (i.e., meaning) of the competing speech, (b) the rhythmic structure of the language in which the competing speech was spoken, and (c) the individual dif ferences between the vocal /speaking characteristics of different pairs of masking talkers of the same language.

Method

Subjects

All subjects underwent a hearing screening, completed a questionnaire, and were tested in each of the 11 conditions described in the following sections. All research procedures were approved by an institutional review board. Results from 50 monolingual Englishspeaking women were analyzed. Subjects ranged from 20 to 44 years of age, with a mean age of 23.72 years. All subjects were recruited for participation using direct person-to-person solicitation and posted notices of solicitation. To participate, each subject was required to meet each of the following criteria: (a) be 18-55 years of age; (b) have English as his or her first language, with little to no familiarity with any languages other than English; (c) be at least a high school graduate; (d) have no history of a diagnosed permanent hearing loss, auditory processing disorder, language disorder, learning disability, and/or dyslexia; and (e) pass a hearing screening at 15 dBHLin each ear at 250-8000 Hz (measured through TDH 50P Telephonics headphones or E-A-R Tone 3A insert earphones).

Results from four subjects were excluded, including three subjects who were unable to complete the testing during a single session due to scheduling conflicts and one subject who failed to comply with the test protocol (i.e., was text messaging during testing). Results from the remaining 50 subjects were included in the data analysis. Previous studies investigating monolingual adult listeners' selective auditory attention abilities included sample sizes ranging from eight subjects (Rhebergen et al., 2005) to 66 subjects (Van Engen &Bradlow, 2007). Therefore, the current study's sample size of 50 approximates the maximum number of subjects included in previous studies in this area.

Questionnaire

After signing an informed consent form, each subject was required to complete a brief questionnaire prior to any testing. The questionnaire addressed topics such as the subject's age, educational degree(s), exposure to/experience with languages other than English, and history of disorders that might affect his or her speech recognition performance.With regard to language experience, subjects were asked to (a) list any languages other than English that they could speak and/or understand and (b) specify when/where these non-English languages were learned. If an individual had experiencewith another language, he or she was then asked to respond to two rating questions/statements included on the questionnaire.

Both rating questions were adapted from the Minnesota Modified Student Oral Language Observation Matrix (MN-SOLOM; Minnesota State Department of Education [MSDE], 2003, as cited in MSDE, n.d.), which is an adaptation of the Student Oral Language Observation Matrix (SOLOM; Ortiz, 1995, as cited in von Hapsburg &Peña, 2002). The SOLOM and MN-SOLOM are informal rating scales designed to allow teachers to evaluate English oral language proficiency among students for whom English is a second language. Although not a standardized measure, the SOLOMhas beenwidely used in California andMinnesota to supplement information gained through standardized tests of language proficiency (MSDE, n.d.).

We used responses to the two rating questions to determine whether the subject met the inclusion criterion of "little to no familiarity with any languages other than English." The subjects rated their familiarity in speaking and understanding languages other than English on a five-point scale. Only native English speakers who scored a 1 or a 2 on both rating questions were included in the study. This included speakers who, at most, spoke in one- to two-word phrases in another language and, at most, understood another language if it was spoken slowly and with "frequent repetitions and rephrasing" (MSDE, n.d., p. 131). This criterion helped ensure that monolingual English-speaking adults participating in the study would be able to understand competing speech spoken only in English and not in the other four languages (i.e., German, Spanish, French, and Japanese). In addition to language experience, the questionnaire also addressed whether the subject had ever been diagnosed with a permanent hearing loss, auditory processing disorder, language disorder, learning disability, and/or dyslexia.

Test Stimuli

Target sentences. Subjects who met all inclusion criteria were tested using 22 test lists in 11 conditions. The target speech signal consisted of sentences from the original version of the Hearing in Noise Test (HINT; Nilsson, Soli, &Sullivan, 1994). The HINT consists of 250 different meaningful English sentences spoken by the same male talker. The sentences are divided into 25 lists of 10 sentences, with all lists reportedly equated for "naturalness, length, and intelligibility" (Nilsson et al., 1994, p. 1095). The HINT was specifically developed for adaptive sentence speech reception threshold (sSRT) measurement, the assessment technique used in each condition of the current study. Adaptive sSRT procedures are used to determine the lowest intensity at which a listener can correctly recognize sentences approximately 50% of the time. Similar to other speech recognition tests, adaptive sSRT measurement can be performed in quiet or in background noise. However, the sSRT is not limited by the floor and/or ceiling effects that can occur when speech recognition testing is administered at a single intensity. On the HINT, researchers have found that 1-dB changes in sSRT values correspond to an 8.94% change in intelligibility (Nilsson, McCaw, &Soli, 1996).

Although data from development of the HINT revealed no significant differences among listeners' performance on the 25 lists, the mean for List 4 was the only list mean that was not within 1 dB of the overall mean (Nilsson et al., 1994). On the basis of these findings, List 4 was excluded from use in the current study. In addition, test development data indicated that use of two HINT lists for each sSRT measurement provided the best balance between test sensitivity and efficiency. Therefore, in the current study, results for two 10-sentence HINT lists were averaged for the quiet condition and for each of the 10 types of competing conditions (i.e., Masker A and Masker B conditions for each of the five languages).

We used Cool Edit Pro Version 2 audio editing software to adapt the original HINTrecordings. The original HINT

recordings were of a male speaker sampled at 20161 Hz (Nilsson et al., 1994). We first edited each list to remove the speech noise saved to the second channel of the original HINT list recordings. We then saved the recording of each HINT list in quiet (i.e., without speech noise) to a Dell Optiplex 745 desktop computer as a one-channel *.wav file. On the basis of pilot data, we used Cool Edit Pro Version 2 to insert a 20-s segment of silence at the beginning of each HINT list and between each sentence in the list to allow time for subjects' responses during testing. The recording of each edited HINT list was normalized to 96% of peak value using Cool Edit Pro Version 2 to ensure that all lists had the same overall root-mean-square (RMS) values.

Competing speech. Subjects' selective auditory attention performance was evaluated in conditions where competing speech was spoken in one of five languages, including English, German, Spanish, French, and Japanese. In each competing test condition, the masking signal consisted of speech from one male and one female native speaker of the masking language assigned to that condition. To more closely approximate real-world listening environments, all masking signals consisted of natural, continuous speech, as opposed to the lists of unrelated sentences used in many previous studies (e.g., Freyman et al., 2001; Johnstone &Litovsky, 2006; Rhebergen et al., 2005; Van Engen &Bradlow, 2007). For the current study, we created the competing speech signals using speech from adult male and female native speakers of English, German, Spanish, French, and Japanese. An individual was considered to be a "native" speaker if he or she had spoken the target language from birth.All talkers for the language recordingswere 18 years of age or older (range = 23-56 years; M = 32.45 years) and had no history of a speech or language disorder.

We made all masking speech recordings in a soundtreated booth using an Isomax headset microphone and a TASCAMDA-P1 digital audio tape (DAT) recorder. For each recording, the talker wore the headset microphone approximately 2-4 in. from his or her mouth. The investigator adjusted the recording sensitivity to be within the target range of +20 dB to +12 dB throughout each recording to compensate for any slight differences between microphone positioning for different talkers. We made all recordings using a sampling rate of 44.1 kHz. Each recording was uploaded and saved to a desktop computer as a one-channel *.wav file using Cool Edit Pro Version 2.

All text used for the recordings met the following criteria: (a) written in the native language at approximately a seventh grade reading level or higher, (b) content appropriate for child or adult listeners, (c) no dialogue among speakers, and (d) no references to well-known American proper names. For the German, French, and Japanese recordings, each talker read continuously from a different passage written in his or her native language. A direct translation of the same bilingual education textbook was used for the recordings made in English and Spanish (Freeman &Freeman, 2006, 2007). The English text was divided into four sections so that no two English masking talkers read the same text. The edited Spanish text was divided into the same four sections so that each Spanish masking talker read a different passage of text. For the recordings in all five languages, talkers were instructed to read the text as smoothly as possible, using a natural speaking rate, an even, natural intonation pattern, and minimal pausing between sentences.

Recordings of 52 native speakers were made. For each of the five languages, the two male and two female recordings that bestmet the study's criteriawere selected (i.e., a total of 20 recordings). We used an informal language questionnaire to ensure that the same general dialect was used by the four native speakers selected for each language. With assistance from a fluent speaker of the target language, we edited each selected recording using Cool Edit Pro Version 2 in order to (a) remove sentences with a marked dysfluency, with a recognizable American proper name, and with a recognizable English word in the non-English recordings and (b) select the best continuous section of the recording. As a native speaker of English, one of the investigators ensured that editing procedures did not violate boundaries of surrounding sentences within each English recording. To maintain the same control within German, Spanish, French, and Japanese recordings, we performed all editing of non-English recordings with assistance from a fluent speaker of the language being edited.

After selecting the best continuous section, we edited the 20 recordings to ensure that all pauses were approximately equivalent within and across recordings. We determined the criterion for maximum allowable pause time on the basis of evidence reported by Smith (2005) regarding typical pause durations that occur between sentences when text is read aloud. For the current study, shorter pauses between sentences were desirable so that we could ensure that target sentences were consistently masked by competing speech recordings. As such, the criterion for maximum allowable pause duration was set at 600-700 ms, based on the shorter mean pause times reported by Smith. We used Cool Edit Pro Version 2 tomeasure pauseswithin each of the 20 individual recordings. All pauses within individual masking- talker recordings that exceeded 700 ms were shortened to 600-700 ms. Each recording was then normalized to 96% of peak value to ensure that all 20 recordings had equivalent RMS values.

The normalized language recordings were used to create two different male-female babble recordings for each of the five languages. Each two-talker babble recording consisted of a different male and a different female masking talker. For each language, one male recording (Male 1) was paired with one female recording (Female 1). Using Cool Edit Pro Version 2, we digitally mixed the Male 1 and Female 1 recordings (i.e., two signals added together in one channel) to create the first two-talker babble signal for each language (i.e., English A, German A, Spanish A, French A, and Japanese A). We digitally mixed the remaining male recording (Male 2) and the remaining female recording (Female 2) for each language to create the second two-talker babble signal for each of the five languages (i.e., English B, German B, Spanish B, French B, and Japanese B). We normalized each two-talker mixed recording to 96% of peak to ensure that the overall RMS value of each mixed signal was equivalent. We then saved each normalized twotalker recording as a single-channel *.wav file. To control for potential individual variability between vocal / speaking characteristics of masking talkers, we tested each subject in the Masker A and Masker B competing conditions for each language.

Experimental Conditions

Each subject was tested twice in a quiet condition (i.e., no competing speech) and twice in each of the 10 types of competing speech conditions (i.e., one Masker A condition and one Masker B condition for each of the five languages). Therefore, testing was performed through use of 22 different tests for each subject. Each test consisted of a unique randomly assigned 10-sentence HINT recording, such that the same HINT list was always presented with the same randomly selected test for each subject. For the 20 tests administered with competing speech, we used Cool Edit Pro Version 2 to digitally mix the recording of each HINT sentence list with its randomly assigned two-talker babble recording, with the masking speech beginning 20 s before the start of the first HINT sentence and continuing uninterrupted for the duration of that list. The masking speech ended after the final word of the last HINTsentence on the list. Each mixed recording of the target and competing speech was saved as a two-channel *.wav file, with the HINT list saved to the right channel and the two-talker babble saved to the leftchannel.

For each subject, testing was performed first through the use of two quiet lists, with the order of testing for the two lists being randomly selected. We randomized the order of the 20 competing test lists using a partial counterbalancing procedure inwhich we created a different order of lists for each subject by using an online random order generator (Carter, 2008). We used iTunes Version 8.1 to create a different digital playlist for each subject. Each playlist included a 1000-Hz calibration tone lasting 15 s, the two HINT lists randomly assigned to quiet tests, and the 20 competing tests in the order randomly generated for that subject. Each playlist was saved to a Dell Latitude D810 laptop under the code name assigned to the associated subject.

Test Setup and Procedures

All subjects were tested in a sound-treated booth. Prior to initiation of the study, all audiometric equipment was calibrated to AmericanNational Standards Institute (ANSI) 2004 standards. For all testing, the subject wore TDH 50P Telephonics headphones or E-A-R Tone 3A insert earphones. Insert earphones were used unless otoscopy revealed significant cerumen in one or both ears, in which case headphones were used. Thirty-nine

subjects were tested using insert earphones, and 11 subjects were tested using headphones. All testing was administered through use of a GSI 61 two-channel audiometer and a Dell Latitude D810 laptop, with the laptop and iTunes volume controls set to the maximum settings. The same investigator administered the testing to all subjects.

Each subject was tested in a single 2-hr session that consisted of 22 sSRT tests, including two tests administered in quiet and 20 tests administered with competing speech (i.e., two tests with Masker A and two tests with Masker B for each of the five languages). The target sentences and competing speech (if applicable) were presented simultaneously to the subject's right and leftear (i.e., diotic presentation). The sSRT for each test list was determined through the use of adaptive procedures described in the HINT manual (Nilsson et al., 1996).

For all subjects, testing was performed first in quiet so that the subject could become familiar with the task. Prior to testing, each subject was given the same set of instructions. To obtain the sSRT, an adaptive procedure was used in accordance with clinical protocols for the HINT (Nilsson et al., 1996). The investigator began by presenting the first sentence of the target HINT list at -10 dB HL (i.e., a level likely to be below each subject's threshold). Using the audiometer attenuator, the investigator increased the presentation level by 4 dB until the subject repeated the first sentence with 100% accuracy. From this point on, a new sentence was presented one time at each intensity level tested. For Sentences 1-5, the presentation level was increased or decreased by 4 dB, depending on whether the sentence was repeated correctly (i.e., intensity increased following incorrect responses and decreased following correct responses). For Sentences 6-10, the presentation level was adjusted in 2-dB steps.

For the competing speech lists, the competing speech signal was presented continuously at 65 dB HL. To begin the testing, the first sentence of the target HINT list was presented at 10 dB below the noise level (i.e., at 55 dB HL). The remaining test procedures were the same as those used in quiet, with the intensity of the target sentences being increased or decreased by 4 dB (i.e., for Sentences 1-5) or 2 dB (i.e., for Sentences 6-10) on the basis of the subject's responses.

Data Analysis

Results obtained through use of the two quiet lists were not analyzed because testing in quiet was performed only to ensure that subjects could perform the sSRT task. We determined the sSRT for each HINT list by calculating the mean presentation level used for Sentences 5-11 (Nilsson et al., 1996). Although each list consisted of only 10 sentences, the presentation level that would have been used for the 11th sentence was determined on the basis of the subject's response to the 10th sentence. To increase sensitivity, testing was performed twice in each of the 10 types of competing conditions (i.e., Masker A and Masker B for each of the five languages), resulting in 20 sSRTscores for each subject (i.e., two scores for English Masker A, two scores for English Masker B, etc.). For each of the 10 types of competing conditions, we determined the mean sSRT by averaging the score obtained on the two HINT lists administered in that condition. This resulted in 10 mean sSRT scores for each subject-one for each of the 10 types of competing conditions. We analyzed these 10 mean sSRT scores across the 50 subjects to investigate potential effects of (a) variability between masking effectiveness of different two-talker maskers within each language (i.e., English Masker A vs. English Masker B, German Masker A vs. German Masker B, etc.) and (b) differences in overall masking effectiveness of competing speech spoken in the five languages (i.e., English vs. German, English vs. Spanish, etc.).

In the current study, we used a completely withinsubjects design with two independent variables (pairs of masking talkers and language of the competing speech) and one dependent variable (sSRT). The pairs of masking talkers factor consisted of 10 levels because a different male-female pair of masking talkers was used in each of the 10 competing conditions. The language factor consisted of five levels: English, German, Spanish, French, and Japanese. As such, the design of the current study did not meet the criteria for a true factorial design because the test conditions did not include "all possible combinations of the levels of the independent

variables" (Keppel &Wickens, 2004, p. 550). For example, there was no condition in which English Male 1 and English Female 1 provided the competing speech for German, Spanish, French, or Japanese conditions. Instead of a true factorial design, the current study involved a nested, within-subjects design in which each level of the pairs of masking talkers factor appeared at only one level of the language factor. For each language, one pair of masking talkers was randomly labeled "Masker A," and the other pair was randomly labeled "Masker B." As such, there was no common factor among Masking A pairs of talkers or among Masking B pairs of talkers. The pairs of masking talkers factor was simply nested within the language factor (Keppel &Wickens, 2004). Because of this nested relationship, tests of the overall relationship between Masker A and Masker B across the five languages would not provide meaningful information and, therefore, were not analyzed.

Results

All subjects were able to complete testing in quiet with no difficulties, thus indicating that they understood the sSRT task. Figure 1 displays mean sSRTs for Masker A and Masker B for each of the five languages. Figure 2 illustrates the collapsed mean sSRT obtained when subjects' scores for the Masker A and Masker B condition were averaged within each of the five languages to create one overall mean for each language. In both figures, higher mean sSRT scores indicate that the intensity of the target sentences had to be higher in order for subjects to repeat the sentences correctly. In other words, higher mean sSRTs suggest that subjects experienced greater difficulty with the task.

We performed a series of statistical analyses to investigate differences between the mean sSRT scores for Masker A and Masker B for each language and differences between subjects' performance across the five language conditions. We analyzed all data using SPSS Version 17.0 and determined statistical significance using a criterion of $p \leq .05$. A repeated-measures analysis of variance (ANOVA) was conducted, with pair of masking talkers (Masker A or Masker B) and language (English, German, Spanish, French, or Japanese) as the within-subjects factors. Because we used a completely within-subjects design (i.e., every subject was tested in every condition), a between-subjects factor was not specified. The main effect of masker, $F(1, 49) = 53.27$, $p < .001$; the main effect of language, $F(4, 196) = 61.73$, $p < .001$; and the Masker ×Language interaction effect, $F(4, 196) = 76.67$, $p < .001$, were significant.

To further investigate the significant Masker ×Language interaction effect, we performed a series of paired t tests using the Bonferroni adjustment to compare the mean sSRT for Masker A and Masker B within each language. Results revealed a significant difference between the mean scores for Masker A and Masker B for English, $t(49) = 15.59$, $p < .001$; German, $t(49) = -4.95$, $p < .001$; Spanish, $t(49) = -5.75$, $p < .001$; French, $t(49) = 10.30$, $p < .001$; and Japanese, $t(49) = 5.90$, $p < .001$. This difference was greatest when the competing speech was spoken in English, with a difference of 4.42 dB between English Masker A and English Masker B. Differences between Masker A and Masker B within the other four languages were 1.93 dB for German, 2.05 dB for Spanish, 2.73 dB for French, and 1.86 dB for Japanese. These differences suggest that for each language, individual differences between the pairs of masking talkers affected the listeners' ability to ignore the competing speech signal, despite the fact that both pairs of talkers included one male and one female native speaker of that language.

We also conducted post hoc comparisons using the Bonferroni adjustment to identify any significant differences between the overall mean (i.e., the collapsed mean for Masker A and Masker B) for each of the five languages. Results revealed no significant difference between the overall mean for the Spanish condition ($M = 56.11$, $SE = 0.20$) and the French condition ($M = 55.77$, $SE = 0.18$, $p = .773$). These results suggest that the listeners' selective auditory attention performance was essentially the same when competing speech was spoken in two unfamiliar languages belonging to the non-native syllable-based rhythmic category. In addition, no significant difference was observed between the overall mean for the English ($M = 58.30$, $SE = 0.21$) and German ($M = 57.82$, $SE = 0.20$, $p = .433$) conditions, indicating that listeners experienced the same degree of difficulty in ignoring competing speech spoken in their native language and in an unfamiliar language belonging to their

native stress-based rhythmic category. However, the overall means for the English condition and the German condition were each significantly greater than the overall means for the Spanish condition (English-Spanish, p <.001; German-Spanish, p <.001) and the French condition (English-French, p <.001; German-French, p <.001). Therefore, listeners experienced significantly greater difficulty in ignoring competing speech spoken in a language from their native rhythmic category as compared with languages from a non-native rhythmic category, regardless of whether the language of the competing speech was meaningful (as in the English condition) or not meaningful (as in the German condition).

No significant difference was seen between the overall mean for the Japanese (M = 58.31, SE = 0.20) condition and the English condition (M = 58.30, SE = 0.21, p = 1.000) or between the Japanese condition and the German condition (M = 57.82, SE = 0.20, p = .514). However, the overall mean for the Japanese condition (M = 58.31) was significantly greater than the overall means for the Spanish condition (M = 56.11, SE = 0.20, p <.001) and for the French condition (M = 55.77, SE = 0.18, p <.001). These results indicate that listeners' sSRT for competing speech spoken in Japanese was similar to the sSRT obtained when the competing speech was spoken in English or German, despite the fact that Japanese is typically classified as belonging to a rhythmic category that was unfamiliar to the listeners (i.e., mora-based).

Due to the significant differences noted between the Masker A and Masker B means for each of the five languages, a univariate ANOVA was also performed, with language as the within-subjects factor and the difference between the Masker A mean and the Masker B mean as the covariate. Results revealed a significant main effect of language, F(4, 244) = 38.47, p <.01, indicating that a significant relationship remained between the language of the competing speech and the mean sSRTscores, even when the significant differences between Masker A and Masker B were taken into account for each language.We performed post hoc comparisons using the Bonferroni adjustment to identify any significant differences between the overall mean sSRT for each of the five languages when the Masker A-Masker B difference was used as the covariate. Results revealed the same pattern of results that was seen with the repeated-measures ANOVA, including (a) no significant difference between the mean scores for the Spanish and French conditions (p = 1.00); (b) no significant difference among the mean scores for the English, German, and Japanese conditions (English-German, p = .74; English-Japanese, p = 1.00; German-Japanese, p = .86); and (c) significant differences among all other pairs of languages, including English and Spanish (p <.01), English and French (p <.01), German and Spanish (p <.01), German and French (p <.01), Japanese and Spanish (p <.01), and Japanese and French (p <.01).

Discussion

The current study provides insight into how adult selective auditory attention is affected by (a) rhythmic structure of the language of the competing speech and (b) variability among vocal /speaking characteristics of different pairs ofmasking talkers.Because three primary categories of language rhythm have been proposed, a test of the relationship between language rhythm and selective auditory attention requires comparison of listeners' speech recognition performance in conditions where competing speech is spoken in multiple languages, including languages from each proposed rhythmic class. However, prior to the current investigation, no study had investigated listeners' selective auditory attention performance in more than two language conditions.

In the current study, we addressed this gap in existing research by assessing monolingual Englishspeaking adult listeners' selective auditory attention performance in conditions where competing speech was spoken in a stress-based language (e.g., English or German), a syllable-based language (e.g., Spanish or French), or a mora-based language (e.g., Japanese; Abercrombie, 1967; Pike, 1945; both as cited in Nazzi et al., 2000). To evaluate effects of vocal/speaking characteristics of different masking talkers, we created two different two-talker competing speech signals (i.e., labeled Masker A and Masker B) for each language. Results from the competing conditions were compared to determine how monolingual adult listeners' selective auditory attention performance was affected by the (a) semantic content of the competing speech, (b) rhythmic structure of the

language in which the competing speech was spoken, and (c) individual differences between pairs of masking talkers of the same language.

Within-Language Comparisons

For each of the five languages used as competing speech, a significant difference was noted between the listeners' mean sSRT in the Masker A and Masker B conditions. In order to interpret these findings, it is important to consider the controls used to ensure that the Masker A and Masker B competing speech signals were as similar as possible. For example, all passages read for the English Masker A, English Masker B, Spanish Masker A, and Spanish Masker B recordings were taken from translations of the same bilingual education textbook, ensuring the same reading level and general topic areas. For German, French, and Japanese, the content of the text varied. However, differences between content of the competing speech were unlikely to have affected performance in the Spanish, German, French, and Japanese conditions because the current subjects were unable to understand these languages.

Other efforts were also made to equate the MaskerA and Masker B conditions for each language. First, the HINT lists used as the target speech were of equivalent difficulty based on data reported by the test developers (Nilsson et al., 1994). All HINT lists were also normalized to be the same overall RMS amplitude, along with recordings of masking talkers and all two-talker mixed recordings being equated for RMS amplitude. In addition, the 20 competing lists were administered to each subject in a different randomly selected order. As such, the order of testing for the Masker A and Masker B conditions for each language did not follow any consistent pattern across subjects.

In light of these controls, differences between the masking effectiveness of the Masker A and Masker B competing speech signals for each language were most likely related to differences between vocal and/or speaking characteristics of individual masking talkers. This finding is consistent with results reported by Freyman et al. (2007), who found differences between the masking effectiveness of five different English-speaking female two-talker maskers (i.e., a different pair of female talkers for each masking signal). However, the current study extends these findings by providing evidence that differences between vocal /speaking characteristics of masking talkers may significantly affect selective auditory attention, even when the competing speech is not meaningful at the sentence or the word level, as was the case in the German, Spanish, French, and Japanese conditions. Individual masking talkers may vary in areas such as their fundamental frequency, vocal quality, prosody, and speaking rate (Freyman et al., 2007), but additional research is needed to specifically investigate the extent to which each of these factors may affect listeners' abilities to separate a target speech signal from competing speech spoken by one or more masking talkers.

Between-Language Comparisons

Comparison among results obtained in each of the five language conditions revealed a number of interesting findings. For example, English competing speech was only significantly more difficult for listeners to ignore than competing speech spoken in Spanish or French, two languages in which the words and underlying rhythm (i.e., syllable-based) were unfamiliar to the listeners. In contrast, no significant differences were seen among listeners' performance in conditions where the competing speech was spoken in English, German, or Japanese, despite the fact that listeners could not understand the German or Japanese competing speech. These results indicate that meaning alone does not determine the masking effectiveness of a competing speech signal. Such findings are consistent with results from previous studies which have shown that at least in some conditions, competing speech spoken in the native language is not significantly more difficult to ignore than competing speech spoken in an unfamiliar language (Freyman et al., 2001; Tun et al., 2002). Together, these findings support the conclusion that linguistic factors other than meaning can influence the masking effectiveness of competing speech.

Evidence from the current study also suggests that adult selective auditory attention performance may be affected by the rhythm of the language in which the competing speech is spoken. The possible influence of

language rhythm is first illustrated by the fact that no significant difference was seen among listeners' performance in conditions where the competing speech was spoken in languages from the same rhythmic category. For example, listeners experienced the same level of difficulty when the competing speech was spoken in English or German, two languages belonging to the listeners' native stress-based rhythmic category. Similarly, no significant difference was seen between listeners' performance in conditions where competing speech was spoken in Spanish or French, two unfamiliar languages belonging to the non-native syllable-based rhythmic category. These findings are consistent with results from two previous studies that compared selective auditory attention performance in conditions where competing speech was spoken in the listeners' native language and one unfamiliar language from the native rhythmic class (Freyman et al., 2001; Tun et al., 2002). In both studies, no significant differences were seen between listeners' abilities to recognize a target speech signal when the competing speech was spoken in English, the native language, versus Dutch, an unfamiliar language belonging to the native stress-based rhythmic class.

Collectively, the results of these two studies (Freyman et al., 2001; Tun et al., 2002) and those of the current study suggest that listeners may be sensitive to the underlying rhythm of the language of the competing speech, such that languages within the native rhythmic category provide the same degree of masking effectiveness, regardless of whether the competing language is meaningful to the listeners. However, unlike the studies by Freyman et al. (2001) and Tun et al. (2002), the current study also compared listeners' selective auditory attention performance between two conditions where the competing speech was spoken in two unfamiliar languages belonging to the same non-native rhythmic category (i.e., syllable-based). As such, languages within a particular rhythmic category provide the same degree of masking effectiveness, regardless of whether the two languages are from the native category (i.e., English and German) or the same non-native category (i.e., Spanish and French).

In addition to these findings, results of the current study also suggest that competing speech spoken in a language from the listeners' native rhythmic category is more difficult for listeners to ignore than competing speech spoken in a language from a non-native rhythmic category, at least for some languages. For example, listeners experienced significantly greater difficulty in selectively attending to the target speech when the competing speech was spoken in English or German, two languages from the native stress-based rhythmic category, than when the competing speech was spoken in Spanish or French, two languages from the non-native syllable-based rhythmic category. These findings are consistent with two previous studies which found that competing speech spoken in the native language was more difficult for listeners to ignore than competing speech spoken in an unfamiliar language from a nonnative rhythmic category (Garcia Lecumberri &Cooke, 2006; Van Engen &Bradlow, 2007). However, in the current study, we extend these findings by providing evidence that speech in an unfamiliar language from the native rhythmic category (i.e., German) is also significantly more difficult for listeners to ignore than an unfamiliar language from a non-native rhythmic category (i.e., Spanish and French).

Another finding of the current study was that listeners did not treat competing speech spoken in Japanese the same as competing speech spoken in Spanish or French, even though all three languages were unfamiliar and were from non-native rhythmic categories. Instead, no significant differences were seen among listeners' performance in the English, German, and Japanese competing speech conditions. Therefore, competing speech spoken in Japanese provided the same degree of masking effectiveness as competing speech spoken in the listeners' native language (English) and an unfamiliar language from the native stress-based rhythmic category (German). These results were unexpected, given that Japanese is typically considered to have mora-based rhythm, a rhythmic structure that should have been unfamiliar to the monolingual English-speaking listeners in the current study.

At the present time, it remains unclear why this pattern of results was observed for the Japanese competing speech conditions. The classification of Japanese as a mora-based language has been primarily based on

behavioral evidence of speech processing strategies used by listeners in quiet listening conditions. For example, previous studies have demonstrated that from birth to 6 months of age, babies from monolingual families can discriminate between Japanese and languages from the stress-based rhythmic class (Nazzi et al., 1998, 2000) and languages from the syllable-based rhythmic class (Nazzi et al., 2000). In addition, it has been found that adult native listeners of Japanese segment continuous speech according to morae, the subsyllabic units believed to underlie the rhythmic structure of Japanese speech (Cutler &Otake, 1994).

Despite this pattern of behavioral results, in acoustic- phonetic studies, researchers have reported conflicting findings regarding whether the rhythmic structure of Japanese is, in fact, significantly different from that of stress-based and syllable-based languages. For example, Ramus et al. (1999) found that Japanese speech was significantly different from speech spoken in stressbased languages (i.e., English, Dutch, and Polish) and speech spoken in syllable-based languages (e.g., Spanish, French, Catalan, and Italian) when the rhythm of each language was quantified on the basis of the duration of vocalic and consonantal intervals.However, Grabe and Low (2002) found that the acoustic-phonetic properties of Japanese were comparable to syllable-based languages or stress-based languages, depending on how language rhythm was quantified.

Therefore, the findings reported by Grabe and Low (2002) and the results of the current study suggest that Japanese may not belong to its own unique rhythmic class. Instead, the rhythmic properties of Japanese may overlap with those of stress-based and syllablebased languages. In the current study, listeners treated competing speech in Japanese the same as competing speech in English and German, two languages from the stress-based rhythmic category. In contrast, significant differences were seen between how listeners performed when competing speech was spoken in Japanese as compared with Spanish or French, two syllablebased languages. This pattern of results may indicate that for monolingual English-speaking adults, the acoustic-phonetic properties shared between Japanese and stress-based languages have a greater impact on selective auditory attention than do the acoustic-phonetic similarities between Japanese and syllable-based languages. However, additional research is needed to further explore the potential relationship between the underlying rhythm of Japanese and stress-based languages, such as English and German.

Together, the current results seem to indicate that selective auditory attention may be impacted by the rhythm of the language in which competing speech is spoken. However, it should be noted that factors other than rhythm may account for the significant betweenlanguage differences noted in the present study. For example, variability between the mean sSRT for maskers within each language (i.e., Masker A-Masker B differences) ranged from 1.86 dB to 4.42 dB, whereas the largest difference in the mean sSRT for a stressbased versus a syllable-based language was 2.53 dB (i.e., difference between English and French). As such, the possible contribution of the rhythm of the language to masking effectiveness is in the range of the variability between maskers within each language. However, a statistical analysis was conducted using the Masker A- Masker B difference as a covariate with a within-subject factor of language. This analysis confirmed the betweenlanguage pattern of results, suggesting that masking effectiveness may have been influenced by the rhythmic category of the language, even when withinlanguage variability between maskers was taken into account.

Although the current pattern of between-language differences may reflect actual differences in masking effectiveness, such differences could be related to variability in the amount of energetic masking provided by each language, rather than influences of linguistic factors such as rhythm. Although energetic masking was not specifically measured in the current study, previous studies have used the long-term average speech spectrum (LTASS) as an estimate of energetic masking (Van Engen&Bradlow, 2007) and have found the LTASS to be fairly equivalent across languages, with only a small amount of variability (e.g., Byrne et al., 1994). However, LTASS is only an approximate indicator of energetic masking, and, as such, the different languages may have variations in fine spectral detail not taken into account in LTASS measurements. On the other hand, the current pattern of between-language differences may be related to factors other than energetic masking, such as informational masking associated with linguistic characteristics of the languages. Although rhythmic differences

between languages may be a contributing factor, one could argue that linguistic characteristics other than rhythm may have influenced results obtained in the different language conditions. For example, English is of Germanic origin; therefore, it is possible that similarities in masking effectiveness between English and German could be related to their shared lexical roots. However, effects of common roots fail to explain the finding that the masking effectiveness of Japanese did not differ significantly from English or German, given that Japanese is not related to English and German in terms of root words. In addition, English has more recent roots in common with French (Finegan, 2009), but in the current study, these two languages differed significantly in terms of masking effectiveness. Therefore, although within-language variables, energetic masking, and common language roots may play a role in selective auditory attention, the development of a pattern in accordance with rhythmic structures indicates a possible contribution of rhythm to masking effectiveness.

Study Limitations and Implications for Future Research

The current study offers insight into how adult listeners' selective auditory attention performance is affected by variability between the vocal/speaking characteristics of different masking talkers and the underlying rhythm of the language in which competing speech is spoken. However, certain limitations of the study must be considered. The first limitation relates to the restricted age range of the subjects. For the 50 subjects included in the data analysis, ages ranged from 20 to 44 years of age (M = 23.72 years). However, only five subjects were over 25 years of age. As such, it remains unknown whether the current pattern of results can be generalized to other age groups, given that young children (e.g., Johnson, 2000) and older adults (e.g., Tun et al., 2002) have been shown to experience greater difficulty selectively attending than have young adults.

Another limitation relates to the language background of the subjects. Previous research has shown that language background can affect speech processing, both in quiet (e.g., Cutler &Otake, 1994; Sebastián- Gallés et al., 2000) and in competing speech conditions (e.g., Garcia Lecumberri &Cooke, 2006). Based on these findings, the current study was limited to monolingual American English-speaking adults. Controlling for language background ensured that performance on the experimental taskswould not be influenced by differences in listeners' exposure to languages other than English. However, additional research is needed to determine if the current pattern of results would be seen for listeners from other language backgrounds.

In addition to subjects' age range and language background, other limitations relate to characteristics of the competing speech signals used in the current study. For example, the masking talkers of the five languages did not all read the same text for the recordings used to create the competing speech signals. Various controls were used for the purpose of minimizing differences between the text read for each recording (e.g., reading level, age appropriateness of content, no dialogue, no references to well-known American proper names, etc.). Even without such controls, differences between the content of the text should not have affected listeners' performance in the German, Spanish, French, and Japanese competing conditions, given that these languages were unfamiliar to the subjects. However, if possible, future studies should use translations of the same text for each language to rule out extraneous effects of text differences.

With regard to characteristics of the competing speech, another limitation relates to the fact that acoustic-phonetic properties of the languages were not measured in the current study. Given that the classification of languages into rhythmic classes remains a topic of some debate, it is possible that other characteristics of the competing languages may have affected the current results. In determining the rhythm of a language, studies have taken into consideration phonological properties such as syllable structure, vowel reduction, and consonant intervals, among other aspects (Grabe &Low, 2002; Ramus et al., 1999). Studies have shown that certain languages do exhibit the "prototypical" rhythmic patterns. Specifically, it has been shown that the stress-based and syllable-based languages chosen for the current study follow the prototypical patterns for stress-based (i.e., German and English) and syllablebased (i.e., French and Spanish) rhythms. It should be noted that other aspects of language can impact the rhythmic groupings, such that some languages do not fit into the categories as distinctly (Grabe &Low, 2002). As such, in future studies, researchers should continue to

investigate aspects of language, including rhythm and other areas such as phonotactics and phonological similarity, to determine the potential impact on selective auditory attention.

Prior to generalizing the current results, it is also important to consider the number of masking talkers and the target-masker gender configuration used in the study. All subjects were tested in conditions where the competing speech consisted of one male and one female masking talker (i.e., a mixed-gender two-talker masker). Previous studies have shown that the masking effectiveness of competing speech increases as the number ofmasking talkers increases up to six talkers (Simpson &Cooke, 2005). However, effects of the content of competing speech are reduced or eliminated as the number of masking talkers increases from two to six talkers (e.g., Van Engen &Bradlow, 2007). In addition, evidence from previous studies (e.g., Brungart et al., 2001) also suggests that competing speech from two masking talkers provides essentially the same masking effectiveness, regardless of whether both masking talkers are the same gender as the target talker (i.e., same-gender targetmasker gender configuration) or whether one masking talker is male and one masking talker is female (i.e., mixed-gender target-masker configuration). Based on these findings, we chose a mixed-gender two-talker masking signal to achieve the most effective balance between maximizing masking effectiveness of the competing speech (i.e., by using more than one masking talker) and ensuring that any effects of the linguistic content of the competing signal (e.g., rhythmic structure of the language) could still be detected (i.e., by using only two masking talkers). However, additional research is needed to determine whether selective auditory attention performance is significantly impacted by the language of the competing speech if a different number of masking talkers and/or a different target-masker gender configuration is used, in addition to whether selective auditory attention varies depending on the target material (e.g., sentences, words, or syllables).

A final factor to be considered in generalizing the current results is the measurement technique that we used to assess listeners' selective auditory attention performance in each competing speech condition. Previous studies have shown that complex interactions occur between nonlinguistic characteristics of competing speech signals. For example, it has been reported that effects of SNR on selective auditory attention vary depending on the spatial location of the target and masking talkers (e.g., Freyman et al., 2001), number of masking talkers (e.g., Brungart et al., 2001), and target-masker gender relationship (e.g., Brungart, 2001). However, much remains unknown regarding how effects of the SNR may interact with linguistic characteristics of competing speech, including rhythm of the language spoken by the masking talkers. In light of these uncertainties, an adaptive sSRT procedure was used in the current study, instead of administering sentence recognition testing at a single SNR in each condition. However, additional research is needed to determine whether the same effects of language of the competing speech will be seen if selective auditory attention is measured through the use of other techniques.

Conclusions

Results of the current study indicate that the vocal/ speaking characteristics of different pairs of male- female masking talkers can provide different degrees of masking effectiveness, regardless of whether the masking talkers are speaking the listeners' native language or an unfamiliar language. In addition, the current results extend evidence from previous studies by showing that the rhythm of the native language may shape not only how a listener processes speech in quiet (e.g., Cutler et al., 1983; Cutler &Otake, 1994) but also how he or she processes a target speech signal in conditions where other talkers are speaking simultaneously in the background. Specifically, the current findings suggest that languages within the same rhythmic category provide the same degree of masking effectiveness. However, competing speech spoken in a language from the native rhythmic category is a more effective masker (and, therefore, is more difficult for listeners to ignore) than competing speech spoken in a language from a non-native rhythmic category, at least for some languages. This pattern of results occurred regardless of whether the language from the native rhythmic category wasmeaningful to the listeners, thus suggesting that the underlying rhythm of the language of the competing speech has a greater impact on masking effectiveness than its meaning. In the current study, the exception to

this pattern was that competing speech spoken in Japanese was shown to have the same masking effectiveness as competing speech spoken in languages from the listeners' native stress-based rhythmic category, despite the fact that Japanese has long been classified as having a mora-based rhythmic structure. Therefore, the current findings support previous acoustic-phonetic evidence (e.g., Grabe &Low, 2002) which has shown that Japanese may not exhibit its own unique rhythm but may instead share similarities with at least some stress-based languages.

Given the current results, additional research is now needed to explore how the language of competing speech affects selective auditory attention performance for monolingual and bilingual listeners from different age groups and different language backgrounds. Future studies should also investigate whether the current pattern of results would be replicated if other languages from the stress-based and syllable-based rhythmic categories were used as the competing speech. Together with the current results, evidence from such studies will lead to a better understanding of how exposure to the rhythmic structure of the native language(s) influences how speech is processed in competing conditions.

Acknowledgments

We gratefully acknowledge Steven Zupancic, Renée Bogschutz, Melinda Corwin, Rajinder Koul, and Nick Coppola at the Texas Tech UniversityHealth Sciences Center in Lubbock, TX, as well as Sylvia Martinez at La Casita Elementary in Clovis, NM, for their contributions to this project. We also thank the language recording volunteers, subjects, and all others who generously gave their time to make the study a success.

Abstract: In this study, the authors aimed to identify speech information processed by a hearing aid (HA) that is additive to information processed by a cochlear implant (CI) as a function of signal-to-noise ratio (SNR). Speech recognition was measured with CI alone, HA alone, and CI + HA. Ten participants were separated into 2 groups; good (aided pure-tone average [PTA] <55 dB) and poor (aided PTA ≥ 55 dB) at audiometric frequencies ≤ 1 kHz in HA. Results showed that the good-aided PTA group derived a clear bimodal benefit (performance difference between CI + HA and CI alone) for vowel and sentence recognition in noise, whereas the poor-aided PTA group received little benefit across speech tests and SNRs. Results also showed that a better aided PTA

helped in processing cues embedded in both low and high frequencies; none of these cues was significantly perceived by the poor-aided PTA group. The aided PTA is an important indicator for bimodal advantage in speech perception. The lack of bimodal benefits in the poor group may be attributed to the nonoptimal HA fitting. Bimodal listening provides a synergistic effect for cues in both low- and high-frequency components in speech.

Full text: Headnote

Purpose: In this study, the authors aimed to identify speech information processed by a hearing aid (HA) that is additive to information processed by a cochlear implant (CI) as a function of signal-to-noise ratio (SNR).
Method: Speech recognition was measured with CI alone, HA alone, and CI + HA. Ten participants were separated into 2 groups; good (aided pure-tone average [PTA] <55 dB) and poor (aided PTA ≥55 dB) at audiometric frequencies ≤1 kHz in HA.
Results: Results showed that the good-aided PTA group derived a clear bimodal benefit (performance difference between CI + HA and CI alone) for vowel and sentence recognition in noise, whereas the poor-aided PTA group received little benefit across speech tests and SNRs. Results also showed that a better aided PTA helped in processing cues embedded in both low and high frequencies; none of these cues was significantly perceived by the poor-aided PTA group.
Conclusions: The aided PTA is an important indicator for bimodal advantage in speech perception. The lack of bimodal benefits in the poor group may be attributed to the nonoptimal HA fitting. Bimodal listening provides a synergistic effect for cues in both low- and high-frequency components in speech.
Key Words: speech recognition, electric and acoustic stimulation, acoustic features, signal-to-noise ratio, bimodal benefit

It is well known that combining electric speech processing with residual acoustic hearing leads to an improvement in speech understanding in noise. Some cochlear implant (CI) users wear a hearing aid (HA) in the nonimplanted ear (bimodal CI users; CI + HA), and other CI users wear an HA in the implanted ear (hybrid CI users). In both cases, patients have the opportunity to benefit from the combination of electric and acoustic stimulation (EAS), leading to an EAS benefit, defined as the difference in speech performance between CI + HA and CI alone. The idea behind EAS is that the loss of sensory cells can be compensated for by means of electric stimulation in the mid- to high-frequency range in combination with acoustic stimulation of the remaining low-frequency areas of the cochlear receptors.

Previous bimodal studies showed a clear trend in the improvement of speech intelligibility when acoustic hearing was added to electric hearing. Even though the degree of the bimodal benefit varies with experimental conditions such as test material, subject age, configuration of hearing thresholds for the acoustic side, and presence of a noise masker, generally the bimodal benefit ranges from 8% to 25% relative to the performance for CI alone (Ching, Incerti, Hill, &van Wanrooy, 2006; Dorman, Gifford, Spahr, &McKarns, 2008; Gifford, Dorman, McKarns, &Spahr, 2007; Hamzavi, Pok, Gstoettner, &Baumgartner, 2004; Kiefer et al., 2005; Kong, Stickey, &Zeng, 2005). The bimodal benefit is observed not only in speech perception but also in the perception of four-syllable numbers (Hamzavi et al., 2004). However, it should be noted that the majority of bimodal users received significant benefit in speech perception, but some portion of the subjects received no significant benefit (Beijen,Mylanus, Leeuw,&Snik, 2008; Gstoettner et al., 2006; James et al., 2006; Kiefer et al., 2005; Kong &Braida, 2011).

Previous EAS studies showed similar amounts of an EAS benefit in both bimodal and hybrid CI users. Kiefer et al. (2005) measured sentence recognition in quiet and noise for hybrid, bimodal, and hybrid plus contralateral HA users. The difference in performance among these combinations was less than a few percentage points. Gantz, Turner, Gfeller, and Lowder (2005) and Gifford et al. (2007) also showed similar patterns of results in

bimodal and hybrid plus contralateral HA users. These findings suggest that an EAS benefit is not based on the mechanism of binaural hearing but the integration of speech information independently processed by CI and HA processors.

Another interesting finding in EAS studies is that there is a larger EAS benefit in noise than in quiet for both hybrid and bimodal users. Gstoettner et al. (2004) reported a significant EAS benefit (30%-50%) for sentence recognition in noise for hybrid users and a few percentage point benefit in quiet. Turner, Gantz, Vidal, Behrens, and Henry (2004) compared the speech reception threshold (SRT), defined as the signal-to-noise ratio (SNR) required for 50% correct performance in sentence recognition, between hybrid and traditional unilateral CI users. A significant EAS advantage (about 9 dB SNR) was observed even though speech scores in quiet were similar between two groups. Kiefer et al. (2005) also reported an EAS benefit of 23% for sentence recognition in noise but only 8% in quiet. Even though the amount of residual hearing varied widely across studies, the EAS benefit in quiet for consonant-nucleus- consonant (CNC)word recognition is only a fewpercentage points, but the improvement in sentence recognition in noise was more than 10 percentage points (Gifford et al., 2007; Mok, Grayden, Dowell, &Lawrence, 2006). Turner, Gantz, and Reiss (2008) also reported that a significant EAS advantage (4.2 dB SNR in simple reaction time [SRT] measures) for sentence perception between hybrid and traditional unilateral CI users was observed even though consonant recognition performance in quiet was equivalent. Dorman et al. (2008) also demonstrated that the EAS benefit in sentence recognition was 10 percentage points higher in noise than in quiet for 15 bimodal users.

When the benefit of EAS in speech recognition is addressed, the audiometric threshold of the acoustic ear should be considered as a covariate. The range of pure-tone sensitivity that is known to provide a reliable bimodal benefit has been proposed. However, this is not an absolute requirement for a bimodal benefit because of poor correlation between EAS benefit and pure-tone sensitivity for the acoustic side. Ching, Incerti, and Hill (2004) found no significant correlations between hearing thresholds at .25, .5, and 1 kHz for the acoustic ear and bimodal performance and the difference between CI + HA and CI-alone performance. Gifford et al. (2007) also reported no significant relationship between bimodal benefit and the slope of hearing thresholds for frequencies of .25 kHz and 1 kHz or .5 kHz and 1 kHz. In addition, no significant correlation was reported between a bimodal advantage for any CNC measure at 10 dB SNR from 13 school-age children and aided thresholds at .25 and .5 kHz or 1 and 2 kHz (Mok, Galvin, Dowell, &McKay, 2010). These results suggest that better sensitivity to low-frequency pure tones does not necessarily lead to a greater bimodal advantage in speech perception.

In recent studies of EAS, the focus has been on finding the source of theEAS benefit. Some studies were conducted with real EAS patients (e.g., Kong et al., 2005; Mok et al., 2010; Turner et al., 2004), and other studies were acoustic simulations of CI processing with normal hearing subjects (Brown &Bacon, 2009a; Chang, Bai, &Zeng, 2006; Kong &Carlyon, 2007; Turner et al., 2004). The effect of the fundamental frequency, F0, on speech perception has been primarily evaluated as one of the possible sources of an EAS benefit. Turner et al. (2004) reported that there is a significant EAS benefit in word recognition in a simulation study for a talker background masker but not for a white noise masker; this result was confirmed with three hybrid users (Turner et al., 2004). This result suggests that voice pitch perception, which aids in separating voices in a background of other talkers, contributes to anEAS advantage. Similarly for sentence recognition in noise, the bimodal benefit is largest when the difference in F0 between the target and talker masker was largest (Kong et al., 2005). Two other studies (Chang et al., 2006; Qin &Oxenham, 2006) also showed significant improvement in sentence recognition when low-pass filtered speech containing F0 was presented to the acoustic ear. Using acoustic simulations of CI processing, Brown and Bacon (2009a) measured the EAS benefit with a tone modulated both in frequency with the dynamic F0 changes and in amplitude with the envelope of the 500 Hz low-pass filtered speech. A significant EAS benefit was observed (ranging from 25% to 57%) with a tone carrying F0 and envelope cues. The EAS benefit was even greater when both cues were combined compared

with either cue alone. This benefit was unaffected by the presence of a tone carrying these cues from a background talker. For both real hybrid and bimodal users, nearly identical patterns of results were observed with the same stimuli carrying F0 and envelope cues (Brown &Bacon, 2009b). These results strongly suggest the importance of F0 and amplitude-envelope cues in target speech to be sources of an EAS benefit.

The EAS benefit was evaluated in terms of consonant feature perception with children at +10 dB SNR (four-talker babble noise) and in quiet (Ching, Psarros, Hill, Dillon, &Incerti, 2001). It was reported that manner information was a primary contributor to the EAS benefit in quiet. Two other studies measured speech information transmitted using CNC word recognition for adults (Mok et al., 2006) and school-age children (Mok et al., 2010). The results showed that an EAS benefit in quiet arises from improved transmission of the low-frequency components in speech such as nasals, semivowels, diphthongs, and first formant (F1). In contrast, an EAS benefit in noise (+10 dB SNR in fourtalker babble noise) arises from improved perception of both low- and high-frequency speech components. Recently, Kong and Braida (2011) investigated CI users' ability to integrate consonant and vowel acoustic cues across frequencies in quiet. They reported that no sizable bimodal benefits were measured for all consonant features but that significant bimodal benefits were facilitated by better transmission of three vowel features (height in F1, backness in F2, and tense) only for those who demonstrated a significant bimodal benefit.

Previous research shows the existence of an EAS synergistic effect on speech understanding both in noise and quiet. However, the well-defined acoustic cues such as place and manner of articulation for consonants and F1 and F2 for vowels have not been evaluated with adult bimodal users as a function of SNR as a source of a possible EAS benefit. The relation between the aided PTA and the utilization of such acoustic cues in EAS mode for speech perception is also not clear. To ascertain the source of an EAS benefit, it is important to characterize exactly what speech information is affected by EAS. It is also essential to quantify how much information and whether the use of such information is determined by the aided pure-tone average (PTA). The purpose of the present study was to characterize the source of an EAS benefit in consonant and vowel recognition in terms of acoustic features in patients with a conventional CI in one ear in conjunction with an HA in the other ear. Specifically, the issues were which acoustic features for consonant and vowel recognition contributed to EAS benefit, whether such EAS benefits are related to the aided PTAof the acoustic side, whether such an EAS benefit was a function of SNR, and whether sentence performance scores could be predicted from phoneme performance scores.

Method

Subjects

Ten bimodal users (all postlingually deafened except Subject 2 [S2]) participated in the study. Subjects were native speakers of American English and were between the ages of 25 and 77 years old. Subjects were recruited with no particular consideration of age at implantation, duration of profound deafness, period of bimodal experience, etiology, CI/HA type and configuration, and processor strategy. Subject demographics are shown in Table 1. A subject's unaided and aided audiometric thresholds along with mean threshold (thicker dotted line) in the nonimplanted ear are given in Figure 1 along with the range of hearing threshold for the candidacy criteria in bimodal fitting suggested by MED-EL (dashed dot line). The top panels of Figure 1 show audiometric thresholds for each of five listeners (average age of 69) with PTA ≥55 dB hearing level (HL), and the bottom panels show hearing thresholds for the other five listeners (average age of 45) with PTA <55 dB HL over frequencies of 0.25, 0.5, 0.75, and 1 kHz. The cutoffof 55 dB HL for grouping was chosen because it is the upper cutofffor themoderatehearingloss range (41-55 dB HL). However, this standard audiological definition was not strictly applied to avoid having the S4 with a PTA of 55 dB in the good group and the S7 with a PTA of 56 dB in the poor group. All subjects provided informed consent, and all procedures were approved by the local Institutional Review Board.

Stimuli and Testing

Consonant recognition was measured in quiet and in noise at +5 dB and +10 dB SNR. Medial consonants included /b/, /d/, /g/, /p/, /t/, /k/, /m/, /n/, /f/, /s/, /S/, /v/, /ð/, /z /, /?/, and /?/, presented in an /a/-consonant-/a/ context produced by five male and five female talkers (Shannon, Jensvold, Padilla, Robert, &Wang, 1999). Consonant recognition was measured using a 16-alternative forcedchoice (16AFC) paradigm. During testing, a stimulus was randomly selected (without replacement) from the stimulus set. The subject responded by pressing on one of the 16 response buttons labeled in a /a/-consonant-/a/ context. Each consonant syllable was presented 20 times (10 talkers ×2 repetitions) for each noise condition. No training or trial-by-trial feedback was provided during testing.

Vowel recognition was measured in quiet and in noise at +5 dB and +10 dB SNR. Medial vowels included 10 monophthongs (/i/, /I/, / /, /æ /, /u/, /?/, /A/, /Ã/, //, /?/) and two diphthongs (/??/, /eI/), presented in an /h/-vowel-/d / context (heed, hid, head, had, who'd, hood, hod, hud, hawed, heard, hoed, hayed) produced by five male and five female talkers (Hillenbrand, Getty, Clark, &Wheeler, 1995). Vowel recognition was measured using a 12AFC paradigm. During testing, a stimulus was randomly selected (without replacement) from the stimulus set. The subject responded by pressing on one of the 12 response buttons labeled in an /h/-vowel-/d/ context. Each vowel syllable was presented 20 times (10 talkers ×2 repetitions) at each SNR. No training or trial-by-trial feedback was provided during testing.

Sentence recognition was measured in quiet and in noise at 0 dB, +5 dB, and +10 dB SNR using hearing-innoise test (HINT) sentences (Nilsson, Soli, &Sullivan, 1994). The HINT sentences consist of 26 lists of 10 sentences each produced by a male talker and are of easy difficulty. During testing, a sentence list was selected (without replacement), and a sentence was randomly selected from within the list (without replacement) and presented to the subject who then repeated the sentence as accurately as possible. Because there was a total of 12 conditions for the HINT test (3 listening modes ×4 SNRs) and each condition was tested with three sentence lists (i.e., a total of 36 lists are required), HINT lists that were presented at 0 dB SNR were repeated to reduce the effect of familiarization. The experimenter calculated the percentage of words correctly identified in the sentences. Sentence recognition for each set (10 sentences) was measured three times (for a total of 30 different sentences) for each noise condition. No training or trial-by-trial feedback was provided during testing.

Consonant, vowel, and sentence recognition was measured under three listening conditions: CI alone, HA alone, and CI + HA. For testing in noise, speechweighed steady noise (1000-Hz low-pass cutofffrequency, -12 dB/oct) was used. TheSNR was calculated in terms of the long-term root-mean-square of the speech signal and noise. Speech and noise were mixed at the target SNR. The combined speech and noise signal was delivered via an audio interface (Edirol UA 25) and amplifier (Crown D75A) to a single loudspeaker (Tannoy Reveal). Subjects were seated in a double-walled sound-treated booth (Industrial Acoustics Company) directly facing the loudspeaker (0° azimuth) one meter away. Subjects were tested using their clinical speech processors and settings. The output level of the amplifier was set at either 65dBor 70 dB sound pressure level (SPL) for each listening condition (CI alone, HA alone, and CI + HA) according to the Cox Loudness Rating scale (Cox, 1995) in response to 10 sentences in quiet. The output levels for each listening condition are listed for each subject in Table 1.

The subject's CI was turned offin the HA-alone condition, and his or her HAwas turned offand the nonimplanted ear was plugged with an ear plug for the CI-alone condition. These three listening conditions were evaluated in random order for each subject. Throughout this article, bimodal or EAS benefit refers to the difference between performance with CI + HA and performance with the better ear (CI alone). For the present study, all listeners showed higher performance with CI alone than with HA alone.

Data Analysis for Speech Information Transmission

Information transmission analyses were performed (G. A. Miller &Nicely, 1955). For consonant perception, three acoustic categories (nine speech cues) were analyzed: voicing (voiced and unvoiced), manner of articulation

(stop, nasal, fricative, and affricate), and place of articulation (front, middle, and back). For vowel perception, three acoustic categories (eight speech cues) were also analyzed: height of the first formant, F1 (high,middle, and low); place of the second formant, F2 (front, central, and back); and duration of sound (short and long). These speech information groups were chosen so that the frequencies important for their perception covered the range of frequencies in speech.

Vowel height refers to the vertical position of the tongue relative to either the roof of the mouth or the aperture of the jaw and is defined as the relative frequency of the F1. The F1 value is inversely related to the vowel height. Vowel backness is named for the position of the tongue during the articulation of a vowel relative to the back of the mouth and is defined as back or front according to the relative frequency of the F2. The F2 value is inversely correlated to vowel backness. Classification of these acoustic features is given in Table 2.

Results

Individual Speech Recognition Performance

Figure 2 shows individual performance scores along with mean scores (rightmost column) for the poor group on consonant (top row), vowel (middle row), and sentence (bottom row) recognition with CI + HA, CI alone, andHA alone. To make direct comparisons and be consistent with the presentation of consonant and vowel recognition scores, sentence recognition scores were plotted over three common SNRs used for all test materials. Note that the bimodal benefit for consonant recognition was fewer than 5 percentage points for all subjects across SNRs except S1 at +5 dB SNR (11.4% benefit). Similarly for vowel recognition, fewer than 5 percentage points of the bimodal benefit was observed for the majority of the cases except S5 (7% at two lower SNRs; 13% in quiet) and S10 at +5 dB SNR (8% benefit). The bimodal advantage for sentence was also fewer than 5 percentage points except S1 at +10 dB SNR (8% benefit), S5 at +5 dB SNR (16% benefit), and S7 at +10 dB SNR (19% benefit). There was a noticeable ceiling effect in sentence recognition in quiet for all subjects. As expected, there was significant performance variability among listeners. S4 and S10 are relatively high performers across test materials and SNRs, whereas S1 is a low performer for consonant and S7 is a low performer for vowel and sentence. Variability is also substantial for each listening condition. For example, for consonant recognition with CI alone, the difference between the lowest (S1 at +5 dB SNR) and the highest (S10 at +5 dB SNR) performance is approximately 45%.

Individual and mean (rightmost column) data for the good group are shown in Figure 3 for consonant (top row), vowel (middle row), and sentence (bottom row) recognition with CI + HA, CI alone, andHAalone. Note that the bimodal benefit for consonant recognition was larger than 5 percentage points for all subjects across SNRs except S3 and S9 at +10 dB SNR and in quiet. The largest benefit was observed for S6 and S8. For vowel recognition, more than 10 percentage points of the bimodal benefit was observed in four out of five subjects across SNRs. The bimodal benefit for sentence recognition was larger than 10 percentage points for all subjects except S9. Similar to the poor group, there was a clear ceiling effect in sentence recognition in quiet for all subjects. The variability for the good group is also noticeable mainly due to two poor performers (S2 and S8). For example, for consonant recognition with CI alone, the score of S2 at +5 dB SNR was only 10%, but that of the best performer (S3)was 57%.

Speech Recognition Comparisons Between Two Groups

Group mean recognition scores with standard error are presented in Figure 2 (rightmost column) for the poor-aided PTA group and in Figure 3 (rightmost column) for the good-aidedPTAgroup as a function of SNR. In general, bimodal benefit was more evident for listeners with good-aided PTA than for listeners with poor-aided PTA. We performed two-way repeated measures analyses of variance (ANOVAs) with SNR and listening condition as factors. For the poor-aided group, there was a significant effect of listening mode on consonant, $F(2, 16) = 67.3$, $p < .001$; vowel, $F(2, 16) = 17.5$, $p < .001$; and sentence recognition,$F(2, 16) = 88.3$, $p < .001$. The main effect of SNR was also significant for consonant, $F(2, 16) = 46.5$, $p < .001$; vowel, $F(2, 16) = 23$, $p < .001$; and sentence recognition, $F(2, 16) = 18.5$, $p < .001$. For the good-aided group, the main effect of listening mode

was significant for consonant, $F(2, 16) = 10$, $p < .005$; vowel, $F(2, 16) = 29.7$, $p < .001$; and sentence recognition, $F(2, 16) = 27.5$, $p < .001$. There was also a significant main effect of SNR for consonant, $F(2, 16) = 54.7$, $p < .001$; vowel, $F(2, 16) = 21.4$, $p < .001$; and sentence recognition, $F(2, 16) = 25.9$, $p < .001$. However, post hoc pairwise comparisons (Sidak method) showed that the bimodal advantage is significant for the good-aided group for vowel and sentence perception at the lower two SNRs, indicated by asterisks in Figure 3 ($p < .05$). For the poor-aided group, any pairwise comparisons were not significant for each test material ($p > .05$).

Bimodal Benefit and Aided PTA

To evaluate the influence of aided thresholds on speech perception, comparisons were made between the two groups of listeners' mean performance scores (see Figure 2, rightmost column for the poor group and Figure 3, right panel for the good group) for the HA-alone condition. We performed two-way ANOVAs with aided PTAgroup andSNRas factors. The difference in group mean was significant for vowel, $F(1, 24) = 5.44$, $p < .05$, and sentence recognition, $F(1, 24) = 13.5$, $p < .001$, but not for consonant recognition, $F(1, 24) = 3.9$, $p > .05$. The main effect of SNR was also significant for consonant, $F(2, 24) = 4.93$, $p < .05$, and sentence recognition, $F(2, 24) = 6$, $p < .05$, but not for vowel recognition, $F(2, 24) = 1.98$, $p > .05$. Post hoc pairwise comparisons (Sidak method) showed significant differences in performance for the HA-alone condition between the two groups at higher SNRs for vowel and sentence recognition and in quiet for consonant recognition, denoted by plus symbols in Figure 3 (right panel) ($p < .05$).

To evaluate the effect of aided PTA on the bimodal benefit, we performed a correlation analysis between the magnitude of the bimodal benefit and aided PTA at audiometric frequencies of 0.25, 0.5, 0.75, and 1 kHz for each speech test; these results are shown in Figure 4. The correlation analysis showed no significant association in the bimodal benefit for consonant recognition averaged across SNR, $r(10) = -.47$, $p > .05$, or at a specific SNR, $r(10) = -.25$, $p > .05$, at +5 dB; $r(10) = -.485$, $p > .05$, at +10 dB; $r(10) = -.43$, $p > .05$, in quiet. A correlation between aided PTA and the bimodal benefit for sentence recognition was not significant over SNRs ($r = -.43$, $p > .05$) or at each SNR, $r(10) = -.25$, $p > .05$, at +5 dB; $r(10) = -.54$, $p > .05$, at +10 dB; $r(10) = -.06$, $p > .05$, in quiet. Correlation between aided PTA and the bimodal benefit in vowel perception (see Figure 4, middle panel) was significant at the lower two SNRs, $r(10) = -.68$, $p < .05$, at +5 dB; $r(10) = -.64$, $p < .05$, at +10 dB, and the correlation was also significant between aided PTA and the bimodal benefit averaged across SNR, $r(10) = -.65$, $p < .05$. Further correlation measures revealed that such a bimodal benefit for vowel perception is significantly attributed to the aided threshold at 0.5 kHz, $r(10) = -.72$, $p < .05$.

Bimodal Benefit and Acoustic Features for Consonant

Figure 5 presents percent information transmitted for consonant recognition in terms of voicing, manner, and place of articulation for each group. Note that the good group transmitted most of the consonant features better with CI + HA than with CI alone, particularly for affricate and back in place. The difference in information transmitted between CI + HA and CI alone ranged from 15% to 18% for affricate and from 10% to 18% for back in place. For other features, the transmission was enhanced approximately from 5% to 10% across SNRs in the good group. The range of the feature transmission in HA alone was 20%-40% depending on SNR.

In contrast, for the poor group, the difference in percent information transmitted between CI + HA and CI alone was fewer than 5 percentage points for all features analyzed across SNRs. The amount of information transmitted by HA alone in the poor group was consistently lower than that by HA alone in the good group. On the contrary, the amount of information transmitted by either CI + HA or CI alone in the poor group was consistently higher than that in the good group. For both groups, there was no ceiling or floor effect.

Figure 6 presents a summary of the bimodal benefit in percentage points for consonant recognition in terms of voicing, manner, and place of articulation for each group. In general, the bimodal benefit is always greater for the listeners with better aided thresholds than the listeners with poorer aided thresholds for most of the features. For the poor group, a two-way repeated measure ANOVA showed that none of the acoustic features is significantly different between CI + HA and CI alone; for the good group, the bimodal benefit was significantly

attributed to low- (voicing) and high-frequency (stop and affricate) components in speech along with all three places, which requires a wide range of spectral information. Statistical details are given in Table 3. The effect of SNRfor both groups is significant for each of the acoustic features, but the pattern of the bimodal benefit for each feature is highly SNR specific. For example, the magnitude of the bimodal benefit enhanced by a voicing cue is similar at +10 dB SNR and in quiet, but the bimodal benefit aided by an affricate manner of articulation is greater in quiet and noise at +5 dBSNRthan that at +10 dB SNR.

To evaluate the effect of aided PTA on bimodal benefit, comparisons of the bimodal benefit between the two groups were made. The only significant benefit for the listeners with better aided hearing thresholds stemmed fromacoustic cues: voiced, affricate, and back in place (see Table 3, last column). Other cues did not show a significant difference between groups. The asterisk in Figure 6 indicates a significant difference in bimodal benefit between the two groups by post hoc pairwise comparisons.

Bimodal Benefit and Acoustic Features for Vowel

Figure 7 shows the results of vowel feature analyses in terms of F1 and F2 along with duration for each group. For the good group, overall, relatively good enhancement was made for all features analyzed in CI +HAcompared with CI alone. The improvement ranged from 8% to 20% depending on SNRs. Particularly central information in F2 was consistently transmitted 15% higher in CI + HA than in CI alone.

For the poor group, the transmission of the features improved fewer than 5 percentage points for all features across SNRs except for low in F1 at +5 dB SNR. The amount of information transmitted by CI + HAwas similar between the two groups, but in CI alone, the poor group transmitted higher percentage of vowel information than the good group. The amount of information transmitted in HA alone was consistently lower in the poor group than in the good group. There were no ceiling or floor effects for either group.

A summary of the bimodal advantage for vowel recognition was presented in Figure 8 in terms of F1 (first row) and F2 (second row) along with duration (last row) between the two groups. For the poor group, the transmission of speech information was not significantly improved with the bimodal mode compared with CI alone; for the good group, all of the information features known to be embedded both in low- and high-spectral components in speech, except for short-duration cues, were significantly received with the bimodal setting as opposed t°CI alone.Statistical details are giveninTable 4. In terms of an SNR effect, the bimodal benefit for the poor group was not significantly enhanced with increasing SNR for low in F1 height, central and back in F2 place, and short-duration cues. For the good group, the bimodal benefit was significantly dependent on SNR for all features.

Comparisons in bimodal benefit between the two groups showed that four acoustic features (middle height in F1, central and back place in F2, and long duration) significantly contributed to the bimodal benefit for the good group compared with the poor group (see Table 4 for statistics). Post hoc pairwise comparisons showed a significant difference in the bimodal benefit between the two groups for all features, at least at one of the SNRs, as indicated by the asterisks in Figure 8.

Relationship Between Contextual and Noncontextual Recognition

Figure 9 shows scatterplots in terms of bimodal benefit for consonant (leftpanel), vowel (middle panel), and phoneme (right panel) recognition relative to the bimodal benefit for sentence recognition. We computed the bimodal benefits for phonemes with [the square root of]CCIHAV ×CIHA [the square root of]CCI ×VCI (Boothroyd &Nittrouer, 1988), where CCIHA and VCIHA are the percent scores for consonant and vowel recognition in the bimodal mode, and CCI and VCI are the percent scores for consonant and vowel recognition in the CI-alone mode. Each open circle in Figure 9 represents an individual data point at each SNR. Linear regression analysis demonstrates that the magnitude of the bimodal benefit in sentence perception was significantly associated with the bimodal benefit for consonants ($r^2 = .56$, $p < .05$) and for phonemes ($r^2 = .60$, $p < .05$). However, the linear relationship between vowel and sentence recognition was not significant ($r^2 = .47$, $p > .05$).

Discussion

In this study, we characterized acoustic cues in speech recognition enhanced in a bimodal configuration. The bimodal benefit was greater for listeners with better aided PTA than that for the listeners with poorer aided PTA across SNR for all speech materials. The poorer aided PTA group received little bimodal benefits, probably due to HA input being at or below threshold in some or all frequencies. For consonant and vowel recognition, the specific acoustic features were responsible for the bimodal benefit regardless of low- and high-frequency components in speech. Such an enhancement in the acoustic features is significantly influenced by aided hearing threshold as well. The bimodal benefit for sentence recognition is significantly correlated with that for consonant recognition, and the correlation becomes stronger when relating the magnitude of the advantages between sentence and phoneme scores.

Mean Bimodal Benefit inQuiet and inNoise

In the present study, the magnitude of mean bimodal advantage for consonant perception for the good group in quiet and in noise is 6 and 8 percentage points, respectively (see Figure 3, rightmost column), which is comparable with the results of Dorman et al. (2008), who reported a benefit of 8% in quiet, and of Mok et al. (2010, 2006), who reported a similar range at 10 dB SNR. For vowel perception (see Figure 3, rightmost column), the amount of the bimodal benefit in the present study,7%in quiet, is lower than the 18% benefit reported in Dorman et al. (2008). The benefit for sentence recognition in the present study is 13% in noise and only 2%in quiet (see Figure 3, rightmost column). This is somewhat lower than values reported in the literature. Multiple studies reported a bimodal benefit of approximately 20% in noise at +5 dB SNR and/or +10 dB SNR (Chang et al., 2006; Dorman et al., 2008; Gifford et al., 2007; James et al., 2006; Kong et al., 2005). Dorman et al. (2008) reported that the bimodal benefit was 25% both at +5 dB and at +10 dB SNR.

The reasons for the somewhat lower values of the bimodal benefit in the present study might be due to the different use of noise maskers and/or audiometric configurations for the acoustic side. Because the hearing thresholds are widely varied across these studies, a different type of noise masker might be a source for such a difference. Speech-weighted noise was used in the present study, but single or multiple talker babble noise was used in the other studies mentioned above. Brown and Bacon (2009a) demonstrated using a hybrid configuration simulation that the performance score for a speech-shaped masker was approximately 10 percentage points lower than that for the talker babble masker.

For the poor group in the present study, both the bimodal and CI-alone performance curves are almost identical across SNR and test materials (see Figure 2, rightmost column). This suggests that no new speech information was added via HA or that speech cues provided by HA are not used by the auditory system. Little bimodal benefit for the poor group may be the result of impaired frequency difference limens in the region of elevated thresholds (Peters &Moore, 1992; Tyler, Wood, &Fernandes, 1983) and inaudible F2 or higher formants. Thus, no difference in the performance between CI + HA and CI alone suggests that HA does not add any further information regarding pitch and the first two formants when aided threshold is high enough (i.e., ≥55 dB HL at frequencies ≤1 kHz) or when the HA does not substantially improve thresholds.

Performance Comparisons for CI-Alone Condition

One interesting observation from the group data (see Figures 2 and 3) is that the CI-alone condition was consistently lower (about 20 percentage points) in the good group (see Figure 3, rightmost column) compared with the poor group (see Figure 2, rightmost column). Such a discrepancy might be simply attributed to performance variability across CI users. As shown in Figures 2 and 3, two top performers (S4 and S10) in the poor group outperformed (more than 15% higher) any of the subjects in the good group for consonant recognition. In addition, performances of the two poor performers (S2 and S8) in the good group were far below that of group mean scores. Consequently, two good performers in the poor group and two poor performers in the good group are major contributors to higher scores for the CI-alone condition in the poor group than in the good group. As mentioned in the Method section, subject S2 in the good group is only one with prelingual deafness. It is interesting to see how scores from S2 influenced the difference in CI alone between two groups.

We performed a two-way ANOVA for CI alone between two groups with and without data from S2, with group and SNR as factors.With data of S2, significant difference between two groups was observed for consonant, $F(1, 24) = 10.3$, $p < .004$, and for sentence, $F(1, 24) = 4.2$, $p < .05$, but not for vowel, $F(1, 24) = 14$, $p > .05$. In contrast, without the S2 data, the difference in CI alone between two groups was not significant for consonant, $F(1, 21) = 5.8$, $p > .05$; vowel, $F(1, 21) = 1.3$, $p > .05$; and sentence, $F(1, 21) = 0.95$, $p > .05$.

Correlation Between Aided PTA and Bimodal Benefit

The present study shows that bimodal benefit is greater for the listeners with better aided thresholds than for the listeners with poorer aided thresholds (see Figures 2 and 3). This result is consistent with the result of Moket al. (2006) but not of Moket al. (2010).Moket al. (2006) showed a significant correlation between bimodal benefit and aided threshold at 1 kHz for consonants and vowels and at 2 kHz for consonants. In contrast, Mok et al. (2010) showed a nonsignificant association between the bimodal benefit and low-frequency-aided thresholds (.25 and .5 kHz) for all CNC measures. This inconsistency might be due to the difference in hearing thresholds for subjects across studies. In addition, the study of Mok et al. (2006) was conducted in quiet with adults, and speech perception in Mok et al. (2010) was measured at +10 dB SNR with children. Ching et al. (2004) reported no significant correlation between aided threshold and bimodal benefit in sentence recognition. Chang et al. (2006) also reported in an acoustic simulation study nonsignificant correlations between aided PTA over frequencies of .5, 1, and 2 kHz and bimodal benefit even though the bimodal benefit decreased with an increase in hearing loss.

The correlation analysis in the present study (see Figure 4) shows a significant relationship between aided threshold and bimodal benefit in vowel recognition. This can be explained by Miller's vowel perceptual space theory: Pitch plays a significant role in vowel perception by interacting with the frequency of F1 to form one dimension of a three-dimensional perceptual space (J. Miller, 1989). So, we would expect that vowel recognition would be significantly improved when HA is added. F1 could provide a frequency-appropriate reference against which higher frequency information provided by the CI would be integrated. F1 could aid in perception of high- and mid-height vowels and formant transition (Strange, Jenkins, &Johnson, 1983).

The results of the present and Mok et al. (2006) studies suggest that individual variability in bimodal outcome could be partially accounted for by the differences in aided thresholds, and a better aided threshold does not necessarily result in a greater bimodal advantage for all test materials.

Information Transmission Analyses for Consonant Recognition

The results of the consonant feature analysis for the good group in the present study (see Figure 5) are consistentwith those of Kong and Braida (2011),whomeasured similar quantities with 11 bimodal users in quiet. In both studies, the HA provided the most information about nasal cues. Voicing information was similarly transmitted in CI alone between the two studies (55% in the good group of the present study and 56% in Kong &Braida, 2011). CI + HA provided a similar amount of benefit in voicing information transmitted in the two studies (58% in Kong &Braida, 2011, and 62% in the good group). For other consonant features (stop and fricative), similar percent information transmitted was observed in the two studies as well.

The result of the present study in consonant recognition also shows that speech information required for the perception of higher frequency components (i.e., affricate and back in place) was also enhanced when HA was added, particularly for the listeners with goodaided thresholds (see Figures 5 and 6). This result is consistent with those of Mok et al. (2010). This study characterized the bimodal benefits measured with 13 school-age children at +10 dBSNR(four-talker babble masker). Data were analyzed in nine phonetic categories: fricatives, sibilants, plosives, F2, bursts, semivowels, nasals, diphthongs, and F1. Mok et al. (2010) reported a relatively large bimodal advantage (5%-10%) for some of the other phoneme groups, including those that require perception of higher frequency information (e.g., fricatives, sibilants, F2). The results of the present study and Mok et al. (2010) suggest that the perception for cues embedded in higher frequencies is more important when listening in noise.

In contrast, our results are inconsistent with those of Mok et al. (2006) and of Kong and Carlyon (2007). Mok et al. (2006) tested 14 adult bimodal users for CNC word recognition in quiet and analyzed the data in terms of the same features analyzed in Mok et al. (2010). They showed that only lower frequency features such as semivowel, nasal, diphthongs, and F1 contributed to the bimodal benefit. Kong and Carlyon (2007) also reported a similar result for sentence recognition in noise, which they demonstrated by removing the phonetic cues in the HA side (preserving the F0, voicing, and temporal envelope cues) and not observing a bimodal benefit at +10 dB and +15 dB SNR. This indicates that low-frequency phonetic cues are important for bimodal benefit, particularly at higher SNRs.

There could be a few factors contributing to the unexpected results between Mok et al. (2006) and Mok et al. (2010). First, the bimodal adults in Mok et al. were tested in quiet, whereas bimodal children in Mok et al. were tested at +10 dB SNR. Combined with the result of the present study, high-frequency speech cues were used more when listening in noise. Second, the bimodal children had been using the bimodal input since a young age, whereas the bimodal adults only received CI in adulthood. Hence, it is possible that the children have learned to better integrate the signals from the two ears and that the mismatch between the ears at higher frequencies is less significant for children.

Relationship Between Voiced/Unvoiced Cue and F0

We have demonstrated in the present study that in the good group, both voiced and unvoiced information for consonant perception (see Figure 6) was significantly enhanced in the CI + HA condition in noise compared with CI alone. Previous studies in which speech information transmission in consonant perception was examined also revealed significant transmission of voicing information with bimodal setting compared with CI alone (Brown&Bacon, 2009a, 2009b). One reasonable thought related to voicing is that if F0 is one of the primary cues used by low-frequency acoustic hearing to improve electric hearing, then improvement for voiceless consonants should be minimal. The present results, however, indicate that this is not the case. These results suggest that voicing cues are not necessarily enhanced proportionally with F0 information. The results of the two previous studies support this idea as well (Brown &Bacon, 2009a, 2009b).

Brown and Bacon (2009a) showed 9 percentage points of bimodal benefit migrated by voicing cue alone under speech-shaped noise for sentence recognition using acoustic simulation. The same trend was observed with two bimodal CI users under a male and babble backgrounds (Brown &Bacon, 2009b). These results are in good agreement with the present result for voicing cue. Brown and Bacon (2009b) also showed that an additional 17 percentage points of the benefit were observed beyond voicing alone when a tone was modulated in frequency with the target talker's F0. These results suggest that the F0 cue provides more cues, not accordingly with voicing cue. However, the sample size is too small to interpret this result in a meaningful way. In addition, these two subjects in a study of Brown and Bacon (2009b) were tested in unaided condition under a male and babble background, and more importantly, no background was presented in the acoustic ear. It might be interesting to test whether F0 and temporal envelope cues are robust under a speech-shaped noise environment in the HA side.

F0 has also been shown to be important for the manner of articulation (Faulkner &Rosen, 1999). Ching et al. (2001) showed that significantly more manner information was received when listeners used bimodal hearing devices compared with using CI alone in quiet. In the present study, two manner cues, stop and affricate, were significantly better perceived only for the listeners with better aided threshold, whereas information in nasal and fricative cues was not significantly enhanced for either group.

Information Transmission Analyses for Vowel Recognition

The results of the vowel feature perception in the present study (see Figure 7) are consistent with those of Kong and Braida (2011), who evaluated bimodal benefit in terms of vowel features in quiet. CI alone provided similar information transmission in height of F1 (61% in the good group of the present study and 53% in Kong &Braida, 2011) and place of F2 (69% in Kong &Braida, 2011, and 63% in the good group) between the two studies. In CI

+ HA, height in F1 and place in F2 were similarly transmitted between the two studies. However, the HA provided height information of F1 about 46% for the good group, 27% in Kong and Braida (2011), and place in F2 about 43% for the good group, and only 4% in Kong and Braida (2011) (mainly due to the greater variability ranging from 1% to 44%). Kong and Braida (2011) also reported that only those who demonstrated a substantial bimodal benefit showed significant improvement in all vowel features tested, which is consistent with our findings.

All vowel features, except short duration, analyzed in the present study were significantly better perceived in a bimodal setting for the listeners with better aided PTA, whereas none of the features, including short duration, were significantly perceived for the listeners with poorer aided PTA (see Figure 8). For the good group, the aided threshold at the range of F2 frequencies between 1 and 3 kHz is from 40 dB HL to 80 dB HL. This finer spectral information provided by HA can aid perception of some vowels required for higher spectral components.

It is obvious that bimodal listening enhances acoustic cues in low height of F1 and high place of F2 spectral elements in vowels. Dellattre, Liberman, Cooper, and Gerstman (1952) showed a significant drop in vowel perception when any portion of the spectrum of F1 and F2 was removed. Dorman, Spahr, Loizou, Dana, and Schmidt (2005) showed that if all of the F2 information that fell under 2.1 kHz was eliminated, then there was no decrease in vowel perception with larger gaps above 2.1 kHz in frequency between CI in one ear and HA in the opposite ear using simulations. Previous studies focused on F0 as a primary source for bimodal benefit (Brown &Bacon, 2009a, 2009b; Kong et al., 2005; Kong &Carlyon, 2007; Qin &Oxenham, 2006), but the result of the present study shows that F1 and F2 are also important components for vowel perception in a bimodal setting.

Contextual and Noncontextual Comparisons in Bimodal Benefit

It is frequently stated, and maybe widely believed, that the perception of continuous speech is a complex process because the integration of perceptual cues is governed by high-level language such as lexical, morphological, syntactic, and semantic constraints (Chomsky &Halle, 1968). Figure 9 shows that the advantage of a bimodal arrangement for sentence perception is significantly related with nonsense consonant and phoneme perception. This result is consistent with one of the findings that Rabinowitz, Eddington, Delhorne, and Cuneo (1992) reported: Consonant recognition is highly correlated with sentence recognition. It is known that consonants can be more affected by removing low-frequency information, ≤0.8 kHz (Lippmann, 1996; Warren, Bashford, &Lenz, 2004). Therefore, it is possible that sentence recognition was affected as well by better spectral resolution in the low-frequency range for the better PTA group.

Cues in continuous speech can be classified into two types: acoustic and context cues. The context cues refer to redundancy, recoverable once given sufficient acoustic cues, along with the associated context information (Boothroyd &Nittrouer, 1988; Bronkhorst, Bosman, &Smoorenburg, 1993).Onthe basis of significant correlations in speech perception between contextual and noncontextual speech materials (see Figure 9), it can be stated that sentence understanding in noise can be accounted for by the acoustic cues extracted from random syllables (nonsense consonants and vowels). This result suggests the existence of such a connection between acoustic and context cues in a bimodal setting.

The Bimodal Benefit and Audibility/HA Fitting

All of the subjects in the present study have been fitted by the same protocols and same audiologists to make sure that the HA provides audible sounds. However, aided thresholds for the poor group were much poorer even though unaided thresholds were similar between groups (see Figure 1). It indicates a possibility that spectral gain prescribed to HAs might not be optimal for the poor group. This possibility is supported by the results of Ching et al. (2001). They showed that 15 of the 16 children required 6 dB more gain than prescribed (National Acoustic Laboratories-Revised, Profound) to balance the loudness of the implanted ear for a speech signal presented at 65 dB SPL. It suggests that adjustment of HA gain to match loudness in the implanted ear for the poor group can facilitate integration of speech information across ears, leading to bimodal advantage.

To test this idea, a subject (S4) in the poor group was retested with a fixed 80 dB SPL presentation level for sentence recognition in noise and quiet for the HA-alone, CI-alone, and CI + HA condition. This level provides the subject about 30-dB sensational level at frequencies between .25 and 1 kHz and about 15-dB sensational level at frequencies between 1 and 3 kHz (see aided audiogram for S4 in Figure 1). Figure 10 shows performance with a presentation level of 80 dB SPL (right panel) along with original data (leftpanel) measured at 70 dB SPL for HA alone and at 65 dB SPL for the CI-alone and CI + HA condition. No bimodal benefit was observed with the 80 dB SPL presentation level even though performance improved for HA alone at +10 dB SNR and in quiet, but not at +5 dB SNR. In contrast, the performance dramatically dropped approximately 30% due to clipping for both the CI-alone and CI + HA condition in noise, leading to bimodal interference at 80 dB SPL presentation level. This result suggests that optimal bimodal loudness balancing is needed to facilitate bimodal benefit; it is likely that some degree of bimodal benefit could be observed when 80 dB and 65 dB SPL levels for the HA side and CI side are presented.

Age Effects on Bimodal Benefit

In the good group (average age is 45), the three youngest subjects (S2: 44 years old, S6: 25 years old, and S9: 47 years old) showed the greatest EAS benefit, particularly for vowel and/or sentence recognition. S6 showed the benefit regardless of test materials, but S9 demonstrated the benefit only for vowel recognition. Two elderly subjects (S3 and S8) in the good group also showed a benefit for vowel and sentence tests. In the poor group, the youngest subject (S7: 56 years old) did not show a benefit. This inconsistent age effect is also reported in the study of Kong and Braida (2011). The four youngest bimodal subjects (<27 years old) out of 12 did not show a benefit in consonant and vowel recognition. However, substantial benefit was observed from two other subjects (64 and 57 years old) in vowel recognition.Therefore, it is unlikely that the bimodal benefit is accounted for by age only.

Limitations

In the present study, as subjects were tested in their clinical setting for each device, an optimization of an HA to complement a CI was not administrated in a systematic way. The frequency response of the HAshould be optimized for speech understanding for each subject so that HAs have enough compression capability in dynamic range. Another issue is that loudness balancing should be performed and that sounds must be maintained at a comfortable listening level for input levels when the HA is used with a CI. As described in the Method section of this article, loudness was roughly balanced by adjusting the output level of the amplifier as the most comfortable level for each listening condition (CI alone, HA alone, and CI + HA). If serious consideration for loudness balance is necessary, then a loudness-balancing procedure should be used to adjust the gain of the HA for different input levels so that loudness of speech is similar between ears. It is possible that bimodal benefit for the poor group might be enhanced with adjustment of gain for better loudness balance with CI.

Another limitation related to an HA device is unknown interactions between the bimodal benefits and HA setting parameters. Each device and model have some unique features such as different number of bands, channels, degree of compression, signal processing algorithm, and noise reduction technology along with different listening programs. All of these factors may affect their aided PTA thresholds and HA performance. Even though it is difficult to expect how these features influence the outcome in bimodal settings, it is possible that one or more aspects of HA fitting will affect their bimodal benefits. Particularly considering a situation in which a noise reduction algorithm is not used for the CI side, but is included in the HA side, the CI-alone performance could drop significantly, which could explain greater bimodal benefit in noise, but lack of the benefit in the quiet condition.

The lack of training prior to testing might be problematic, particularly for the CI-alone and HA-alone conditions-given that performance for unilateral listening conditions was commonly measured by having bimodal CI users switch offone of their devices. This arrangement generates immediate disadvantage as this configuration does

not characterize subjects' everyday listening experience and, in essence, changes how a given subject's auditory system processes cues for speech recognition. Consequently, CI-alone performance may be higher for listeners with poorer acoustic hearing threshold due to insufficient amplification in theHA side.

Conclusions

In the present study, the source of the bimodal advantage in speech perception was characterized in terms of acoustic features for consonant, vowel, and sentence recognition in noise and in quiet. Speech recognition was measured in three conditions: CI alone, HA alone, and CI + HA conditions; speech and noise were presented at 0° azimuth. Results showed that bimodal advantage for vowel and sentence recognition depends on aided thresholds at audiometric frequency below 1 kHz, especially in noise. The poorer aided PTA group received little bimodal benefits probably due to HA input being at or below threshold in some or all frequencies. The results of information transmission analyses revealed that bimodal listening helps enhance the acoustic features both in low- and high-frequency components. For consonant recognition, low-frequency voicing and high-frequency stop and affricate cues along with place cues are the main sources of the bimodal benefit for the good-aided group, whereas none of these features contribute to the bimodal benefit for the poor-aided group. Three acoustic cues-voiced, affricate, and back in place-are primary components used to differentiate the magnitude of the bimodal benefit in consonant recognition between the two aided PTA groups. For vowel recognition, low-frequency cues (F1), high-frequency cues (F2), along with long-duration cues are significant contributors to the bimodal benefit for the good-aided group, whereas none of these features are significant sources for the poor-aided group. The magnitude of the bimodal advantage between the two aided PTA groups is differentiated by middle height in F1, central and back place in F2, and long-duration cues. The enhancement of sentence recognition in the bimodal setting is significantly associated with the bimodal benefit for consonant recognition, and the correlation is stronger when relating the magnitude of the advantage between sentence and phoneme recognition (scores combined for consonants and vowels). The results suggest that aided hearing threshold should be carefully considered in order to maximize the advantage of the bimodal use in speech perception. The results also suggest that speech information processed by CI in conjunction with HA not only aided in the perception of low-frequency components in speech but also helped process some of the high-frequency components.

Abstract: To determine whether children with mild-to-moderately severe sensorineural hearing loss (CHL) present with disturbances in working memory and whether these disturbances relate to the size of their receptive vocabularies. Children 6 to 9 years of age participated. Aspects of working memory were tapped by articulation rate, forward and backward digit span in the auditory and visual modalities, Corsi span, parent surveys, and a sequential encoding task. Articulation rate, digit spans, and Corsi spans were also administered in low-level broadband noise. CHL and children with normal hearing (CNH) demonstrated auditory advantage in forward serial recall. CHL demonstrated slower articulation rates than CNH, but similar memory spans. CHL with poor executive function presented with poorer performance on the Corsi span task. The presence of background noise had no effect on performance in either group. CHL presented with significantly smaller receptive vocabularies than their CNH peers. Across groups, receptive vocabulary size was positively correlated with digit span in quiet, Corsi span in noise, and articulation rate. In the presence of mild-to-moderately severe hearing loss, children demonstrated resilient working memory systems. For all children, working memory and vocabulary were related; that is, children with poorer working memory had smaller vocabulary sizes.

Purpose: To determine whether children with mild-to-moderately severe sensorineural hearing loss (CHL) present with disturbances in working memory and whether these disturbances relate to the size of their receptive vocabularies.

Method: Children 6 to 9 years of age participated. Aspects of working memory were tapped by articulation rate, forward and backward digit span in the auditory and visual modalities, Corsi span, parent surveys, and a sequential encoding task. Articulation rate, digit spans, and Corsi spans were also administered in low-level broadband noise.

Results: CHL and children with normal hearing (CNH) demonstrated auditory advantage in forward serial recall. CHL demonstrated slower articulation rates than CNH, but similar memory spans. CHL with poor executive function presented with poorer performance on the Corsi span task. The presence of background noise had no effect on performance in either group. CHL presented with significantly smaller receptive vocabularies than their CNH peers. Across groups, receptive vocabulary size was positively correlated with digit span in quiet, Corsi span in noise, and articulation rate.

Conclusions: In the presence of mild-to-moderately severe hearing loss, children demonstrated resilient working memory systems. For all children, working memory and vocabulary were related; that is, children with poorer working memory had smaller vocabulary sizes.

Key Words: children, working memory, hearing aids, vocabulary

The auditory experience of children with sensorineural hearing loss (CHL) is not equivalent to that of children with normal hearing (CNH). Hearing loss reduces the quality and quantity of auditory input. Audiologic interventions may increase a child's access to the acoustic signal but cannot fully compensate for the underlying hearing loss. The inherent differences in auditory experiences may have a cascading effect on the linguistic and cognitive development of a child with hearing loss.

One potential effect is deficient vocabulary development. CHL have smaller vocabularies than their CNH peers (Blamey et al., 2001; Davis, Elfenbein, Schum, &Bentler, 1986; Gilbertson &Kamhi, 1995; Moeller, 2000). In addition to the direct reduction of access to speech input, there may also be an indirect effect of hearing impairment on vocabulary development.Working memory is essential to the word-learning process (Gathercole &Baddeley, 1989; Gupta&MacWhinney, 1997; Gupta& Tisdale, 2009) and is known to be reduced in children with profound hearing loss who wear cochlear implants (Burkholder &Pisoni, 2003). Working memory skills correlate to reading skills in CHL (Daneman, Nemeth, Stainton, &Huelsmann, 1995). Hansson, Forsberg, Löfqvist, Mäki-Torkko, and Sahlén (2004) found a significant correlation between complex working memory and word learning in 9- to 13-year-old CHL. Working memory was assessed in a reading span test, and novel word learning was assessed in a mutual exclusion test. Children with better working memory performance learned more novel words. Working memory was also correlated to receptive vocabulary size. The CHL performed the same as their CNH age-mates on working memory and word learning but exhibited significantly smaller receptive vocabulary sizes (Hansson et al., 2004). It is possible that the smaller receptive vocabulary sizes are a residual effect of delayed development of working memory. We do not know whether the working memory systems of younger children with milder hearing losses are also deficient or whether such deficits, if present, contribute to the vocabulary problems that characterize these learners. Our aim was to address these critical gaps in the literature. We asked whether mild-to-moderately severe hearing loss affects development of the working memory system and whether working memory predicts vocabulary size similarly in children with and without mild-to-moderately severe hearing loss.

Working Memory

Working memory has been described as a fractionated system, including a central executive mechanism and two subsystems devoted to storage and processing: the visuospatial sketchpad and the phonological loop (see Baddeley, 2000). The phonological loop is of particular importance as it is engaged in linguistic processing. The phonological loop consists of a phonological store and a subvocal rehearsal mechanism. The subvocal rehearsal mechanism refreshes the items in the store to maintain their integrity in working memory. The executive mechanism of working memory is often described as one of managing the processing of incoming information and prevention of the decay of item traces already in storage (maintenance). It is not fully understood how the executive system allocates resources to processing and maintenance functions. In the Baddeley (2000) model, poorer working memory performance may reflect inefficient processing, which leaves fewer resources to the maintenance of the memory traces (Towse, Hitch, &Hutton, 1998) and demands of the processing task which consumes cognitive resources that would otherwise be used for preserving the memory traces (Barrouillet, Bernardin, &Camos, 2004).

Various behavioral tasks allow indirect measurement of the working memory system. One of these is a measure of articulation rate on a sentence-repetition task. The strong correlation between articulation rate and verbal working memory suggests that the mechanism controlling articulation speed is related to the subvocal rehearsal mechanism in the phonological loop (Baddeley, Thomson, &Buchanan, 1975). Serial recall tasks are also informative. These may include forward recall tests (e.g., digit and letter span), which measure storage capacity, and backward recall and reading span tests, which measure storage capacity plus processing.

Serial recall tests have revealed relationships between working memory and language. For example, better serial recall predicts better production of syntactically complex speech in preschool children (Adams &Gathercole, 1995) and higher levels of literacy (Gathercole &Baddeley, 1993; Gathercole, Tiffany, Briscoe,

Thorn,& the ALSPAC team, 2005;Mann, Liberman, &Shankweiler, 1980; Shankweiler, Liberman, Mark, Fowler, &Fischer, 1979). A suboptimal working memory system will result in poorer integrity of memory traces involved in word learning and can thus impede development of vocabulary and literacy (see Gathercole &Baddeley, 1993).

It is concerning that children with cochlear implants exhibit working memory deficits relative to CNH on measures of serial recall (Burkholder &Pisoni, 2003). Deficits in working memory may thus be a consequence of hearing loss. As it is with CNH, digit span is highly correlated to language and reading in children with cochlear implants (Pisoni &Geers, 2000). In children with cochlear implants, better serial recall on digit span predicts better speech recognition (Pisoni &Cleary, 2003). Sensitivity of the digit span measure is strong enough that, after having controlled for such demographic variables as chronological age, communication mode (oral vs. total communication), duration of deafness, duration of use of cochlear implant, and age of onset of deafness, digit span is still significantly correlated to closed- and open-set word recognition tests.

There may also be strategic aspects of working memory where differences in children's use of this system might be evident. For example, children who are deaf use a different strategy to encode series of visual items into memory (O'Connor &Hermelin, 1973). When presented with three digits sequentially in varying positions on an array, CNH recited back the digits in chronological order, whereas children who are deaf repeated them back based on their physical position. This suggests that CNH develop a temporal (phonological loop) preference, whereas children who are deaf develop a visual (visuospatial sketchpad) preference for encoding items into memory. The encoding patterns of children with milder degrees of hearing loss is as yet unknown.

Typical adults have a robust benefit of auditory input in serial recall tasks; this is called the auditory advantage. Research participants were able to repeat back more items from a list they heard than from a list they read (Penney, 1975). Penney (1989) proposed a model of verbal memory that incorporates modality effects. In this model, information presented via audition is processed in a stream separate from information presented via vision. Both visual and auditory information end up in a phonological code; however, this information is also retained in either an acoustic code or a visual code, depending on the modality of input. The acoustic modality ismore adeptwith sequentially presented items,whereas the visual modality is more adept at simultaneously presented items. This yields the auditory advantage for forward recall that characterizes adults with normal hearing. Manipulation of items in memory, such as in a backward recall task, obliterates the auditory advantage. A review of the literature did not yield evidence confirming or denying the auditory advantage in children; however, our experimental design permitted an investigation of this phenomenon.

Working Memory in Noise

The working memory system is supported by a finite amount of cognitive resources; stress on the system may reduce performance levels. One potential stressor is noise. Noise may be a distracter in the environment. Cognitive resources would then be harnessed to inhibit reaction to the noise, allowing the listener to maintain concentration on the signal and support auditory processing (Pichora-Fuller, Schneider, &Daneman, 1995). Noise may also mask acoustic cues used to identify speech sounds. Cognitive resources would then be harnessed for decoding the message from fewer available cues (Rönnberg, Rudner, Foo, &Lunner, 2008). In noisy environments, listeners expend more resources on attending to and decoding the signal, which leaves them fewer resources to support maintenance processes. In a compromised system, such as that of a CHL, cognitive support for working memory tasks may be further impaired by this reallocation. The decrease in speech perception caused by the presence of noise has been well documented in normal-hearing populations; however, effects of background noise on the working memory of children fit with amplification have not been determined.

In adults, the complexity of background noise affects performance on serial recall tasks for phonological material (i.e., irrelevant speech effect; Murphy, Craik, Li, &Schneider, 2000). The presence of nonspeech noise does not affect word recall presumably because no phonological features are present in the noise (Salamé&

Baddeley, 1987). As the phonological similarity of the background speech babble to the target items increases, recall performance decreases (Salamé&Baddeley, 1982). Speech babble has thus been considered a more taxing distracter for the central executive, drawing resources away from the storage domains of memory to support the processing and decoding of the auditory signal. However, recall of items with low predictability may be less impervious to interference from nonspeech noise. Adults have poorer recall of nonsense syllables in the presence of nonspeech noise relative to quiet (Surprenant, 1999).

Few studies have investigated the influence of background noise on working memory in people with hearing loss. Pichora-Fuller et al. (1995) assessed working memory in older and younger participants by asking them to remember the final word of each sentence in a list while listening in varying levels of background noise. This study did not target adults with hearing loss specifically (all participants had normal hearing between 250 and 3000 Hz); however, older participants with hearing loss at frequencies above 3000 Hz were included. For the older participants, performance was significantly worse when listening in 0 dB signal-to-noise ratio (SNR) than when listening in +5 dB SNR. This difference was interpreted as evidence that resources that had been used for recall in the +5 dB SNR condition were now being reallocated for processing in the 0 dB SNR condition, to the detriment of memory performance in older adults.

In summary, the addition of random noise to a working memory task does not affect adults' performance unless the test items are of low predictability. The addition of speech babble reduces adults' performance regardless of the predictability of the test items. It is not known whether and to what extent background noise affects children's performance on tests of working memory. CHL may experience greater declines in the presence of background noise than CNH due to their already atypical auditory perception.

Current Study

In this study, we asked whether children with mildto- moderate hearing loss, like their peers who are deaf, present with deficits in working memory and whether their working memory abilities correlate with the size of their receptive vocabularies. Our predictions, listed below, pertain to differences between CHL and CNH in vocabulary, working memory capacity, and strategies for utilizing working memory.

1. In accord with previous findings, we predicted that CHL would present with smaller vocabularies than their CNH peers.
2. Given the working memory deficits that characterize children with cochlear implants, we hypothesized that milder forms of hearing loss would also impede the development of working memory. Table 1 depicts the relationship between the assessment tools, input modality, and the related components from Baddeley's (2000) working memory model. We did not predict group differences in executive function, but we did classify children in both CHL and CNH groups as having high or low executive function because of the known influence of executive ability on working memory processing.We predicted that theCHL in our sample would demonstrate phonological loop deficits and would show deficits in performance on the forward and backward digit span task and on the McGarr sentence task compared to their CNH peers. We did not predict group differences in Corsi block performance; this should not be influenced by phonological loop integrity.
3. We hypothesized that hearing loss would result in different encoding preferences. We tested this hypothesis by comparing the recall strategies of the CHL and CNH groups on the sequential encoding task of O'Connor and Hermelin (1973).
4. We hypothesized that hearing loss would impede development of the auditory advantage for serial recall. We tested this hypothesis by comparing performance on the auditory and visual modalities of the forward and backward digit span tasks.
5. We hypothesized that stressing the working memory system would impede working memory processes in real time, particularly in maintenance of item traces in storage. We tested this hypothesis by comparing performance on serial recall in noise and in quiet. We predicted that the performance of CHL would be particularly vulnerable to the presence of noise, as cognitive loading in these children may already be

disproportionately allocated to the decoding of the auditory signal in quiet.

6. Because of the hypothesized relationship between working memory and vocabulary development, we predicted that performance on the working memory measures-in particular, on the forward and backward digit span-would correlate with receptive vocabulary size.

Methods Participants

To be included in the study, CHL met the following criteria: (a) their primary means of communication was oral, (b) they were enrolled in an oral classroom, and (c) they were fit with nonfrequency compression hearing aids in both ears. Children with or without hearing loss were required to pass a vision screening (20/40 criterion) and have middle-ear admittance greater than 0.2 mmho in either ear. The University of Iowa Institutional Review Board approved the study protocol, and all participants received compensation upon completion of the study.

Participants were 18 children with mild-to-severe sensorineural hearing loss fit with bilateral hearing aids (CHL) and 28 CNH enrolled in the study. One CHL was excluded for using frequency compression amplification and one due to behavioral difficulty. One CNH was excluded for identification of unilateral hearing loss and three to better match the age range of the CHL group. The mean ages of the resulting groups- 16 CHL (6 boys, 10 girls, mean age 92;3 [year;months]) and 24 CNH (13 boys, 11 girls, mean age 94;9)-did not differ, $t(38) = 0.728$, $p = .47$. These same children participated in tasks designed to measure their access to the speech signal, results of which are reported in Stiles, Bentler, and McGregor (in press).

Table 2 shows mean and standard deviation of audiometric thresholds for the CNH and CHL groups. Groups did not differ in nonverbal aptitude as measured with the Block Design and Picture Completion subtests of the Wechsler Intelligence Scale for Children-Third Edition (WISC-III; Wechsler, 1991), $t(38) = 0.108$, $p = .91$; $t(38) = 0.713$, $p = .48$, respectively.

When testing members of the CHL group, hearing aids were kept at the user settings. Real-ear measures were performed to ensure that participants had access to the average speech spectrum. All participants had functioning amplification. The hearing aid fitting of most participants was consistent with desired sensation level (DSL) targets, although some participants' fittings did not reach DSL targets. During the experiment, the examiner ensured that all children reported understanding of test instructions. The examiner made no changes to the hearing aid programming but did notify the caregiver of any concerns regarding the hearing aid fitting (e.g., output not to DSL targets) upon completion of the experiment.

Tasks

Tasks used in the experiment included the Peabody Picture Vocabulary Test-III (PPVT-III; Dunn &Dunn, 1997), which is often administered by speech-language pathologists, and working memory tasks that may typically be administered by a psychologist. All tasks were administered by the principal investigator or a trained graduate assistant. The PPVT-III was administered early in the first visit along with the WISC-III subtests and lexical tests reported in Stiles, Bentler, and McGregor (in press). Children returned within two weeks for the working memory portion of the experiment. The order of working memory tasks were sequential encoding, forward digit span, backward digit span, and Corsi span. This test order was maintained across subjects because it was the most efficient order for setting up and breaking down the various conditions. Participants took a short break between backward digit span and Corsi span tasks to allow the examiner time to set up the equipment. Total test time was approximately 2.5 hr, although this could vary depending on how soon participants reached ceiling set in the PPVT-III and memory span tasks.

Peabody Picture Vocabulary Test. Researchers assessed receptive vocabulary using the PPVT-III and following the procedures described in the test manual. Children sat opposite the examiner facing a stimulus book consisting of a series of four-alternative picture plates. The examiner gave the target word, and the participant selected the response they believed represented the target.

Six measures tapped different aspects of memory span: (a) The Learning, Executive, and Attentional Functioning (LEAF) scale (Kronenberger, 2006) provided an index of executive function based upon parent

assessment, (b) articulation rate reflected the subvocal rehearsalmechanismof the phonological loop, (c) forward digit span reflected short-term verbal memory supported by long-term lexical knowledge (digit stimuli are familiar to and rehearsed by children in serial recall tasks; Gathercole &Adams, 1994), (d) backward digit span added a "working" component by measuring the participants' ability to recall and manipulate verbal strings, (e) the Corsi span provided a visuospatial analog to the forward digit span, and (f) sequential encoding indicated whether children engage the phonological loop for a visually presented sequence of items.

LEAF. Parents described their child's executive function with the Planning and Sequential Processing subscale of the LEAF scale. Examples of items from this subscale include "Doesn't plan ahead" and "Loses track of step-by-step directions."

McGarr Sentence Repetition. The McGarr sevensyllable sentences (McGarr, 1983) were used to obtain articulation rate information. The test contains two lists of 6 seven-syllable sentences. For this task, each child wore a lavalier microphone connected to a digital audio recorder. Each child was instructed to repeat the sentence after they had finished hearing it. Participants simultaneously saw and heard each seven-syllable sentence as it was presented. Six sentences were presented in quiet and six in the presence of background noise (see below). The lists presented in quiet and noise were counterbalanced across children. We used Adobe Audition Version 1.0 software to measure sentence duration after conversion to .wav format. The mean sentence duration was calculated separately for the six sentences in quiet and the six sentences in noise for each child.

Forward Digit Span.We evaluated working memory capacity using the forward digit span task. In this task, each child repeated back a string of digits in the same order in which they were presented. Digits were presented at 1-s intervals.Within any given string, no digits were repeated. Additionally, the number "7" was excluded from presentation so that all digits were monosyllabic. Children repeated two strings at each length. Testing began with strings of three digits. If either of the 3-digit strings were repeated accurately, then the number of digits increased to 4 digits per string. This incremental growth in string length continued until both strings of a single length were repeated back incorrectly or until the child reached a ceiling of 8 digits per string, at which point the examiner terminated the procedure.

The forward digit span was administered in four conditions: auditory-quiet, auditory-noise, visual-quiet, and visual-noise. The presentation order of these conditions was counterbalanced across children within each group. In the auditory conditions, participants heard digits spoken at a rate of one per s at a level of 65 dB SPL from a monitor-mounted speaker at 0° azimuth at a distance of .5 m. In the visual conditions, digits 3 in. in height were presented sequentially at a rate of one per s, in the center of the monitor, each one replacing its predecessor. Unlike the sequential encoding task, serial order was only defined temporally; there was no variation in spatial information. In the noise conditions, background noise was presented from two speakers at ±110° azimuth at a distance of 1 m.

Scoring was adapted from the procedure used in the WISC-III. We calculated forward digit span scores with the following formula: 2 + 0.5 ×(number of correct responses). Because the forward digit span begins at three digits, the constant (2) represents the baseline span. Two strings are presented at each length; each item is worth one half point. If a participant gets no items correct, his score would be 2. If he gets both items correct at a level, his span score increases by one, as does the number of digits he will hear in the next stimulus presentation. Thus, the score approximates the maximum span length the participant can accurately recall.

Backward Digit Span. Working memory capacity and processing were evaluated using the backward digit span task. In this task, each child repeated back a string of digits in the reverse order of presentation. For example, if the stimulus were "2 - 5 - 9," then the target response would be "9 - 5 - 2." Test administration was the same as for forward digit span with one exception: Testing began with strings of two digits instead of three. As it was in the forward digit span task, the backward digit span was administered in four conditions: auditoryquiet, auditory-noise, visual-quiet, and visual-noise. Equipment setup for backward digit span was the same as for forward digit

span. Backward digit span scores were calculated as 1 + 0.5 ×(number of correct responses).

Corsi Span. The Corsi block array consists of nine cubes mounted on a board (Corsi, 1972). In this task, the examiner taps a sequence of blocks, one block per s. The child then taps the blocks in the same order in which they were tapped by the examiner. Testing begins with two trials of one block each and continues in twotrial intervals to a maximum eight-block sequence. For any given test taker, if both trials at a given level are repeated back incorrectly, then the examiner terminates the procedure.

The examiner administered the Corsi span in two conditions: quiet and noise. Corsi span scores were calculated as 0.5 ×(number of correct responses).

Sequential Encoding. We assessed phonological encoding using a test adapted from O'Connor and Hermelin (1973). The premise of this test is that children with a preference for phonological encoding will consistently repeat back visually presented items in relation to their temporal order (i.e., first to last), and children with a preference for visual coding will consistently repeat back the items in relation to their spatial location (i.e., leftto right). Three digits were presented sequentially, one per s, in each of 10 trials. Each digit appeared in the left, center, or right third of the monitor. Within a trial, no digit appeared in the same location more than once (i.e., all three locations were used in each trial), and the order of locations could be any, excluding left-middle-right. Each child was instructed to repeat back the numbers they saw at the end of each trial.

During the articulation rate, digit span, and sequential encoding tasks, children sat approximately 0.5 m in front of a monitor. A speaker was mounted below the monitor for presentation of auditory stimuli. All auditory stimuli were calibrated to 65 dBA SPL at 0.5 meters from the speaker, where the participant would be seated. The sequential encoding task was administered in quiet only. The other tasks were administered in a quiet condition and a noise condition.

Experimental Background Noise

The forward digit span, backward digit span, Corsi span, and McGarr sentence repetition tasks included the presence of background noise in at least one condition. As mentioned above, noise can be a masker, a distracter, or both. For the purposes of this study, we were interested in a noise that would not be loud enough to mask the stimuli of interest but may represent a common distraction: air conditioning noise. Tang and Yeung (2006) described the noise spectrum of an unoccupied classroom (windows closed, air conditioning on), which we replicated for this study (see Figure 1). It was not certain how CHL would perform in the presence of random noise, although performance of adults with normal hearing typically does not vary with random noise. If adults with normal hearing demonstrate poorer memory in the presence of speech babble, then it is almost certain that CHL will as well.We were more curious to learn whether CHL would suffer in the presence of a background noise typically considered innocuous.

Using Adobe Audition Version 1.0, we filtered a broadband signal to match the spectrum presented in Tang and Yeung (2006). We verified the spectrum in the soundfield of a sound-treated audiometric booth in the conditions of the study, with noise presented from the same speakers used to present noise and the microphone of a Grason-Stadler sound-levelmeter placed in the center of the booth, approximately 1 m from the speaker. A 20-min sample was generated within Adobe Audition Version 1.0 and saved to a portable digital audio player.

Results

Statistical analyses were performed using SPSS software, Version 17 (Statistical Package for the Social Sciences, 2008). Age and socioeconomic status were included as covariates in the analyses of variance because of their known relation to memory and vocabulary development (Gathercole, Pickering, Ambridge, &Wearing, 2004; Hart &Risley, 1995).

Vocabulary

Receptive vocabulary level was quantified with the PPVT-III standard scores. These results are reported in Stiles, Bentler, and McGregor (in press). Mean scores were 93.94 (SD = 13.95) for CHL and 110.00 (SD = 13.38) for CNH. As predicted, CHL had smaller receptive vocabulary than CNH, $t(38) = 3.66$, $p = .001$, $d = 1.18$.

Executive Function

Performance between CNH and CHL was not significantly different on the Planning and Sequential Processing subscale of the LEAF scale, $t(38) = 0.64$, $p = .53$. Children were classified as high or low executive function via a median split of scores for all participants. High executive function ratings were given to 7 CHL and 13 CNH, and low executive function ratings were given to 9 CHL and 11 CNH. This executive function variable was included in analyses of working memory performance.

Articulation Rate

Analysis of covariance (ANCOVA) was performed with average sentence duration as the dependent variable and group, list, and presence of background noise as independent variables. Age was found to be a significant covariate, $F(1, 79) = 13.76$, $p < .001$, with younger children demonstrating longer durations than older children. There were no significant main effects for list or presence of background noise. There was a significant main effect for group, $F(1, 79) = 13.90$, $p < .001$. Mean sentence duration was 2.26 s (SD = 0.37) for CHL and 2.01 s (SD = 0.23) for CNH ($d = -.87$). Figure 2 shows the average sentence duration in quiet and noise for each participant as a function of age. Although the group difference within our sample was only 0.25 s, the articulation rates of CHL are equivalent to rates of CNH more than a year younger.

Table 3 summarizes the scores of CHL and CNH on the digit span and Corsi span tests. Figure 3 displays the scores for CHL and CNH on forward and backward digit span by modality and by noise condition. For all digit span analyses, age and maternal education were covariates, and group, modality, presence of background noise, and executive function classification were independent variables.

Forward Digit Span

Table 4 summarizes the ANCOVA performed with forward digit span points as the dependent variable. The effect of maternal education was significant, $F(1, 159) = 8.82$, $p < .01$; higher maternal education level was associated with longer digit spans. There was no significant contribution of age. There was a significant main effect for modality, $F(1, 159) = 13.64$, $p < .001$. Digit spans were longer when stimuli were presented via the auditory modality (see Figure 4). There were no significant main effects for group, $F(1, 159) = 2.87$, $p = .09$, presence of background noise, or executive function classification.

Correlations between articulation rate and forward digit span were calculated for each group. There were no significant correlations for CNH ($r = -.11$, $p = .60$) or for CHL ($r = .04$, $p = .89$).

Backward Digit Span

We performed an ANCOVA with backward digit span points as the dependent variable. The effect of age and maternal education was not significant. There was no significant main effect for group, $F(1, 151) = 2.80$, $p = .10$, nor any other main effects nor any interactions.

Corsi Span

Table 5 summarizes the ANCOVA performed with Corsi span points as the dependent variable. Significant main effects were found for group, $F(1, 79) = 4.49$, $p < .05$, and executive function, $F(1, 79) = 4.28$, $p < .05$. CHL demonstrated shorter Corsi spans than CNH. Children with better executive function had longer Corsi spans than children with poorer executive function. No significant main effect was found for presence of background noise. A significant interaction between group and executive function was present, $F(1, 79) = 12.46$, $p < .01$. CHL with low executive function had shorter spans than CHL with higher executive function. CNH had the same Corsi span regardless of executive function (see Figure 4).

Phonological Encoding

Repetitions on the sequential encoding task that matched the temporal order of presentation were coded as phonologically biased. The number of phonologically biased responses, out of a possible 10, was calculated for each child. Mean score for the CHL group was 7.88 (SD = 2.60). Mean score for the CNH group was 8.38 (SD = 2.95). There was no significant difference in phonologically biased responses between groups (Mann- Whitney

U = 141.5, p = .14, d = .18). Both groups demonstrated high phonological bias suggesting active engagement of the phonological loop over the visuospatial sketchpad in recall of visually presented digits.

Relationship Between Memory and Vocabulary

We examined the relationship between receptive vocabulary and the working memory tasks using a correlational analysis. Including data from all participants, PPVT-III standard score was found to significantly correlate to digit span in the quiet condition (Pearson's r = .33, p <.05), to Corsi span in the noise condition (Pearson's r = .33, p <.05), and to McGarr sentence duration (Pearson's r = -.52, p = .001). However, when correlational analyses were performed separately for CNH and CHL groups, PPVT-III standard score did not correlate to any working memory task nor to sentence duration (see Figure 5). This may have been due to a lack of variance in either group, as CHL tended to cluster at the lower end and CNH at the higher end of the spectrum of PPVT-III scores.

Summary

CHL had significantly smaller receptive vocabularies than CNH. The articulation rate of CHL was significantly slower than that of CNH. Digit spans did not differ between groups. Corsi span was significantly weaker in CHL and children with low attention ratings. CHL and CNH did not differ significantly in their performance on the sequential encoding task; both groups demonstrated a phonological (nonvisuospatial) coding preference. Both groups demonstrated auditory advantage, that is, better performance for items presented via the auditory modality than the visual modality. The presence of low-level random background noise during the working memory span tasks did not cause a significant decline in performance for either CHL or CNH. Children with larger vocabularies had faster articulation rates and performed better on the digit span in the auditory-quiet condition and on the Corsi span in the noise condition.

Discussion

In this study, we examined whether 6- to 9-year-old children with mild-to-moderate degrees of hearing loss have deficient working memory and, if so, whether this deficit is associated with their smaller vocabulary sizes. With the exception of articulation rate, an indicator of subvocal rehearsal, we found no significant effects of hearing loss on the development of working memory overall. These results were similar to the results of Hansson and colleagues' (2004) study of 9- to 13-yearold children. There also was no disruption of the working memory system in a noisy environment. Despite this, CHL did show smaller vocabularies than CNH. In the following paragraphs, we discuss the resilience of these children as well as some areas of continued concern.

We hypothesized that CHL would demonstrate deficits in the phonological loop of working memory in favor of visual encoding strategies. Instead we found evidence of the phonological bias and auditory advantage in CHL. Unlike children who are deaf (O'Connor &Hermelin, 1973), CHL were attuned to the temporal sequence of visually presented items, suggesting active engagement of the phonological loop to encode these items into memory. Also, CHL, like CNH, could recite back longer strings of digits when presented in the auditory modality than presented in the visual modality. This finding suggests that the mechanism supporting the auditory advantage in working memory is present and active in children with mild-to-moderately severe hearing loss communicating orally.

The selection criterion of children educated in oral classrooms may also contribute to these results. Indeed, it was found that children with cochlear implants in oralonly programs demonstrated longer memory spans than children with cochlear implants in total communication programs (Pisoni &Cleary, 2003). Canadian children in oral education programs demonstrated similar reading spans as CNH (Daneman et al., 1995). It is possible that the oral learning environment is conducive to working memory development. Another possibility is that CHL with working memory impairments may have been previously identified with learning difficulties and placed in a total communication learning environment.

On the other hand, CHL articulated more slowly than CNH. Sentence durations of CHL in this sample were significantly longer than those of CNH. In CHL, articulation rate may vary depending on auditory feedback

experience, which allows children to self-monitor and improve their speech articulation, motor control, and intelligibility (Burkholder &Pisoni, 2003). Slower articulation rates are associated with a less efficient subvocal articulatory mechanism in working memory.With slower rehearsal, fewer items can be refreshed in the phonological loop in a given time (Cowan &Kail, 1996). Some researchers have suggested that the slower articulation rate and smaller digit spans of cochlear implant users reflect a compromised verbal rehearsal process that limits their processing capacity (Pisoni &Cleary, 2003). In our study, the difference between sentence durations of CHL and CNH did not translate to a significant group difference in digit span in a sample of this size. This may be related to the very narrow range of sentence durations found in this sample. Children with cochlear implants demonstrated a wide range of sentence durations, some as long as 6 s (Pisoni &Cleary, 2003). CHL in our study were able to articulate faster than the cochlear implant users. Although CHL andCNH differed in their mean sentence durations, the mean difference was less than a half s, and the mean durations for both groups were less than 2.5 s. This higher rate of articulation on the part of CHL may partially explain how they were able to demonstrate similar memory spans as CNH.

Another area of weakness among CHL was their performance on the Corsi span task, used to assess visuospatial short-term memory. The spans of CHL with high executive function were not different from the spans of CNH, regardless of executive function, but CHL with low executive function had significantly shorter spans than CHL with high executive function and CNH. This pattern of results was rather surprising. The Corsi span represented the one working memory test that was both the least phonological and the least auditory. We would have expected the difference in performance to appear in an auditory and phonological test, such as the digit span.

We speculate that this unexpected finding is an effect of fatigue. We administered the memory span tasks in the same order for all participants: forward span, backward span, and Corsi span. Those who found these tasks more difficult, namely CHL with low executive function, may have tired by the time the Corsi span was administered. Our results could be considered an interaction between group, executive function, and time wherein, by the time of the third task, CHL with low executive function could no longer maintain performance. In the future, administration of the tasks in counterbalanced order would enable a test of this hypothesis.

Effects of Noise

We used background noise with the intention to divert executive resources from maintaining working memory to decoding the compromised input signal. This did not occur. This may not be unusual, as previous studies in adults have failed to show a negative effect of background random noise on memory tasks (Salamé &Baddeley, 1987). The current study has extended these findings to children with and without hearing loss. Performance on the digit and Corsi span tasks was the same whether in the presence of noise or in quiet. This may be explained because either (a) the background noise was not disruptive enough to require the reallocation of executive resources in the working memory tasks, or (b) the resources necessary to decode the signal in noise are not related to the resources used in the working memory tasks. Of these two explanations, we favor the former.

In this study, the background noise was essentially low-pass random broadband noise filtered to match the spectrum of a classroomwith an air conditioner running (Tang &Yeung, 2006). This type of noise was selected for its minimal masking effect. Although this noise was audible, its energy was primarily at frequencies below 1000 Hz. Auditory digit span stimuli would have been presented at an approximate +15 dB SNR, which is considered to be a rather good SNR for a classroom(American National Standards Institute, 2002). The background noise was also unmodulated and therefore less disruptive than a modulated noise like speech babble may have been. Other studies have found that speech babble has a greater negative effect than random noise, and that random noise needs to be louder than speech noise to equally degrade working memory in adults (Andrade, 2001; Murphy et al., 2000). Future studies may systematically investigate the effect of different noise types and levels on working memory in children.

With the exception of articulation rate, CHL were not at a disadvantage for working memory compared to CNH.

We had hypothesized that CHL would have poorer performance in the presence of this background noise. Although the children's hearing aids may have included a noise reduction algorithm, it is unlikely that it was activated at the level of background noise present during the working memory tasks (Bentler &Chiou, 2006). It may simply have been that, as in adults, the background noise was not intrusive enough to affect the children's cognitive processes. Ultimately, we cannot conclude that this type of background noise is never detrimental to CHL; stimuli that are more complex or less probable than digits may take more effort to preserve in the presence of low-pass random noise, as is the case with nonsense syllables for adults (Surprenant, 1999). With the stimuli used here, however, CHL were not at any disadvantage relative to CNH. Future studies that include noise more typical of a classroom setting- that is, noise that mimics not only air conditioning but also children moving about and talking-would be valuable.

Typical vocabulary acquisition requires intact peripheral and central domains, such as hearing and working memory (Gathercole &Baddeley, 1989). Although CHL are known to have smaller vocabularies than CNH, there has not been an attempt to determine whether this discrepancy is driven only by hearing loss or whether secondary factors such as working memory may also come into play. Considering that children with profound hearing loss and children with cochlear implants demonstrate working memory deficits, it was cogent to hypothesize that children with milder degrees of hearing loss would as well and that this would impede vocabulary acquisition. In our sample, the CHL group had a significantly smaller vocabulary size than the CNH group. However, there was no evidence to support the hypothesis that this discrepancy is fundamentally related to a working memory deficit.

Conclusion

We hypothesized that CHL would demonstrate poorer working memory compared to CNH. The working memory differences we found were limited to the Corsi span (CHL with lower executive function had reduced visuospatial working memory relative to CHL with higher executive function and CNH) and articulation rate (CHL had slower rates than CNH, but no subsequent phonological working memory deficits were noted). Overall, the performance of CHL defied our expectations, as these children showed resilience in working memory, even when low-level background noise was present.

In addition to performing like their peers with normal hearing on tests of working memory, CHL and CNH were not rated differently on the parent surveys of executive function. CHL were not any more likely to be rated as having difficulties with attention and processing. We do have some evidence that, although the incidence of lower executive function (per parent rating) is not different, the effect of lower executive function may be more detrimental for CHL, as those children with both hearing loss and low executive function showed decreased performance on the final memory task of the series compared to all other children in the study. Further research may help determine whether an evaluation of attention in CHL can be used as a flag for academic risk.

Considering the similar performance of CNH and CHL, it is unlikely that the domains of working memory measured in this study are responsible for the smaller vocabulary levels of CHL.Rather, theymay simply reflect these children's reduced access to the acoustic signal, resulting in an accumulation of missed word-learning opportunities. We report evidence of this from these same participants in Stiles, Bentler, and McGregor (in press).

This research is a first step in examining working memory in CHL. In a controlled environment with stimuli of high predictability, the presence of low-pass random background noise did not reduce working memory performance for either CNH or CHL. Thus, in optimal conditions and conditions where the working memory system was slightly stressed, CHL performed like CNH. These results indicate a resilient working memory system among CHL. Given that CHL continue to demonstrate poorer language outcomes than their normal hearing peers, it is important to determine under what conditions the working memory system may break down and, as a consequence, limit language-learning opportunities for these children. Further research using stimuli with lower predictability or more speechlike background noise will help determine whether CHL continue to

show typical working memory performance under more difficult conditions. Determining the degree to which differences in working memory factor into lexical development of CHL will clarify whether and to what extent interventions focusing on working memory are appropriate for this population.

Acknowledgments

We would like to acknowledge the assistance of Joan Marttila and Laurie Cooley at Iowa Area Education Agency No. 9; Dawn Violetto at Illinois Child's Voice; and David Pisoni, Christopher Turner, Sandie Bass-Ringdahl, and Kristin Perk for their contributions and support of this study.

Abstract: To understand the components of auditory learning in typically developing children by assessing generalization across stimuli, across modalities (i.e., hearing, vision), and to higher level language tasks. Eighty-six 8- to 10-year-old typically developing children were quasi-randomly assigned to 4 groups. Three of the groups received twelve 30-min training sessions on multiple standards using either an auditory frequency discrimination task (AFD group), auditory phonetic discrimination task (PD group), or visual frequency discrimination task (VFD group) over 4 weeks. The 4th group, which was the no-intervention control (NI) group, did not receive any training. Thresholds on all tasks (AFD, PD, and VFD) were assessed immediately before and after training, along with performance on a battery of language assessments. Relative to the other groups, both the AFD group and the PD group, but not the VFD group, showed significant learning on the stimuli upon which they were trained. However, in those instances where learning was observed, it did not generalize to the nontrained stimuli or to the language assessments. Nonspeech (AFD) or speech (PD) discrimination training can lead to auditory learning in typically developing children of this age range. However, this learning does not always generalize across stimuli or tasks, across modalities, or to higher level measures of language ability.

Full text: Headnote

Purpose: To understand the components of auditory learning in typically developing children by assessing generalization across stimuli, across modalities (i.e., hearing, vision), and to higher level language tasks.
Method: Eighty-six 8- to 10-year-old typically developing children were quasi-randomly assigned to 4 groups. Three of the groups received twelve 30-min training sessions on multiple standards using either an auditory frequency discrimination task (AFD group), auditory phonetic discrimination task (PD group), or visual frequency discrimination task (VFD group) over 4 weeks. The 4th group, which was the no-intervention control (NI) group, did not receive any training. Thresholds on all tasks (AFD, PD, and VFD) were assessed immediately before and after training, along with performance on a battery of language assessments.
Results: Relative to the other groups, both the AFD group and the PD group, but not the VFD group, showed significant learning on the stimuli upon which they were trained. However, in those instances where learning was observed, it did not generalize to the nontrained stimuli or to the language assessments.
Conclusions: Nonspeech (AFD) or speech (PD) discrimination training can lead to auditory learning in typically developing children of this age range. However, this learning does not always generalize across stimuli or tasks, across modalities, or to higher level measures of language ability.
Key Words: auditory learning, generalization, children, training

Auditory learning can be defined as an improvement in the ability to detect, discriminate, or categorize a sound or a set of sounds. Typically, this follows and is caused by a period of auditory training, where the listener has to repeatedly judge sounds in some way via a task. Training almost invariably results in improved performance on the stimulus encountered during training, but a question of greater practical and theoretical importance is whether the training improves performance on an untrained stimulus or task, referred to as generalization. Although a growing number of studies are now assessing auditory learning and generalization in adults (for a review, see Wright &Zhang, 2009a, 2009b), there is a relative dearth of studies examining these phenomena in children. However, this area is of particular interest because of the existence of several auditory training programs that are already being used both in research and in a clinical context, particularly in children with communication and/or learning disorders (for a review, see Moore, Halliday, &Amitay, 2009).To assist in interpreting the results of these applications, it is important that we investigate-under more controlled conditions-the factors that underlie auditory learning and, in particular, generalization in typically developing children.

Studies of auditory learning in adults have identified a number of principles. Auditory learning can be observed through the use of a variety of stimuli and across a variety of tasks (e.g., signal detection, frequency discrimination, temporal-interval discrimination, relative timing, amplitude-modulation rate discrimination, interaural level and time differences, intensity discrimination, phonetic discrimination; seeWright &Zhang, 2009a, for a review; Kraus et al., 1995; Tremblay, Kraus, Carrell, &McGee, 1997). It can occur rapidly, over the course of a single session (e.g., Hawkey, Amitay, &Moore, 2004; Ortiz &Wright, 2009), but it can also be prolonged and observed overmultiple sessions (Wright&Zhang, 2009a). It has been observed following passive exposure as well as active stimulus engagement (e.g., Amitay, Irwin, &Moore, 2006;Wright,Sabin, Zhang, Marrone,&Fitzgerald, 2010), and even following training on an impossible discrimination task in which there are no physical differences between the stimuli (Amitay et al., 2006; but see Micheyl, McDermott, &Oxenham, 2009).

Following auditory training, the extent to which generalization occurs-along with the patterns of generalization-allows us to make inferences about the components of learning as well as the neural processes affected by training. Auditory learning in adults has often been shown not to generalize (a) across stimuli when the task is held constant or (b) across tasks when the stimuli are held constant (Ortiz&Wright, 2009; for a review, see Wright &Zhang, 2009a; cf. Hawkey et al., 2004; Lakshminarayanan &Tallal, 2007). These findings have been interpreted as evidence for stimulus and task learning, respectively. There are some reports, however, of generalization of learning across both stimulus and task when all other aspects of training remain the same

(Beard, Levi, &Reich, 1995; Sireteanu &Rettenbach, 2000; cf. Hawkey et al., 2004). These findings suggest some degree of learning the more general aspects of the training procedure (termed procedural learning).

The handful of studies that have been conducted in children have shown that, as in adults, auditory learning can be observed using a variety of stimuli on a variety of tasks, including pure-tone frequency discrimination (Halliday, Taylor, Edmondson-Jones, &Moore, 2008), dichotic pitch perception (Edwards, Giaschi, Low, &Edgell, 2005), temporal-interval discrimination (Huyck &Wright, 2011), glide direction identification (Merzenich et al., 1996), and phonetic identification (Merzenich et al., 1996) and discrimination (Moore, Rosenberg, &Coleman, 2005). Learning in children has also been observed following training with single (Halliday et al., 2008; Huyck &Wright, 2011) as well as multiple (Moore et al., 2005) standards, and following single (Halliday et al., 2008) as well as multiple (Huyck &Wright, 2011; Merzenich et al., 1996; Moore et al., 2005) training sessions.

Qualitative differences in auditory learning have, however, been reported between adults and children. Halliday et al. (2008) found that 6- to 11-year-olds varied both across and within age groups, according to their pattern of learning on a frequency discrimination task. A general developmental trend of more consistent learning was obtained, but even the oldest group had mean thresholds considerably above those of an adult group. Within all age groups, however, some children performed in an adultlike fashion, whereas others showed a fluctuating pattern of learning. Recently, Huyck and Wright (2011) also reported learning on a temporalinterval discrimination task that remained immature into adolescence, beyond 14 years of age. Similarly, Sarro and Sanes (2009) showed a protracted development of auditory learning in immature gerbils. Therefore, these findings agree that auditory learning has a prolonged developmental time course.

Some evidence suggests that nonsensory factors might be particularly important for auditory learning in children. For instance, Halliday et al. (2008) found that learning was predicted not only by chronological age but also by attention and IQ. Stevens, Fanning, Coch, Sanders, and Neville (2008) reported electrophysiological evidence for changes in selective attention in 6- to 8-year-olds following a high-intensity intervention that included auditory training. Temple et al. (2003) found functional changes in brain regions associated with attention and memory in 8- to 12-year-old children with dyslexia following participation in a similar program.

The few studies that have assessed generalization of auditory learning in children have yielded conflicting results. Halliday et al. (2008) found that learning did not generalize either to a different stimulus or to a different presentation paradigm, suggesting that it was confined to the trained stimulus. In contrast, several studies reported broad generalizations of learning to higher level language assessments following auditory training in typically developing children (Moore et al., 2005) as well as in children with language and reading impairments (Habib et al., 1999; Merzenich et al., 1996; Schäffler, Sonntag, Hartnegg,&Fischer, 2004; Strehlow et al., 2006;Tallal et al., 1996; cf. Cohen, Hare,O'Boyle,& McCartney, 2005; Given, Wasserman, Chari, Beattie, &Eden, 2008; McArthur, Ellis, Atkinson,&Coltheart, 2008).

In the present study, we aimed to assess generalization of auditory learning in typically developing children assigned to one of four groups. Three of the groups received 6 hr of training over 4 weeks on either (a) a frequency discrimination task; (b) a phonetic discrimination task that had the same procedure and modality as (a) but a different task and different stimuli; or (c) a visual frequency discrimination task that had the same procedure as (a) but a different modality, task, and different stimuli. A fourth group, which served as the control, received no training. To assess learning, we examined changes in the performance of the three trained groups on their trained stimuli and tasks both during the training phase and immediately before (pre-) and after (post-) training. To assess generalization of learning, we compared the pre- and post-training performance of children on the stimuli and tasks upon which they did not receive training and on a battery of standardized phonological processing and reading fluency tests. We reasoned that if learning on any of the tasks was due to procedural factors, we would expect to see broad generalization of learning to the untrained stimuli and tasks. If, on the other hand, learning was due to each specific stimulus/ task trained, little or no generalization to the untrained

stimuli or tasks would be seen. Any other pattern of results would indicate generalization of stimulus/task learning. Either stimulus/task or procedural learning could contribute to broad generalizations to language ability.

Method

Ethics

All methods were approved by the Nottingham National Health Service Research Ethics Committee.

Participants

The parents/guardians of 94 children from years 4 and 5 (ages 8-9 years, and 9-10 years, respectively) of two mainstream primary schools in Nottingham, United Kingdom, gave written consent for their children to be included in this study. Prior to being included, children were required to (a) pass an audiometric screen in a quiet roomin their school using sound-attenuating headphones (pure-tone thresholds≤30 dBHL at 1 kHz, 2kHz, and 4 kHz, to allow for reduced sound-attenuated testing); (b) have no known physical, neurological, or psychological problems; and (c) have no previous experience of psychophysical testing. Parent/guardian responses to questionnaires indicated that four children failed to meet the second inclusion criterion, owing to diagnoses of cerebral palsy (n = 1), epilepsy (n = 1), and autism spectrum disorders (n = 2). These children were not included in the study. In addition, four children went on holiday during the training phase and, thus, were excluded from the study. This lefta total sample size of 86 children. Of these, parental/guardian reports indicated that 74 spoke English as their first language. Of the 12 children who did not speak English as their first language, nine children had been learning English for between 3 and 6 years (M = 4.17 years, SD = 1.17 years). The remaining four children were reported to be bilingual. Including these children in the analyses did not affect the results of the study.

Children were quasi-randomly assigned to one of four groups: auditory frequency discrimination (AFD group), phonetic discrimination (PD group), visual frequency discrimination (VFD group), and no-intervention control (NI group). Participant allocation was stratified according to gender (male or female), year group (4 or 5), and native English status (native or non-native). Furthermore, children who were reported to have any visual problems (n = 2; strabismus, astigmatism) were not included in the VFD group.

Participant characteristics for each of the four groups are showninTable 1. Although, in theory, randomization of participants to each of the four groups should result in similar distributions of participant characteristics across the four groups, this was confirmed using a series of analyses of variance (ANOVAs) and c2 analyses. The four groups did not differ significantly (criterion of $p < .05$) by age, $F(3, 82) = 0.19$, $p = .906$, or by nonverbal IQ, $F(3, 82) = 0.62$, $p = .606$, as assessed through use of the Matrix Reasoning subtest of the Wechsler Abbreviated Scale of Intelligence (WASI; Wechsler, 1999). Across the four groups, there were no differences in gender, $c2(3) = 0.36$, $p = .948$; English-speaking status, $c2(6) = 3.21$, $p = .782$; or parental education levels [mother, $H(3) = 6.16$, $p = .104$; father, $H(3) = 1.50$, $p = .682$].

Design

Great care was taken to balance the distribution of children across groups, to provide each group with a highly similar and encouraging environment and social setting, and to make the training programs procedurally similar to each other. Three (AFD, PD, and VFD) of the four groups of children completed a training program plus a pre- and post-training assessment. The NI group completed only the pre- and post-training assessments and participated in their usual classroom activities during the training phase. However, in order to control for experimenter familiarity, experimenters met with the NI group for approximately 5 min per week during the training phase. Children in the three training groups were not aware that the other groups were receiving different forms of training. Experimenters were not blind to the children's group status. However, each child was tested by a different experimenter in the pre- and posttraining phases, ensuring that experimenters at posttraining were blind to the children's pre-training scores. At each school, the three training groups were trained in separate sessions on a whole-group basis. Children were tested individually for their pre- and post-

training assessments. All testing and training were conducted in a quiet room in each of the two schools.

Training Phase Procedure

Following the procedure used by Moore et al. (2005), training comprised three 30-min sessions per week for 4 weeks. At each school, sessions for each of the three training groups took place at the same times each week. Two experimenters coordinated each training session and provided encouragement and assistance when needed. Training was delivered via a series of computerized training games (see Tasks section). Training session attendance and motivation to complete the tasks were reinforced through the use of three tactics. First, children could control the appearance (e.g., training characters, background) of each game (see Figure 1). Second, for each game, children were encouraged to record the number of tokens that they had collected on a score card. At the end of each session, the total number of games that the children had played was calculated, and children were rewarded with a sticker for every game played. Finally, a prize scheme was introduced whereby participants could claim a small prize at the end of each session (e.g., bouncy balls, stationery); a medium prize at the end of each training week (e.g., frisbees, toy cars); or a large prize at the end of the training phase (e.g., craftkits, remote-controlled cars). The NI group was also entitled to choose one or several prizes and was awarded their prizes during the post-training week.

Tasks

Child-friendly computer games (System for Testing Auditory Responses [STAR]; see Figure 2) on laptop computers were used to train performance on the psychophysical tasks. Auditory stimuli and feedback were presented binaurally via Trust HS-4100 USB headphones at a comfortable listening level. For each game, 25 trials were presented through use of a three-interval, three-alternative forced choice (3I-3AFC) oddball design. We used a fixed number of trials to ensure that children received a similar amount of exposure to each stimulus set. Each trial comprised three temporally distinct intervals that were separated by 500 ms of silence. Total trial length was kept constant at 3,300 ms. For the two groups that received auditory training (AFD and PD groups), the three intervals corresponded to three sounds (pure tones and speech stimuli, respectively). For the group that received training on a visual task (VFD group), the three intervals corresponded to three visual gratings that appeared in the center of the screen. These were preceded by the appearance of a red fixation cross (È1°) that appeared in the center of the screen for 1,000 ms. In all tasks, two intervals contained a standard tone/ phonetic contrast/spatial frequency grating, and the third randomly determined interval contained a higher frequency tone, a contrasting speech sound, or a higher frequency grating (the target). Children were instructed to choose the interval that they believed contained the "different" (target) sound/image. Participant responses were recorded via the laptop keyboard with custommade response keys. There was no time limit in which to respond, and the initiation of each new trial was selfpaced. Participants were given the opportunity to repeat a trial (up to amaximumof two times) if desired. Children received trial-by-trial feedback on their performance success.

The difference between the standard and the target stimulus (D) was controlled through the use of an adaptive staircase procedure. For the AFD task, the initial D corresponded to a 50% difference in the frequencies of the standard and target tones. For the PD task, the initial D corresponded to the two endpoints of the continuum (e.g., sound file 1 vs. sound file 94, or 100%). For the VFD task, the initial D was 100%. For the AFD and VFD tasks, D was initially halved through the use of a onedown, one-up procedure until the first incorrect response, at which point the same rule was used until the next correct response. At this point, the staircase was moved to a three-down, one-up phase targeting 79% correct on the psychometric function (Levitt, 1971). During this phase, D was multiplied or divided by a factor of 3⁄42. A similar adaptive procedure was used for the PD task, except that D (in %) was rounded up or down to the nearest sound file in the continuum. Thresholds were calculated as the geometric mean of the last two reversal points in the final adaptive rule. For the AFD and VFD tasks, thresholds are reported as DF/F (%). For the PD task, thresholds are reported as D (%).

Children in the three training groups each received training on 11 different stimulus sets that were cycled through in a fixed order. Children in the AFD group were trained on an AFD task that used the following

standard frequencies: 570 Hz, 700 Hz, 840 Hz, 1000 Hz, 1170 Hz, 1370 Hz, 1600 Hz, 1860 Hz, 2160 Hz, 2510 Hz, and 2920 Hz. These frequencies were selected so that each was in a different critical band of hearing according to the Bark scale (Zwicker, 1961), in order that each standard frequency should excite separate auditory filters. Each stimulus was a 200-ms pure tone (10-ms rise-fall times shaped with a raised cosine function). Children in the PD group were trained through the use of a subset of the phonetic contrast continua that are included in the commercially available auditory training program known as Phonomena (MindWeavers Ltd.) and were used in the Moore et al. (2005) study. Briefly, these were the continua b_d (/bi:/_/di:/), d_g (/da:/_/ga:/), e_a (/e/_/a/), er_or (/e:/_/c://), i_e (/I/_/e/), l_r (/i:/_/_/n:/), m_n (/ma:/_/na:/), s_sh (/sa:/_/ja:/), s_th (/sa:/_/0a:/), v_w (/va:/_/wa:/), and a_uh (/a/_/v/). The two endpoints of each continuum were derived by analysis and resynthesis of naturally spoken recordings of those syllables produced by a single male speaker of Southeast British English dialect. There were 94 sound files between these endpoints, which were obtained by linear prediction analysis and resynthesis of the spectral parameters of the endpoint files. The spectral parameters were 15 reflection coefficients over a 6.7-ms window, and the four voice source parameters included fundamental frequency (f0) and voicing. Children in the VFD group were trained on a VFD task with vertical, sinusoidally contrastmodulated gratings, with edge fading, at the following standard spatial frequencies (in cycles/degree [cpd]): 0.5 cpd, 1 cpd, 1.5 cpd, 2 cpd, 2.5 cpd, 3 cpd, 3.5 cpd, 4 cpd, 4.5 cpd, 5 cpd, and 5.5 cpd. Each grating was contained within a 10° circle and had an equal mean luminance to the surrounding gray area. Stimuli were presented on the screen for 600 ms, with 50-ms rise-fall times shaped with a raised cosine function.

Pre- and Post-Training Phases Procedure

The pre-training assessments were conducted for each child by one of five experimenters in the week immediately preceding the 4 training weeks. During this session, children underwent the audiometric hearing screen. They also completed a battery of psychophysical tests assessingAFD, PD, and VFD. These psychophysical tests were interspersed with a battery of psychometric tests assessing nonverbal intelligence (Matrix Reasoning subtest of theWASI), phonological processing (Nonword Repetition, Alliteration, Rhyme, and Spoonerisms subtests of the Phonological Assessment Battery [PhAB; Frederickson, Frith, &Reason, 1997]), and reading fluency (Sight Word Reading Efficiency and Phonemic Decoding Efficiency subtests of the Test of Word Reading Efficiency [TOWRE; Torgesen, Wagner, &Rashotte, 1999]). Except for the psychophysical tests that were presented in counterbalanced order, the remaining audiometric hearing screen and psychometric tests were presented in a fixed order. Each session lasted approximately 1 hr.

The post-training assessments took place during the week following the 4 training weeks and were identical to the pre-training assessments but with two exceptions. First, for psychometric assessments where two versions of the test were available, a different test version was used at pre- and post-training to minimize risk of test-retest effects. This applied only to the subtests of Sight Word Reading and Phonemic Decoding. Second, participants' hearing and Matrix Reasoning abilities were not assessed during the post-training session.

Tasks

Psychophysical Assessments

Performance was assessed through use of the computer games from the training phase. In an effort to minimize training effects during the pre-training session, children's performance was assessed on only one of the 11 available stimulus sets for each of the three training tasks-AFD, PD, and VFD. For the AFD and VFD tasks, the stimulus sets were 1,000 Hz and 2 cpd. For the PD task, we conducted a pilot test to identify a stimulus set that was not too difficult (i.e., no floor effects) but that, nonetheless, showed a robust training effect in adult listeners. The continuum that met these criteria and was therefore selected was e_a.

The psychophysical assessments were identical to those used in the training phase, with three main differences: First, prior to the administration of each psychophysical task, participants completed a short practice game in which they received five trials where D was set to the maximum initial level. In order to

proceed to the psychophysical assessments, children had to obtain four out of five correct responses on these practice trials. If this criterionwas notmet, the practice gamewas repeated (up to a maximum of four times). During the pre-training session, all children were able to proceed to the psychophysical assessments for the PD and VFD tasks. Two children (one from the VFD group, one from the NI group) did not achieve four out of five correct responses on the AFD practice game even after four repetitions, and so their AFD ability was not assessed at pre-test. The post-training AFD thresholds for these children are excluded from the analyses. All childrenmet criterion for all three tasks during the post-training assessment. Second, in the event that a child made an error during either the first or the second (easy) trial, the experimenter abandoned and restarted that assessment. This was to ensure that the child had understood the task instructions, in order for a reliable threshold to be measured. Third, to ensure that a minimum number of reversals was achieved per task, each game terminated after two reversals in the final three-down, one-up rule.

Psychometric Assessments

Nonverbal intelligence. Nonverbal ability was assessed through use of the Matrix Reasoning subtest of the WASI (Wechsler, 1999). Participants were asked to complete an incomplete matrix of patterns and abstract designs by choosing one of five response options.

Phonological processing. Phonological memory and receptive and expressive phonological processing were assessed through use of the Nonword Repetition subtest from the NEPSY (Korkman, Kirk, &Kemp, 1998). Thirteen nonsense words ranging from two to five syllables in length were presented over headphones at a comfortable listening level. Children were required to repeat each nonsense word out loud. The original items, which were delivered by a North American speaker, were re-recorded by a female native speaker of East Midlands British English dialect, in a sound-attenuated booth.

Phonological awareness was assessed through the use of three subtests of the PhAB (Frederickson et al., 1997): Alliteration, Rhyme, and Spoonerisms. The Alliteration subtest has 10 items that are divided into two parts of five items each and is graded in difficulty. For each item, children were asked to state which two of three words, read aloud by the examiners, started with the same sound. The Rhyme subtest has 12 items in Part 1 and nine items in Part 2, and it is also graded in difficulty. For each item, children were asked to state which two of three words, read aloud by the examiners, ended with the same sound. Finally, the Spoonerisms subtest is again divided into two parts and is graded in difficulty. In Part 1, examiners read a word aloud, and children were required to replace the first phoneme of that word with a specified new phoneme (e.g., "fun with a / b/ gives bun"). In Part 2, examiners read two words aloud, and childrenwere asked to exchange the initial phonemes of the two words (e.g., "fed man gives med fan").

Reading fluency. Reading fluency was assessed through use of the SightWord Reading Efficiency subtest (hereafter referred to asWord Reading) and the Phonemic Decoding Efficiency subtest (hereafter referred to as Nonword Reading) of the TOWRE (Torgesen et al., 1999). In each subtest, children were presented with a list of eight practice items and a longer list of test items that were of increasing difficulty. Children were required to read aloud as many words/nonsense words as possible in 45 s.

Data Handling Missing Data

For the pre- and post-training assessments, 12.01% of the pre- and 5.81% of the post-training psychophysical assessments were restarted, owing to early task failure. For the training games, two reversals had not been achieved by Trial 25 for 0.29% of tracks; therefore, threshold estimates were missing. This lefta total of 1,226, 1,225, and 953 threshold estimates during training for the AFD, PD, and VFD groups, respectively.

Just over half of all participantswere at ceiling during the pre-training assessment for the Alliteration subtest of the PhAB. Therefore, data for this task are included in the figures, but no further analyses are reported.

Several children (AFDgroup, n = 3; VFD group, n =1) were unable to read the practice trials of the Word and Nonword Reading subtests of the TOWRE at pre-training; therefore, the test items for these two subtests were not administered. All of these children spoke English as their first language. Although two of these four children

were able to complete the Word and/or Nonword Reading subtests, respectively, during the post-training assessment, these scores are not included in the analyses.

Data Transformation

We conducted a log10 transformation on threshold estimates for the auditory and visual FD tasks to stabilize the between-groups variance and to correct for positive skew in the distributions.

Analyses

For analyses of the training phase, the effects of training and stimulus set on thresholds were investigated for each training group using a linearmixed-models procedure, assuming a random intercept-only model structure. This permits the inclusion of threshold data for subjectswhere other thresholds are missing. All validmodels incorporating some or all of the main effects and interactions of the factor Stimulus and the covariate Training were fit, and the model minimizing Akaike's information criterion (AIC) was selected on the grounds of providing the best data fit subject to an allowance for model parsimony.

A series of ANOVAs confirmed that the four groups did not differ significantly in their performance on the psychophysical or psychometric tasks at pre-training ($p > .05$; see Table 2). In order to assess any differential improvement among the four groups between pre- and post-training, we used univariate analyses of covariance (ANCOVAs) to assess group differences at post-training, controlling for performance at pre-training (see Hatcher, Hulme, &Ellis, 1994). For the psychometric measures, all analyses were conducted on raw scores. However, for ease of interpretation, standard scores are shown in the tables and figures.

Results

Learning

We first assessed whether the three trained groups received an equivalent amount of training during the training phase. Table 3 shows the mean and range of training games played and stimulus sets repeated by children in each of the three training groups. A univariateANOVA confirmed that although there was considerable variability in the number of training games played by individual children, the three groups did not differ significantly, $F(2, 61) = 2.91$, $p = .062$.

We assessed whether the three trained groups showed significant learning on the psychophysical tasks upon which they were trained in two ways. First, the mean threshold change as a function of training is shown in Figure 3 for each of the three trained groups for each of the 11 stimulus sets. For the AFD task, thresholds of the AFD group improved significantly with training, $F(1, 17) = 43.52$, $p < .001$. Thresholds also varied as a function of stimulus type, $F(11, 186) = 9.40$, $p < .001$. However, the interaction between training and stimulus type was not significant, $F(10, 316) = 0.64$, $p = .776$, suggesting that learning was consistent across the 11 stimulus sets. For the PD task, there were significant effects of training, $F(1, 24) = 20.18$, $p < .001$, and stimulus set, $F(11, 171) = 226.69$, $p < .001$, as well as a significant interaction between the two, $F(10, 337) = 3.56$, $p < .001$. Post hoc analyses (contrast estimates) showed significant learning for the stimulus sets "a_uh," "e_a," "l_r," "s_sh," and "s_th" only ($p < .05$). Finally, for theVFDtask, there were significantmain effects of training, $F(1, 26) = 5.10$, $p = .032$, and stimulus, $F(11, 552) = 227.57$, $p < .001$, and a significant Training ×Stimulus interaction, $F(10, 493) = 1.93$, $p = .039$. Post hoc analyses showed that the gradient of the learning curve was significantly different from zero for the stimulus sets 2 cpd, 2.5 cpd, and 5.5 cpd. However, none of these stimulus sets showed a pattern that was consistent with learning, and indeed, thresholds for these stimuli appeared to worsen with training.

Second, we asked whether any of the trained groups showed pre- to post-training improvements on the psychophysical tasks upon which they were trained that were significantly greater than those of the other trained groups or of no-intervention controls (see Figure 4). The analyses supported the training data in that there were main effects of group on post-training thresholds for all of the three psychophysical tasks-AFD task, $F(3, 79) = 7.67$, $p < .001$; PD task, $F(3, 81) = 6.16$, $p = .001$; VFD task, $F(3, 81) = 5.19$, $p = .002$-once pre-training thresholds had been covaried. Post hoc analyses (least significant difference [LSD]) confirmed that

these main effects were driven by (a) the AFD group having lower (better) thresholds at post-training on the AFD task relative to the other three groups, $p \leq .001$; (b) the PD group having lower thresholds at post-training on the PD task relative to the other three groups, $p = .001$; and (c) the VFD group having higher (poorer) thresholds at post-training on the VFD task relative to the other three groups, $p < .05$. Together, these findings confirm that the two groups who received auditory training showed greater learning than the other groups on the tasks upon which they were trained, whereas the group who received visual discrimination training showed less.

Generalization

Generalization data for the nontrained psychophysical tasks are shown in Figure 4. Post hoc analyses (LSD) confirmed that none of the groups differed significantly in their post-training thresholds for any of the tasks upon which they did not receive training, once pre-training thresholds had been controlled ($p > .05$). Therefore, these findings suggest that learning did not generalize to any of the stimuli/tasks or to the modality for which participants did not receive training.

Finally, we asked whether any of the groups showed generalization of learning to the phonological processing and reading fluency tasks. Pre- and post-training scores on these tasks are shown in Figure 5. Univariate ANCOVAs indicated that, after controlling for pretraining scores, post-training scores did not differ between groups on any task except Spoonerisms-Nonword Repetition, $F(1, 81) = 0.28$, $p = .843$; Rhyme, $F(1, 81) = 1.82$, $p = .150$; Word Reading, $F(1, 77) = 0.35$, $p = .791$; Nonword Reading, $F(1, 77) = 0.25$, $p = .863$. For the Spoonerisms subtest, there was a significant effect of Group, $F(1, 81) = 2.75$, $p = .048$, although this was not significant after controlling for multiple comparisons (Bonferonni corrections for five comparisons, $p = .001$). Post hoc analyses (LSD) indicated that this effect on the Spoonerisms subtest was driven by the poorer post-training scores of the VFD group relative to those of the other three groups ($p < .05$), after pre-training scores had been controlled. These findings clearly show that none of the trained groups significantly outperformed the no-intervention controls at post-training on any of the psychometric assessments and, therefore, that learning did not generalize to significant improvements in language abilities.

Discussion

The aim of this study was to assess generalization of auditory learning in typically developing children across stimuli and tasks, across modality, and to higher level language tasks.We found that typically developing children who trained on an AFD task or a PD task showed learning on the tasks upon which they were trained, whereas children who trained on a VFD task did not. However, relative to no-intervention controls and to other trained groups, none of the trained groups showed significant generalization of learning to the psychophysical tasks and stimuli upon which they did not receive training. Moreover, none showed significant generalization to any of a battery of phonological processing and reading tests.

The findings that children showed learning on the AFD and PD tasks are consistent with previous findings from both the adult literature (e.g., Amitay, Hawkey, &Moore, 2005; Demany, 1985; Demany &Semal, 2002; Delhommeau, Micheyl, &Jouvent, 2005; Delhommeau, Micheyl, Jouvent, &Collet, 2002; Grimault, Micheyl, Carlyon, &Bacon, 2003; Irvine, Martin, Klimkeit, &Smith, 2000; Kraus et al., 1995; Tremblay et al., 1997) and the child literature (Halliday et al., 2008; Moore et al., 2005). Therefore, our results confirm previous findings that children can, in some instances, show auditory learning across multiple training sessions (Huyck &Wright, 2011; Moore et al., 2005). However, our results also add to the literature in several respects. First, they show that children of this age range can learn on a much broader set of stimuli than previously demonstrated. Second, they indicate that there may be different developmental trajectories of learning for different auditory psychophysical tasks. Although we found significant learning on both an AFD and a PD task in 8- to 10-year-old children, Huyck and Wright (2011) failed to find learning in 11-year-olds on a temporal-interval discrimination task and reported learning on the same task in only a subset of 14-year-olds. Although not all the children in our sample showed learning (as also found by Halliday et al., 2008), the significant group effects indicate that

learning can be induced on these tasks, even if it is not fully mature. Differences in the patterns of learning with age as a function of task, therefore, suggest that different underlying processes may be necessary for learning on different tasks, each of which matures at a different rate.

The current finding that learning failed to generalize to different tasks or stimuli that were either of the same or different modality suggests that the learning we observed was specific to the task or to the stimuli and was not due to procedural learning. Because we did not test generalization of learning to stimuli that were not included in the trained stimulus sets,we are unable to determine from our results whether it was task or stimulus learning that took place. This is a shortcoming of our study, but one that was due to time restrictions involved in testing children of this age range. Therefore, our results leave open two possibilities regarding what the children learned. First, it is possible that learning comprised the formation of relatively fixed and fine-grained representations of the trained stimulus sets. This would predict that the children would also have failed to show generalization to untrained auditory frequency and phonetic stimuli on the tasks on which they were trained. Alternatively, children might have learned something about the task (e.g., heightened ability to attend to the relevant stimulus dimensions) without forming stimulusspecific representations (Holt &Lotto, 2006; see also Xiao et al., 2008, for a similar argument in visual training). This would allow for the possibility that the AFD and PD groups would have showed learning on other nontrained frequencies and phonetic stimuli, respectively. Future studies that better distinguish between tasks and stimuli could help determine what sort of learning (stimulus/task) is taking place.

The apparent lack of procedural learning in this study was surprising to us, particularly given that the participants involved were children. There is considerable evidence that top-down, nonsensory factors including selective and sustained attention and working memory are major contributors to auditory perceptual discrimination and learning in children (Halliday et al., 2008; Moore, Ferguson, Halliday, &Riley, 2008). Given that procedural learning is thought to encompass the broad attentional/memory demands of the task, a strong prediction would be that it might be particularly marked in studies involving child participants. Our findings do not support this prediction. Note, however, that they also do not rule out a possible role of top-down processes in other aspects of perceptual learning in children. There now is evidence from adults to suggest that top-down processes could have an effect on stimulus and/or task learning, instead of or in addition to procedural learning (Ahissar, Nahum, Nelken, &Hochstein, 2009; Li, Piech, &Gilbert, 2004; Polley, Steinberg, &Merzenich, 2006). For instance, a recent study found evidence for auditory learning that was specific to the stimulus dimension that was attended to during training (Halliday, Moore, Taylor, &Amitay, 2011). Further research is needed to ascertain the relative contribution of top-down processes to auditory learning in children.

The learning we observed also failed to generalize to higher level measures of phonological processing and reading. Here, our findings differ from those of several previous studies showing improvements in a range of measures of language and literacy in children following auditory training (Habib et al., 1999; Merzenich et al., 1996; Moore et al., 2005; Schäffler et al., 2004; Strehlow et al., 2006; Tallal et al., 1996). One possible reason for this is that we trained children on a single stimulus type. The majority of studies have trained children on a range of different auditory stimuli, including both speech and nonspeech sounds. It could be that training on a range of different stimuli leads to a greater generalization of learning. However, this does not fit with studies that have trained on a single stimulus type and found positive effects (e.g., Habib, Davaure, Camps, Espesser, &Joly-Pottuz, 2002; Moore et al., 2005) nor with studies that have trained on multiple stimuli and have not found positive effects (McArthur et al., 2008). A second possibility is that we did not train our participants for a long enough time period. Most auditory training studies have trained their participants for longer than the 6 hr completed in the current study (ranging from 10 hr in Schäffler et al., 2004, to 25 hr in Habib et al., 2002). A third possibility is that greater improvements would have been observed had we used children with language impairment rather than typically developing children.

A challenge to the above explanations is that several design features used here (i.e., training on a single

stimulus set, for only 6 hr, with typically developing children) also applied to the study of Moore et al. (2005), where substantial pre- to post-training improvements in phonological awareness and nonword reading were reported. Nevertheless, there were a number of key differences between our study and that of Moore et al. (2005). For instance, it is possible that the variable presentation paradigm used by Moore et al. (2005) resulted in the recruitment of more cognitive resources and, therefore, a greater likelihood of generalization. It is also possible that the longer duration of the training games (60 trials each) in the Moore et al. (2005) study may have meant that children spent more time "around threshold"-that is, listening to difficult discriminations, a factor that has been shown to induce learning (Amitay et al., 2006). Finally, in the current study we used a single-blinded, randomized, controlled design, whereas Moore et al. (2005) did not. Where other randomized controlled trials have been conducted, the positive effects of auditory training on language have not always been replicated (Cohen et al., 2005; Given et al., 2008; Pokorni, Worthington, &Jamison, 2004; cf. Gillam, Loeb, Champlin, Thibodeau, &Friel-Patti, 2008). Our results suggest, at least, that auditory training does not always generalize to improvements in language and literacy in typically developing children of this age range, even when auditory learning is observed.

Children in our study failed to show learning on the VFD task. Learning has been observed in children with amblyopia using a similar task, albeit over a much more prolonged timescale (40 hr over 20 weeks; Polat, Ma-Naim, &Spierer, 2009). We present three possible explanations for our findings. The first is that there was inadequate stimulus control. Testing occurred under various ambient light levels and at different test distances, which likely resulted in variability in both the contrast of the gratings and the spatial size of the gratings at the children's eyes both between and within sessions. Consequently, children in the VFD group may have received a set of more variable stimuli during training than is necessary for learning. A second explanation is that training on the VFD task was insufficient to demonstrate learning in terms of number of trials or the sensitivity of the measurement technique. Finally, the VFD task may have been more challenging in terms of task demands than the two auditory training tasks. Although we tried to match the three training tasks, fundamental differences between the auditory and visual modalities meant that this was not strictly possible. Greater task demands could equate to either a lack of resources available for learning (cf. Amitay et al., 2005) or to less enjoyment of the task, either of which might explain our current findings.

The failure to see learning on the VFD task was unfortunate because it means we cannot rule out the possibility that auditory discrimination training failed to generalize to this task (and vice versa) not because of a lack of transfer of procedural learning but because the VFD task was not learnable. However, we find this interpretation unlikely. Should any generalization have taken place in the current study,we would have expected this to have occurred between the two tasks and stimuli that were most similar-the auditory frequency and phonetic discrimination tasks-yet we did not see this. Moreover, the VFD group showed worsening performance between pre- and post-training on the VFD task only, suggesting that changes were occurring during and following training, albeit changes that were not consistent with a conventional learning pattern.

The current data contribute to a growing body of evidence demonstrating that it is possible to induce auditory learning in children following training (Edwards et al., 2005; Halliday et al., 2008; Merzenich et al., 1996; Moore et al., 2005; cf. Huyck &Wright, 2011). We do not yet know the conditions that stimulate these processes, nor do we fully understand the components of learning in children or how learning changes during maturation. However, our results suggest that either stimulus or task learning (or a combination of both), rather than procedural learning, is likely to underlie the behavioral improvements in performance reported here. Moreover, they suggest that this learning does not always generalize to higher level measures of language and literacy.

Acknowledgments

This research was funded entirely by the intramural program of the Medical Research Council (MRC) to the MRC Institute of Hearing Research. At the time of writing, Lorna F. Halliday was funded by the Economic and Social Research Council.

We are grateful to Sygal Amitay,MRCInstitute of Hearing Research, and Stuart Rosen, University College London, for helpful comments on an earlier draftof this article; Mark Edmondson-Jones, MRC Institute of Hearing Research, for advice on statistical analyses; and Terri Lewis, McMaster University, for advice on the reporting of visual psychophysical data. Thanks toDavidMcDonald and SarahDeed for assistance with data collection. Special thanks to the children, parents, teachers, and staffat St. Margaret Clitherow and Warren Primary Schools in Nottingham.

Abstract: In perception studies, it is common to use vowel stimuli from standardized recordings or synthetic stimuli created using values from well-known published research. Although the use of standardized stimuli is convenient, unconsidered dialect and regional accent differences may introduce confounding effects. The goal of this study was to examine the effect of regional accent variation on vowel identification. The authors analyzed formant values of 8 monophthong vowels produced by 12 talkers from the region where the research took place and compared them with standardized vowels. Fifteen listeners with normal hearing identified synthesized vowels presented in varying levels of noise and at varying spectral distances from the local-dialect values. Acoustically, local vowels differed from standardized vowels, and distance varied across vowels. Perceptually, there was a robust effect of accent similarity such that identification was reduced for vowels at greater distances from local values. Researchers and clinicians should take care in choosing stimuli for perception experiments. It is recommended that regionally validated vowels be used instead of relying on standardized vowels in vowel perception tasks.

Purpose: In perception studies, it is common to use vowel stimuli from standardized recordings or synthetic stimuli created using values from well-known published research. Although the use of standardized stimuli is convenient, unconsidered dialect and regional accent differences may introduce confounding effects. The goal of this study was to examine the effect of regional accent variation on vowel identification.

Method: The authors analyzed formant values of 8 monophthong vowels produced by 12 talkers from the region where the research took place and compared them with standardized vowels. Fifteen listeners with normal hearing identified synthesized vowels presented in varying levels of noise and at varying spectral distances from the local-dialect values.

Results: Acoustically, local vowels differed from standardized vowels, and distance varied across vowels. Perceptually, there was a robust effect of accent similarity such that identification was reduced for vowels at greater distances from local values.

Conclusions: Researchers and clinicians should take care in choosing stimuli for perception experiments. It is recommended that regionally validated vowels be used instead of relying on standardized vowels in vowel perception tasks.

Key Words: dialect, identification, vowels

(ProQuest: ... denotes formula omitted.)

This study consists of two experiments with two related goals: to determine (a) the degree to which vowels in the Pacific Northwest region matched General American English vowels and (b) the degree to which acoustic dissimilarity has an effect on vowel identification accuracy. Although any number of dimensions of the speech signal may be studied to examine differences across regional dialect, we chose to make vowels the focus of this study for several reasons. They are high-intensity quasi-periodic components of the speech signal; moreover, they occupy lower frequencies (below 3 kHz) compared with many consonants that have aperiodic cues distributed in the higher frequencies (above 3 kHz). The frequency distribution and the high intensity of vowels make them important perceptual toeholds for hearers who are listening under less-than-optimal conditions, such

as in noise or with hearing loss. Vowels are also important because their formants carry information about not only the vowel's quality itself but also the flanking consonants through their formant transitions. Again, this may be particularly true under conditions of multiple distortions. Recent work by Webster (2002) indicates that as noise increases, listeners shifttheir weighting of cues away from the aperiodic cues associated with consonants, increasing their reliance on formant transitions. Accordingly, vowels represent a methodologically important object of study (e.g., Kewley-Port, Burkle,&Lee, 2007; Nishi&Kewley-Port, 2008).

The exigencies of perceptual research and especially clinical testing encourage researchers and clinicians to use stimuli that havewell-known properties-in particular, stimuli that have been widely normed. These stimuli are sometimes described as General American English. In North America, this has led to the widespread use of a relatively small set of prerecorded or synthetic stimuli drawn from well-known published data. Because the standard stimuli are taken from a small number of specific geographic regions at specific points in time, there is often a mismatch between the regional accent in the stimuli and the perceiver's regional accent. This mismatch introduces a potential problem: Even relatively subtle differences in accent may introduce a stimulusgoodness effect that varies by laboratory or clinic, depending on geographic location, and that may even vary by listener if the target population is dialectally diverse.

Regional dialect and accent effects are not uniform across the different regions in North America; neither are they uniform across speech sounds. Some accents are more similar to the standard stimuli than others, and some speech sounds vary more by region than others (e.g., Clopper, Pisoni, &de Jong, 2005; Labov, Ash, &Boberg, 2006). For example, in several dialects spoken in New England and in the northern cities, urban areas on the southern shores of the Great Lakes-such as Chicago, Illinois; Detroit, Michigan; Cleveland, Ohio; and Buffalo, New York-there is a phonemic contrast between an open-mid vowel // and a low-central vowel /a/ (as in the words caught and cot, respectively), whereas in much of the West and the South, this contrast is replaced with a single low-back vowel /A/ (e.g., Clopper et al., 2005; Eckert, 1989; Labov et al., 2006). Moreover, different dialects typically have distinct allophonic processes for otherwise similar phonemes. Take, for example, a process often referred to as Canadian raising: the diphthong phoneme /aI/ (as in "ride" [?aId] or "rise" [?aIz]) has a "raised" allophone [ÃI] before all voiceless coda consonants (as in write [?ÃIt] or rice [?ÃIs]; e.g., Vance, 1987). This allophonic variant occurs in several dialects spoken in the northern and eastern United States but not in other dialects spoken in the South and West. Thus, even with identical phonemic inventories, there may be context-specific (allophonic) differences in pronunciations of particular words or syllables.

Although not all regions have been fully documented, existing documentation indicates that regional dialects differ not only in the number of vowel contrasts and phonetic realization of vowel allophones but also in the acoustic values that phonemes have even if they are conventionally transcribed using the same phonetic symbol. Although this last point may seem obvious to researchers who are familiar with regional variation and transcription conventions, the symbols that are used to represent vowel categories are often taken as true values by researchers in clinical and psychological settings who are not trained in regional variation. As a result, it is common to assume that standardized vowels should be used in all regions of the country where the phonetic symbols match the symbols used in the standard descriptions. For example, whereas the symbol /u / is used to represent a vowel that is present as a phoneme in all dialects of North American English, the acoustic realization of this vowel varies from a high-back variant in Wisconsin to a high-central variant in southern California and parts of the Deep South (e.g., Clopper et al., 2005; Hagiwara, 1997; Jacewicz, Fox, &Salmons, 2007; Labov et al., 2006). In a study of six regional vowel systems, Clopper et al. (2005) found that each region had its own realization of the vowel system even though the vowels are typically represented with the same symbols and phonetic descriptors. Their findings led them to conclude that vowels are best characterized in terms of regional systems rather than in terms of General American English, a finding that echoed Hagiwara's (1997) observation about southern Californian English and Hillenbrand, Getty, Clark, and Wheeler's (1995) observation about regional effects in their study of southern Michigan speakers.

These findings have potentially serious implications for researchers who use speech stimuli in perception experiments or as comparison points for speech production. In the absence of acoustic validation through regional sampling, there is no guarantee that a particular phoneme's acoustic realization in North American English will be the same from one region to the next. Ignoring regional dialect and accent variation may result in regional asymmetries in category goodness of stimuli across listeners in perception studies.

Phonetic differences in stimuli may seem relatively unimportant if the task is not tapping into low-level phonetic perception, but there is evidence that accented speech may impose a processing delay or a cognitive load. For example, Clarke and Garrett (2004) found that initial exposure to foreign-accented speech introduced a temporary perceptual-processing deficit. More relevant to the current research, regional accent differences may have a cascading effect that percolates up to higher level tasks. Adank and McQueen (2007) conducted a noun-animacy (animate vs. inanimate) decision task in which listeners were presented with auditory stimuli in a familiar accent and an unfamiliar accent. Subjects' response times were slower for words presented in the unfamiliar accent. The effect persisted even when listeners were exposed to 20 min of speech in the unfamiliar accent prior to the animacy decision task, indicating a lasting effect for unfamiliar accents. Similarly, Floccia, Butler, Goslin, and Ellis (2009) found that unfamiliar accents in certain tasks impose a processing delay that is long lasting; it continues after intelligibility scores reach ceiling. To compound the problem, prosody, intonation, syntax, and lexical choice vary across regions (e.g. Grabe, 2004); therefore, using sentence-length stimuli does not necessarily solve the potential problems at the phone level and may even make them worse. In a study of cross-dialect intelligibility in noise, Clopper and Bradlow (2009) found that dialects that were more similar to General American English, which included New England, the West, and theMidland regions, were more intelligible than regional dialects that were more distant from General American English, including mid-Atlantic, northern, and southern regions. Although not all dialectal regions were equally represented-so true regional effects were not fully probed-on the whole, Clopper and Bradlow's results indicated that there is a negative effect on intelligibility of mismatch between the listener's dialect and the dialect in the stimuli in noisy listening environments.

How concerned should researchers be about the effects of regional accents on category goodness, perceptual processing, and higher level processing in perceptual research? After all, there appears to be counterevidence in that listeners seem to be able to adapt to foreignaccented speech (e.g., Clarke &Garrett, 2004; Ferguson, Jongman, Sereno, &Keum, 2010; Munro &Derwing, 1995a, 1995b). Moreover, the native dialect effects that have been observed for speech perception and processing for Dutch (Adank &McQueen, 2007), French (Dufour, Nguyen, &Frauenfelder, 2007), and English (Cutler, Smith, &Cooper, 2005; Evans &Iverson, 2007; Floccia et al., 2009) involved dialect differences that were larger than those typically observed within North America. This uncertainty about regional effects has led to a general trend in North American research to treat a common set of vowel values as "standard" North American English in perception experiments and in clinical studies. No study has directly tested the effect of dialect vowel distance (as measured using first and second formant [F1 and F2, respectively] differences between dialects) on identification accuracy; therefore, whether distance has a negative impact on vowel identification is unknown.

To test whether vowel differences that are typical in North American English interfere with vowel identification, we conducted two experiments. In the first, we investigated vowels of the region where the research took place, the Pacific Northwest (PNW), to establish whether their formant values differ from two sets of formant values of vowels that are commonly referred to as General American English: (a) Peterson and Barney (1952; PB) and (b) Hillenbrand et al. (1995; HGCW). In the second experiment, we conducted a perceptual identification task using three synthesized vowel sets that differed in spectral distance (F1 and F2 differences in a Euclidean space) from the vowels of the subjects' regional dialect (0 = PNW identical, 1 = PNW similar, 2 = PNW dissimilar) to test the effect of vowel dissimilarity distance on identification accuracy.

Experiment 1: Comparing PNW Vowels With Standard Vowels

Although all dimensions of language vary across regional dialects, vowels are particularly well documented in English and therefore most easily compared. Moreover, there is a widely used comparison metric for vowels: F1 and F2 are typically measured at midpoint or steady state. This measure was used in Peterson and Barney's (1952) study as well as Hillenbrand et al.'s (1995) research and other recent vowel studies (e.g., Clopper et al., 2005; Hagiwara, 1997).We predicted that there would be study effects such that both PB and HGCW vowels would differ from the PNW vowels. We also predicted that there would be Vowel ×Study interactions, such that PB and HGCW vowels would differ from PNW vowels in study-specific ways.

Method

Talkers

Six adult men and six adult women participated in vowel recordings. All of the talkers had grown up in the PNW (Washington, Idaho, Oregon) and were monolingual speakers of English.Talkerswho had lived elsewhere or had significant experience with other languages were excluded from participation. ThePNWwas defined broadly to include the amount of local variation that is likely to occur in an experimental or clinical population.1 None of the talkers had a history of speech therapy, and all had normal hearing, defined as pure-tone thresholds of 20 dB HL or better (see American National Standards Institute, 2004) at octave frequencies between 0.25 kHz and 8 kHz, bilaterally. All procedures were reviewed and approved by the local institutional review board, and talkers were reimbursed for their time.

Recording Procedure

Words containing eight monphthong vowels (/ i, I, e, ?, æ, A, ?, u/) were recorded using randomized word lists. The mid-back vowel /o / was excluded because it is a diphthong in the PNW region (Ingle et al., 2005). The midfront vowel /e / was included for qualitative comparison but excluded from the statistics because it was absent in the PB study. Talkers were seated in a double-walled sound-attenuated chamber during the recordings. All vowels except for /e / and /A/ were read in the /hVd/ context from a word list following the procedure of Hillenbrand et al. (1995). The vowels /e/ and /A / were spoken without the preceding /h/ in the words aid and odd due to unfamiliarity of the words hayed and hawed. The eight words were read in five randomizations to control for list effects on pronunciation, thus minimizing the need for a carrier phrase. All talkers were instructed to read the list of words at a natural pace and vocal intensity. Vocal level was monitored with a volume unit meter to ensure sufficient output levels without clipping. We used a Tucker-Davis Technologies System 2 with an AP2 sound card and a Shure BG 1.0 omnidirectional microphone for all of the recordings. Four talkers were recorded direct to disc at a rate of 44.1 kHz. The remaining eight talkers were recorded at a rate of 22.05 kHz. All recordings were quantized at 16 bits and down-sampled to 11.025 kHz prior to signal processing and acoustic analysis.

Spectral Analysis

We selected one representative token of each vowel for each talker on the basis of two criteria: (a) recording fidelity and clarity of each subject's voice without hoarseness, pitch breaks, or other disfluencies, and (b) visual inspection of the vowel for F1 and F2 steady states and accompanying pitch steady state. We determined formant steady state using a wideband spectrogram and accompanying linear predictive coding (LPC) formant track with 12 coefficients. We determined pitch steady state using an autocorrelation pitch track with a 25-ms window overlaid on a narrow-band spectrogram. A formant was considered to be steady state if a straight line could be traced through the middle 50 ms of the vowel and the pitch remained constant over the same section. Once the vowel was selected and the steady-state portion identified, the first four formants (F1, F2, F3, F4) were estimated at the center of the steady state. The F1 through F4 values and recordings had been used in a separate study on hearing aid compression (Bor, Souza, &Wright, 2008). In the current study, we used only F1 and F2. To minimize the risk of error, formant measurements were taken from an LPC spectrum overlaid on a fast Fourier transform power spectrum with a sample window of 128 points and visually compared with its broadband spectrogram. In the event that there were LPC errors for a particular talker, the number of filter

coefficients (poles) was adjusted up or down for that entire talker's set of vowel measures. The sample window of the LPC was 25 ms, and the number of coefficients ranged between 10 and 12, depending on the talker.

Results

Vowels from the PNW study were compared with HGCW and PB vowels using the F1 and F2 values. Because we had a reasonably large sample (six men and six women), we were able to make comparisons within gender rather than normalizing the data, thus preserving vowel space shape and individual vowel variability. Because there were grossly different sample sizes between studies, we used a random sample of six speakers from each of the larger studies (PB, HGCW). To ensure that there were no sampling artifacts, we plotted the mean of the resulting sample within a 95% confidence interval ellipse representing all data within gender for adults. In all cases, our sample fell near the center of the F1 ×F2 ellipse, indicating that our sample was representative of each study while still retaining variability within vowel. The results of the within-gender sample were submitted to a series of analyses of variance (ANOVAs) with F1 and F2 as dependent variables, and study (PNW, HGCW, or PB) and vowel (i, I, e, æ, A, ?, u) as independent variables. ANOVA results are presented in Table 1 (male vowels) and 2 (female vowels).

The results of the ANOVAs indicated the expected reliable effect of vowel on F1 and F2 for both men and women, indicating that in each study, the vowels were reliably separated on both dimensions. More interesting is that there was an effect of study on F2 for men and a Study ×Vowel interaction for F1 and F2 in the data for both the men and women. The interactions indicate study-specific differences for individual vowels. To probe which vowels were contributing to the interactions, we submitted the formant values to a series of Bonferroni-Dunn post hoc t tests with an alpha of .05 (corrected to .0167). For men's PNW F1 values, the vowel [æ] was different from its HGCW counterpart, but none were different from their PB counterparts. For men's PNW F2 values, the vowels [æ], [a], [?], and [u] were all different from their HGCW counterparts, and the vowels [?] and [u] were different from their PB counterparts. For women's PNW F1 values, the vowels [i], [æ], [A], and [?] were all different from their HGCW counterparts, but none were different from their PB counterparts. For women's PNW F2 values, the vowels [?], [æ], [A], [?], and [u] were all reliably different from their HGCW counterparts, and the vowels [i], [?], [?], and [u] were all reliably different fromtheir PB counterparts.

To illustrate the Study ×Vowel effects, we plotted men's and women's vowel means in Figures 1 and 2, respectively, with thePNWvowel plots overlaid onHGCW and PB vowels. Notable differences include a lowered (higher F1) and backed (lower F2) PNW /æ / relative to the HGCW counterpart, a raised (lower F1) and backed (lower F2) PNW /A/ relative to the HGCW counterpart, and a fronted (higher F2)PNW/?/ and /u/ relative to the PB and HGCW counterparts. The PNW /e/ also appears slightly raised (lower F1) and fronted (higher F2) relative to theHGCWcounterpart. Formant values are summarized in Table 3.

To investigate the relative differences further, we calculated Euclidean distances from each PNW vowel's F1 ×F2 point in the vowel space to its gender-matched counterpart from the PB and HGCW values.2 We used Equation 1 to calculate distance:

... (1)

Throughout this study, we used this formula to calculate distance. In the formula, s is the distance between points in a two-dimensional Euclidian vowel space defined by F2 on the x axis and F1 on the y axis, and where F1p is an individual PNW speaker's F1 value for a particular vowel and F1i is a comparison value for the equivalent PB or HGCW vowel F1 mean, and where F2p is an individual PNW speaker's F2 value for a particular vowel and F2i is a comparison value for the equivalent PB or HGCW vowel F2 mean. Because we were interested in relating these differences to perceptual effects, we also calculated the Euclidean distances in Bark using the formula published in Traunmüller (1990).

The results of the Euclidean distance measures are summarized in Table 4, which displays the mean distance and SDs by vowel and by study in Hz and in Bark, respectively. The distance patterns are similar in Hz and Bark because in the frequency region of F1 and F2, there is a fairly linear relationship between Hz and Bark.

Nevertheless, the transformations are presented to ease comparisons to other studies for the reader.
On the whole, the Hillenbrand et al. (1995) and the Peterson and Barney (1952) studies showed large mean distances to the PNW vowels: HGCW vowels at 333 Hz (1.67 Bark) and PB vowels at 275 Hz (1.38 Bark). Only a slight difference of 57 Hz (0.29 Bark) is seen between the average HGCW-PNW distance and the average PB-PNW distance. This accounts for the general lack of effect of study in the ANOVA. However, as indicated by the Vowel ×Study interactions and subsequent post hoc tests, in some regions of the vowel space, the PB-PNW distances are larger, whereas in others, the HGCW-PNW distances are larger: the back vowels /?, u/ show greater distances to PB, and the low vowels /æ , A/ show greater distances to HGCW. For /æ , A/, the HGCW-PNW distances are 357 Hz (1.66 Bark) and 257 Hz (1.44 Bark) greater than the equivalent PB- PNW distances. On the other hand, for /?, u/, the PB- PNW distances are 106 Hz (0.67 Bark) and 91 Hz (0.41) greater than the HGCW-PNW distances.

Discussion

The results of Experiment 1 indicate that PNW regional vowels vary, sometimes substantially, from standardized vowels in terms of their formants. They also demonstrate that neither of the standardized vowel sets (HGCWor PB) is optimal in terms of the vowel mismatch because each has vowels that show larger distances than those of the other study. This result should be unsurprising to readers who are familiar with the sociolinguistic literature. After all, nearly all of the subjects in the Hillenbrand et al. (1995) study were from regions that participate in the well-documented "Northern Cities" vowel shift. As described recently in detail by Labov et al. (2006), Clopper et al. (2005), and Jacewicz et al. (2007), the Northern Cities vowel space is characterized by large differences in the low vowels; in particular, it has a raised /æ / compared with other regions and a relatively fronted /a / vowel compared with other regions' back /A /. At the same time, much of the West is characterized by a fronting relative to other regions of the high-back vowels [?] and [u], as noted by Eckert (1989) and as documented instrumentally by Hagiwara (1997) and Clopper et al. (2005). However, in agreement with Ingle et al. (2005), neither of these back vowels in our data show as much fronting as is seen in southern California.

Given the tolerance to variation in normal speech, whether such differences will lead to errors when nonregional vowels are presented in identification studies remains to be seen. Moreover, whether dissimilarity distance has an increasingly negative impact on perception such that at greater distances, recognition accuracy declines, or whether the negative effect is equivalent across distances, also remains to be determined.We tested these questions in Experiment 2 using a forced-choice vowel identification task in which subjects identified synthetic vowels that varied by distance (as defined in Equation 1) in varying amounts of noise.

Experiment 2: Effect of Dissimilarity Distance on Vowel Identification

Method

Listeners

There were 15 listeners: 10 women and five men (M age = 24.6 years, age range: 18-38). All were monolingual English speakers who were native to the PNW. All listeners had bilaterally normal hearing, defined as pure-tone thresholds of 20 dB HL or better at octave frequencies between 0.25 kHz and 8 kHz. Subjects from the production study were excluded from the identification study. All procedures were reviewed and approved by the local institutional review board, and subjects were reimbursed for their time.

Stimuli

There were three steps to creating the stimuli, each of which we describe in more detail below. First, we chose pairs of vowels for the identification task. Second, we compared formant values from different parts of North America to determine the distance steps and to identify individual vowel formant values. Third, we synthesized stimuli using the identified formant values.

We selected two vowel pairs /æ -?, u-?/ for the task on the basis of three criteria. First, the vowels /æ -?, u-?/ represent near neighbors in the acoustic F1 ×F2 vowel space and, therefore, should be more easily confused

than more distant pairs such as /A-?, i-u/. Second, these pairs represent vowels that set the West-and, therefore, the PNW-vowels apart from other regional vowels. Third, on the basis of our review of regional vowel studies across dialect regions of North America, these pairs represent sets for which monophthongs can be identified.

After identifying the two target vowel pairs, we examined published vowel formant values in a large number of sources representing all seven dialect regions: West, North Central, Midland, South, Inland North, Mid-Atlantic, New England (as defined in Clopper et al., 2005; Labov et al., 2006; and Jacewicz et al., 2007). Using the Euclidean distance formula in Equation 1, we calculated a dissimilarity distance from the six PNW vowels to the vowels as described in Clopper et al. (2005), Labov et al. (2006), Hagiwara (2006), and Jacewicz et al. (2007). In calculating distances, we used previously published PNW values (Ingle et al., 2005) to ensure equivalency in the comparisons. After comparing all regions of North America with the PNW results, we selected two non-PNW distances that varied by a consistent amount in dissimilarity distance (values that were closest in terms of differences in F1 and F2). These were designated as either 0 (identical to PNW vowels), 1 (similar to PNW vowels; 111-176 Hz, 0.52- 0.77 Bark), or 2 (dissimilar to PNW; 276-375 Hz, 1.46- 1.70 Bark). We used published values from previous studies to preserve the greatest similarity to existing regional vowels and to ensure the maximal naturalness of the subsequent synthetic stimuli, even though this meant some variation within the Distance 1 and Distance 2 groups. The resulting distances with their regional (study-based) identifier are summarized in Table 5.

Once formant distances had been established, we used the F1 and F2 values from the published studies to create a set of synthetic stimuli at each of the three distance steps (0, 1, and 2). The stimuli were 200 ms long and had a pitch contour that began at 130 Hz and remained steady state for 50 ms, gradually falling thereafter to 90 Hz. This created a male-sounding voice. We took the F1 and F2 frequencies from the published studies, estimated F3 using published regression formulas (Nearey, 1989), and fixed F4 at 3500 Hz. We calculated formant bandwidths from the algorithm described by Johnson, Flemming, and Wright (1993). The values used to synthesize the stimuli are summarized in Table 6. To ensure equivalent signal-to-noise ratios (SNRs) across vowels, the stimuli were root-mean-square normalized following synthesis.

Procedure

Throughout the experiment, listeners were seated in a double-walled sound booth. They were first trained in the orthographic decision labels for vowels by associating visually presented words, such as bet and bat, with the orthographic decision labels. The following are the labels used in the experiment preceded by their IPA symbols: /?/ eh, /æ / ae, /?/ uh, and /u/ oo. When subjects achieved 88% accuracy in the association of the labels with visually presented words, they proceeded to the main experiment.

To measure vowel identification, we presented stimuli monaurally to the right ear via an insert earphone. Each vowel was presented in a background of a masker noise with frequency spectrum matched to the longterm spectrum across all vowels. The masker consisted of a white noise that was low-pass filtered with a 300-Hz cutofffrequency and a 5-dB-per-octave spectral slope. Vowels were presented at SNRs of +2 dB SNR, +6 dB SNR, and +10 dB SNR. In each case, the level of the vowel was fixed at 65 dB SPL, and the level of the noise was adjusted to the desired SNR.

Stimuli were presented blocked by vowel condition (front pairs, back pairs) and SNR, creating six blocks total. The order of the blocks was randomized for each subject. A block consisted of 18 randomly ordered trials (two vowels, three distances, and three repetitions). To mimic clinical (i.e., untrained) presentation, each block was presented once. Subjects responded to each trial in a two-alternative forced-choice paradigm using a touch screen. The choices were presented on the screen as buttons labeled eh or ae for the front vowel block and uh or u for the back pair block. The location of response buttons on the touch screen was randomized on each trial to minimize response bias.

Results

We analyzed the results with a three-way ANOVA with the factors distance (0, 1, or 2), SNR (+2 dB, +6 dB, or +10 dB), and vowel. The results of the ANOVA are reported in Table 7.

The effect of distance for each SNR is shown in Figure 3. In general, scores were similar between distances 0 and 1 and dropped significantly for distance 2 for all SNRs. As suggested by Figure 3, there was no effect of SNR. There was an effect of distance and a significant interaction between distance and SNR. To investigate further, we collapsed the data across vowels and conducted a post hoc analysis by comparing the distance scores within each SNR. The Distance ×SNRinteraction was due to a small difference in the magnitude of the effect whereby the difference between distances 0 and 1 approached significance for SNR 10 ($p = .087$) but not for SNR 6 and 2 ($ps = .475$ and .384, respectively). Note that for SNR 10, there was a slightly higher score at distance 1 compared with distance 0, but given the nonsignificant p value, we considered this as reflecting measurement variability. At all SNRs, there was a significant decrease in score between distances 1 and 2 ($p < .005$ in each case).We used post hoc means comparisons to examine the Distance ×Vowel interaction (see Figure 4). Post hoc analyses indicated that three of the vowels showed a significant effect of distance ($p < .005$ for ?, æ, and u). In each case, the difference between distances 0 and 1 was nonsignificant ($p > .050$), and the difference between distances 1 and 2 was significant ($p < .005$). For the remaining vowel (?), the effect of distance was not significant ($p = .107$).

Discussion

Although we focused on a specific region of theUnited States (PNW), we anticipate that the results seen here can be generalized to other regions of the country. In Experiment 2, the effect of distance 2 was robust, whereas distance 1 did not prove reliable. This may indicate that when making comparisons across dialects, small differences have little or no effect on identification, whereas larger differences have large negative effects. This finding needs to be tested more thoroughly by examining the perceptual effects of subregional or sociolectal variation within dialect-specific vowel systems.

Our production results show that grouping all of the regional accents into any one of the dialect regions (e.g., the South or West) based on overall vowel similarity creates vowel-specific mismatches: Whereas some PNW vowels are typical of other West coast varieties of English, such as the one spoken in southern California, other PNW vowels differ quite dramatically. For example, PNW /æ / shows a Euclidean distance of 157 Hz (1.06 Bark) compared with descriptions of the West in general as defined by Clopper et al. (2005) and Labov et al. (2006), or compared with regionally specific values reported for southern California (e.g., Hagiwara, 1997; Johnson et al., 1993). PNW vowels also show less extreme fronting of /u/ than seen in the generic West or in the specific Southern Californian descriptions. If the distance effects in perception found in Experiment 2 extend to other vowels as predicted, then the treatment of the entire West as a single dialect group may be too broad for many purposes, and this underscores the importance of considering regional-specific vowels rather than broad areas of the United States (e.g., the West, Midwest, South) as is typically done.

The perception results have both methodological and theoretical implications for studies of speech perception. They indicate that vowel category distances related to regional variation have a reliable negative impact on vowel identification. Stated another way, greater dissimilarity increases the risk that a vowel may be identified poorly in perception experiments; however, slight dissimilarities appear to have a negligible effect. It must be noted that in creating our stimuli, we chose a relatively modest distance for the distance 2 condition because we wanted to avoid vowels that were so different that no researcher would use them as stimuli. Accordingly, these results should represent the range of dialects that could be encountered by an individual in a realistic situation. It is important to note that these were vowels presented in isolation, and therefore the task is not directly representative of a listener's everyday experience with accent variation. Whether larger stretches of speech with context effects will showthe same reliability remains to be seen;moreover, the negative impact of dialect differences on speech perceptionmay be mitigated by a variety of factors, such as the experience of the listenerwith other accents. For example, Evans and Iverson (2004) found that listeners were able to shifttheir

perceptual targets to match that of the input accent over time. However, adaptation to an accent may require long-term exposure and may not occur for all individuals (Evans &Iverson, 2007). Sumner and Samuel's (2009) study provided evidence that there are dialect effects in both the immediate perceptual processing and long-term recall of speech stimuli. They concluded that there are individual experienced-based differences that affect one's ability to process stimuli presented in a nonnative dialect.

Research on highly proficient nonnative and bilingual listeners suggests that noise interacts with language background (e.g., Mayo, Florentine, &Buus, 1997; Meador, Flege, &MacKay, 2000; Rogers, Lister, Febo, Besing, &Abrams, 2006). In these studies, listeners appear native-like under ideal listening conditions but experience a more extreme decline in perceptual performance in noise than native listeners do. Age of acquisition also plays a role in these studies; the earlier the second language was acquired, the less noise seemed to affect their perceptual performance. The lack of interaction with noise shown in the present study may be due to an ability of native speakers to dynamically adapt to moderate levels of noise; the more extensive the experience with variation, the more robust the perceptual response in the face of noise. This is consistent with recent findings that the combined effects of dialect variation and noise on speech processing are lessened when the listener has extensive experience with a similar dialect (Clopper &Bradlow, 2009; Clopper, Pierrehumbert, &Tamati, 2010, Sumner &Samuel, 2009).

We believe that these findings also suggest that early and extensive experience with relevant variation creates a robust representation that listeners with normal hearing can draw on under difficult listening conditions, such as in background noise. Individuals with hearing loss may experience an increased difficulty adapting to dialect variability in noise because of the reduced redundancy in the received signal. There is a dearth of research on how listeners with hearing loss respond to dialect variation and other types of phonological distortion. Such work continues to be a focus of interest in our laboratories.

Conclusion

The results of the production study indicate that even when vowels are labeled with the same phonetic symbol (by convention), there can be large acoustic differences between one region's vowels and another's; moreover, there are vowel-specific effects such that some vowels are quite similar across studies and others vary widely. On the whole, the PNW vowels were more similar to the PB vowels than to the HGCW vowels, but for each of the standard vowel sets, some PNW vowels showed larger distances. When presented as stimuli in noise, vowel distance had a reliable (negative) impact on the listener's ability to correctly identify the target vowel. These findings indicate that researchers and clinicians should take care in choosing stimuli for perception experiments. We recommend that researchers use regionally validated vowels instead of relying on standardized vowels in tasks that use vowel perception.

Abstract: This review article provides a theoretical overview of the characteristics of perceptual learning, reviews perceptual learning studies that pertain to dysarthric populations, and identifies directions for future research that consider the application of perceptual learning to the management of dysarthria. A critical review of the literature was conducted that summarized and synthesized previously published research in the area of perceptual learning with atypical speech. Literature related to perceptual learning of neurologically degraded speech was emphasized with the aim of identifying key directions for future research with this population. Familiarization with unfamiliar or ambiguous speech signals can facilitate perceptual learning of that same speech signal. There is a small but growing body of evidence that perceptual learning also occurs for listeners familiarized with dysarthric speech. Perceptual learning of the dysarthric signal is both theoretically and clinically significant. In order to establish the efficacy of exploiting perceptual learning paradigms for rehabilitative gain in dysarthria management, research is required to build on existing empirical evidence and develop a theoretical framework for learning to better recognize neurologically degraded speech.

Purpose: This review article provides a theoretical overview of the characteristics of perceptual learning, reviews perceptual learning studies that pertain to dysarthric populations, and identifies directions for future research that consider the application of perceptual learning to the management of dysarthria.

Method: A critical review of the literature was conducted that summarized and synthesized previously published research in the area of perceptual learning with atypical speech. Literature related to perceptual learning of neurologically degraded speech was emphasized with the aim of identifying key directions for future research with this population.

Conclusions: Familiarization with unfamiliar or ambiguous speech signals can facilitate perceptual learning of that same speech signal. There is a small but growing body of evidence that perceptual learning also occurs for listeners familiarized with dysarthric speech. Perceptual learning of the dysarthric signal is both theoretically and clinically significant. In order to establish the efficacy of exploiting perceptual learning paradigms for rehabilitative gain in dysarthria management, research is required to build on existing empirical evidence and develop a theoretical framework for learning to better recognize neurologically degraded speech.

Key Words: dysarthria, speech perception, perceptual learning

Dysarthria, a neurological disorder of the motor speech system, manifests itself in perceptual disturbances that compromise the integrity of the acoustic signal. It commonly results in impaired speech intelligibility. Indeed, intelligibility disturbances have been classified a "hallmark" feature of this speech disorder (Tikofsky &Tikofsky, 1964; Yorkston, Beukelman, &Bell, 1988) and described as "the most clinically and socially important aspects of dysarthria" (Ansel &Kent, 1992, p. 296). As such, treatments that address improving speech intelligibility are fundamental to the successful management of dysarthria.

Speech intelligibility has traditionally been viewed as a property of the speaker (e.g., Black, 1957; Bond &Moore, 1994; Hood &Poole, 1980). Accordingly, dysarthria management has focused primarily on individual speakers themselves, with emphasis on attempts to improve speech production or equip speakers with strategies or devices to compensate for their impairments (Duffy, 2005). Recent Cochrane reviews have concluded that there are no high-level studies to support or refute the efficacy of speech treatment for progressive and nonprogressive dysarthrias (Deane, Whurr, Playford, Ben- Shlomo, &Clarke, 2009; Sellars,

Hughes, &Langhorne, 2007). Considering the clinical significance of improving intelligibility for individuals with dysarthria, it is critical that research continue to examine the outcomes of behavioral modification on speech production. However, the consideration and development of innovative new forms of treatment is also vital. Speech intelligibility is defined as "the accuracy with which a message is conveyed by a speaker and recovered by a listener" (Klasner &Yorkston, 2005, p. 127). This definition highlights the essential role of both speaker and listener in the communication process. With the speaker-listener process in mind, it was proposed that the intelligibility impairments exhibited by individuals with dysarthria may benefit from treatments that focus on the listener (Liss, 2007). Although conceptually, listener-targeted remediation in dysarthria is novel, its potential should not be underestimated. Dysarthria very rarely occurs in isolation. Physical, cognitive, and memory deficits frequently co-occur, all of which can greatly reduce the individual's capacity to learn and maintain benefits from speaker-oriented interventions (Duffy, 2005). Treatment that focuses on the neurologically intact listener (e.g., family members, friends, carers), thereby bypassing the speaker and any associated conditions that may adversely affect rehabilitation gains, may prove key to optimizing communication success in those with dysarthria.

The notion of training a listener to better understand dysarthric speech is theoretically based in the broader field of perceptual learning. When applied to speech, perceptual learning describes experience-evoked adjustments to the cognitive-perceptual processes required to recognize spoken language. In brief, these perceptual processes-lexical segmentation, lexical activation, and lexical competition-enable the listener to segment a continuous speech stream into individual words (lexical segmentation), to access the lexical items that may match these targets (lexical activation), and to select themost appropriate word for the spoken utterance (lexical competition; Jusczyk &Luce, 2002). Subsequently, word meanings are accessed, and comprehension of the utterance occurs in context. Put simply, perceptual learning implies that a listener can improve his or her ability to recognize a speech signal that is initially difficult to understand.

The past decade has seen much research focused on experimental designs that evaluate perceptual learning of speech. There is now a considerable body of evidence regarding the perceptual benefit for listeners familiarized with an ambiguous or unfamiliar speech signal (e.g., time-compressed, noise vocoded, foreign-accented; see Samuel &Kraljic, 2009). Research has also begun to investigate this phenomenonwith neurologically degraded speech. Although the body of research is small, preliminary evidence suggests that perception of dysarthric speechmay also improvewith training (e.g., Liss, Spitzer, Caviness, &Adler, 2002; Tjaden &Liss, 1995b). This highlights the potential for perceptual learning to be exploited for rehabilitative gain in dysarthria management. However, if this is to occur, a considerable amount of research is first required. This research must build on existing empirical evidence and develop a theoretical framework for a perceptual learning approach to the treatment of dysarthria.

The purpose of this review is threefold: to (a) define perceptual learning and provide an overview of the characteristics of learning within the broader category of atypical speech;1 (b) summarize and synthesize research in which perceptual learning specifically has been examined with dysarthric populations; and (c) identify future directions for this line of research with consideration of its potential role in addressing intelligibility impairments exhibited by individuals with dysarthria.

Perceptual Learning of Atypical Speech

Perceptual learning of speech is defined as "relatively long-lasting changes to an organisms perceptual systemthat improves its ability to respond to its environment and are caused by this environment" (Goldstone, 1998, p. 585) and refers to the experience-evoked capacity to retune or adapt the speech perception system. That is, when listeners are familiarized with a speech signal that is unfamiliar or ambiguous, they are able to modify their perceptual strategies for subsequent processing of the atypical speech (Samuel &Kraljic, 2009). On the basis of interactive models of speech perception, it is proposed that an individual's perceptual system is flexible and dynamically adjusts to match the information provided in the incoming signal (e.g., McClelland

&Elman, 1986).

The laboratory study of perceptual learning has revealed important information about the ways in which familiarization with atypical speech alters subsequent perception. At the phoneme level, it has been shown that perceptual shifts in phoneme category boundaries occur following experience with ambiguous tokens embedded within lexical contexts (e.g., Eisner &McQueen, 2005, 2006; Kraljic &Samuel, 2005, 2006; Maye, Aslin, &Tanenhaus, 2008; Norris, McQueen, &Cutler, 2003). For example, Norris et al. (2003) observed that when Dutch listeners were trained with an ambiguous phoneme (acoustically and perceptually halfway between /s/ and /f/) in real or nonword contexts, listeners were able to extend the boundaries of one of their internal fricative categories (/s/ or /f/) to include the ambiguous phoneme. That is, listeners' internal representations of the acoustic information constituting of /s/ or /f / shifted to accommodate the ambiguous phoneme. The nature of the learning attributed to the phenomenon of category shifting has been termed perceptual adaptation, whereby training facilitates an acoustic-phonetic remapping of phonological information at the segmental level of perceptual processing (e.g., Eisner &McQueen, 2005; Greenspan, Nusbaum, &Pisoni, 1988).

Perceptual learning effects have also been reported as improvements in intelligibility (word recognition accuracy) with atypical speech following a familiarization experience. These unfamiliar or degraded acoustic signals can vary significantly along multiple phonetic and/or prosodic dimensions to that of typically encountered speech. Intelligibility improvements have been demonstrated in listeners who received training with foreign-accented (e.g., Bradlow &Bent, 2008; Weill, 2001) and hearing-impaired speech (e.g., Boothroyd, 1985; McGarr, 1983), as well as artificially manipulated acoustic signals such as noise-vocoded (e.g., Davis &Johnsrude, 2007; Davis, Johnsrude, Hervais-Adelman, Taylor, &McGettigan, 2005), computer-synthesized (e.g., Francis &Nusbaum, 2009; Greenspan et al., 1988; Nusbaum &Lee, 1992), and time-compressed speech (e.g., Golomb, Peelle, &Wingfield, 2007; Pallier, Sebastian- Galles, Dupoux, &Christophe, 1998). As with phonemic category shiftresearch, it is postulated that the source of perceptual benefit occurs primarily at the segmental level of perceptual processing. When listeners are exposed to the atypical speech pattern, the unique and systematic acoustic-phonetic characteristics of the atypical signal are mapped onto a listener's existing phonological space, causing a shiftin perceptual representation of particular phonemes (e.g., Dupoux &Green, 1997; Francis, Nusbaum, &Fenn, 2007; Greenspan et al., 1988). This shiftis thought to benefit the cognitiveperceptual processes of speech perception, particularly lexical activation (e.g., reduced activation of a larger than necessary lexical cohort) and lexical competition (e.g., reduced competition for processing resources and increased likelihood of correct target selection), thereby yielding improved intelligibility.

On the basis of a number of findings, the most plausible account for these segmental benefits is that familiarization with the atypical signal induces an attentional shifttoward more phonetically informative acoustic cues (e.g., Francis, et al., 2007; Nusbaum &Goodman, 1994; Pisoni, Lively, &Logan, 1994). According to this explanation, training does not increase the quality or the quantity of the available acoustic information but rather directs cognitive resources to those cues considered most relevant for recognition of the unique signal. If training does in fact improve the distribution of attentional resources (i.e., increased attention toward more informative cues at the expense of less relevant information), then demands on working memory may decline, and improved recognition may result (Francis &Nusbaum, 2009).

Perceptual learning research using time-compressed speech, a signal characterized by systematic manipulation to its temporal characteristics, has demonstrated that listeners may also learn something about the global prosodic features of the speech signal-specifically, its rhythmic qualities (Pallier et al., 1998; Sebastian- Galles, Dupoux, Costa,&Mehler, 2000). The mechanism for this learning may be described as rhythmic expectancy, whereby listeners can anticipate and focus attention on high-yield aspects of the signal when they have adapted to the systematically varied rate and rhythm. Sebastian-Galles and colleagues (2000) examined perceptual learning of time-compressed speech across different language classes with distinguishably different rhythmic patterns (syllable-timed vs. stress-timed vs. mora-timed). They found that perceptual learning outcomes were

influenced by the rhythmic properties of the training signal. For example, familiarization with syllable-timed languages facilitated improved processing of other syllable-timed languages but not with signals characterized by another rhythmic pattern. This suggests that acoustic-phonetic remapping is not the only source of benefit that underlies experience-evoked intelligibility improvements and that suprasegmental learning may facilitate subsequent lexical segmentation of speech with similar rhythmic structure.

Traditionally assumed to have limited relevance to linguistic processing (e.g., Halle, 1985), a role for indexical information in perceptual learning of speech has recently been acknowledged (e.g., Loebach, Bent, &Pisoni, 2008). Nygaard, Sommers, and Pisoni (1994) found that listeners trained to identify the names of 10 unfamiliar speakers exhibited significantly greater recognition scores when presented with novel words produced by these same speakers relative to listeners presented with novel words produced by unfamiliar speakers. Similar perceptual benefits afforded by attention to indexical properties of the signal were observed with sentencelevel recognition in a follow-up study (Nygaard&Pisoni, 1998). In addition, the benefit of speaker familiarity on subsequent linguistic processing has been replicated with older individuals (Yonan &Sommers, 2000). More recently, Loebach et al. (2008) revealed that the perceptual benefit of training on indexical properties may also extend to the perception of noise-vocoded speech. Listeners engaged in a speaker identification task made significant intelligibility improvements and furthermore, the performance gains were as great as those achieved by listeners engaged in a linguistic-based transcription training task. Thus, these studies generate preliminary evidence that indexical information may also inform recognition of artificially degraded speech.

Taken together, it appears likely that multiple potential sources of perceptual learning exist. Although the evidence regarding learning sources and the relative contribution of different levels of information is limited, it may be presumed that familiarization with atypical speech enables listeners to extract something about the unusual regularities and that this facilitates improved perceptual processing in subsequent encounters. Until now, this tutorial has treated "familiarization" or "training" with atypical speech in a rather nebulous way. However, the specific ways in which listeners receive training vary on a number of levels, including familiarization material, familiarization conditions, and amount of familiarization. Such factors may or may not influence the longevity of learning and whether effects are generalized across stimuli and/or speakers. These characteristics of perceptual learning are discussed in turn.

Familiarization Material

Familiarization material describes the stimuli (usually speech) used to promote perceptual learning of the speech signal. Studies have reported that perceptual learning may be most robust when listeners are familiarized with real-word, rather than nonword, stimuli (e.g., Davis et al., 2005; McQueen &Mitterer, 2005; Norris et al., 2003). This suggests a lexical influence in perceptual learning of speech. When listeners were familiarized with an ambiguous phoneme embedded within word or nonword training material, category boundary shifts were identified only for those listeners trained with real words (Norris et al., 2003). Using noise-vocoded speech, a signal characterized by systematic manipulation to its spectral information, similar findings regarding the benefit of lexical information were reported (Davis et al., 2005). Listeners exposed to sentences containing real words demonstrated improved word recognition of the noise-vocoded speech, whereas a learning response was not identified for listeners exposed to a nonword sentence condition. When the familiarization material was further manipulated to remove sentence-level or syntactic information, it was found that sentence-level meaning did not appear crucial to perceptual learning. Specifically, listeners familiarized with syntactic prose sentences-grammatically correct sentences with real words but no sentence-level meaning (e.g., "the effect supposed to the consumer")- achieved similar perceptual learning effects as those of listeners presented with semantically coherent English sentences (Davis et al., 2005). Although this was the case, syntactic content alone did not appear to be the critical element behind perceptual learning. Listeners who were presented with jabberwocky sentences- sentences with real English function words but nonword content words (e.g., "the tekeen garung to the sumeeun")-exhibited significantly less perceptual learning than listeners trained

with sentences containing only real words. It was concluded that lexical information drove perceptual learning of noise-vocoded speech. However, both word and nonword familiarization conditions facilitated improved word recognition of noise-vocoded speech when exposure material comprised individual words, as opposed to sentencelevel stimuli previously used (Hervais-Adelman, Davis, Johnsrude, &Carlyon, 2008). Thus, lexical information may not be crucial to the facilitation of a perceptual learning response when the stimuli, as is the case with single words, can be accurately retained in short-term memory.

Familiarization Conditions

A second issue relates to the provision, or otherwise, of feedback to augment the auditory stimuli during familiarization-that is, whether knowledge of the atypical productions is required for perceptual learning outcomes to be realized. The evidence on this issue is varied. McQueen, Cutler, and Norris (2006) demonstrated that learning to categorize an ambiguous phoneme could be achieved with a simple auditory listening experience (passive familiarization). However, other studies have demonstrated that learning may necessitate more explicit familiarization, wherein listeners are provided with feedback about classification performance or written information regarding the intended lexical targets (e.g., Davis et al., 2005; Fenn, Nusbaum, &Margoliash, 2003). Learning of synthetic speech has been reported following passive experience with auditory stimuli (Koul &Hester, 2006; Reynolds, Isaacs- Duvall, &Haddox, 2002) and in studies in which a more explicit familiarization procedure has been used (e.g., Greenspan et al., 1988; Reynolds, Isaacs-Duvall, Sheward, &Rotter, 2000; Schwab, Nusbaum, &Pisoni, 1985). Studies comparing passive and explicit familiarization with noise-vocoded speech have reported superior learning when the degraded stimuli is supplemented with undistorted (auditory or written) versions of the spoken targets (Davis et al., 2005; Loebach, Pisoni, &Svirsky, 2010). In summary, it appears that perceptual learning may take place automatically when the learning entails subtle adjustments to an existing phonetic category distinction (e.g., Norris et al., 2003). However, adaptation to an entirely novel category distinction (e.g., Logan, Lively, &Pisoni, 1991) or to an acoustic signal with substantial acoustic degradation may require more explicit familiarization (e.g., Davis et al., 2005; Fenn et al., 2003).

Amount of Familiarization

The amount of familiarization listeners are afforded has also varied substantially across studies. Extremely rapid learning effects have been observed following less than 1 min of familiarization with natural changes in speech rate (e.g., Miller, 1981; Miller &Liberman, 1979) and spectral degradations (e.g., Summerfield, Haggard, Foster, &Gray, 1984; Watkins, 1981). Several minutes of familiarization enabled perceptual learning of time-compressed (Mehler et al., 1993; Pallier et al., 1998) and foreign-accented speech (Bradlow &Bent, 2008; Clarke &Garrett, 2004), whereas 25 min (Davis et al., 2005), nine 20-min sessions (Rosen, Faulkner, &Wilkinson, 1999), and four sessions of 1-2 hr (Stacey &Summerfield, 2007) of familiarization has been observed for learning to better recognize the noise-vocoded speech signal. Similar to the speculations made with familiarization conditions, as speech becomes increasingly degraded, longer periods of familiarization may be required for perceptual learning outcomes to be realized. Although there is no conclusive evidence regarding the amount of familiarization needed to achieve learning, studies to date would suggest that learning occurs relatively quickly, even for severely distorted speech.

Longevity of Learning

It appears that once learning has occurred, it can remain stable over a period of time. Eisner and McQueen (2005) observed that learning to categorize an ambiguous phoneme remained robust following a 25-min time lapse-even when passive listening to speech (which did not contain the ambiguous phoneme) occurred during the delay period. Learning effects were also reported following a lapse of 12 hr and moreover were not dependent on the opportunity for consolidation during sleep (Eisner &McQueen, 2005). In contrast, studies in which synthetic speech has been used have demonstrated the need for sleep to maintain learning effects over a 12-hr period (Fenn et al., 2003). Robust perceptual learning outcomes, measured in terms of vowel, consonant,

word, and sentence recognition, were observed 7-15 days following familiarization with noise-vocoded speech (McGettigan, Rosen, &Scott, 2008), and improved word recognition of synthetic speech was observed at a 6-months follow-up test task (Schwab et al., 1985). Although limited in terms of study numbers, preliminary evidence suggests that perceptual learning may not simply be a temporary adjustment to the listener's perceptual system. Rather, learning of the unusual regularities within the acoustic signal is long-lasting and facilitates permanent perceptual change.

Generalization of Learning

Studies have also demonstrated that perceptual learning effects can generalize between lexical items (e.g., Davis et al., 2005; Francis &Nusbaum, 2000). McQueen et al. (2006) and Norris et al. (2003) observed detectable changes in the categorization of an ambiguous phoneme in words that differed from the targets encountered during the familiarization task. This learning transfer was taken as evidence that learning may transpire at the sublexical level. Generalization of learning to untrained words has also been reported in the recognition of accented speech (Clarke &Garrett, 2004), noise-vocoded speech (Davis et al., 2005; Hervais-Adelman et al., 2008), and synthesized speech (Fenn et al., 2003; Francis &Nusbaum, 2000). Such findings further support the notion that perceptual representations may be modified, at least to some degree, at the level of the phonetic unit. Although the evidence for learning transfer across novel lexical targets is relatively robust, the support for cross-speaker generalization is less conclusive. Eisner and McQueen (2005) found that perceptual learning of an ambiguous fricative did not generalize to a novel speaker (i.e., one not included in the training condition). In contrast, Kraljic and Samuel (2006) reported cross-speaker generalization for perceptual learning of an ambiguous stop phoneme. That phoneme learning generalized across speakers in some situations, but not in others, may indicate variations in the amount of speaker-specific information afforded by particular phoneme productions (Kraljic &Samuel, 2006). Evidence of learning transfer across speakers has also been found in studies with foreign-accented speech (Bradlow &Bent, 2008; Weill, 2001) and time-compressed speech (Dupoux &Green, 1997; Kouider &Dupoux, 2005), when the speakers exhibit similar speech patterns (i.e., speech modified in the same manner). Finally, learning of vocoded speech has been found to generalize between acoustic characteristics (Dahan &Mead, 2010; Hervais-Adelman, Davis, Taylor, Johnsrude,&Carlyon, 2011). Although complete learning was achieved between different frequency regions (low-pass and high-pass filtered signals), carryover was limited between different carrier signals (noise bands, sine waves, and pulse trains; Hervais-Adelman et al., 2011) and stimuli with minimal phonetic similarity (Dahan &Mead, 2010). Taken together, the findings suggest that the ability and extent to which learning can be generalized may be dependent on the acoustic similarity between the training and testing stimuli.

Perceptual Learning of Dysarthric Speech

As the preceding discussion has established, perceptual learning research using healthy speech variants (nonnative) or laboratory-modified speech (e.g., time compressed or noise vocoded) presumes that listeners learn something about the regularities in atypical patterns and can apply that information to subsequent encounters with those atypical patterns. However, it is difficult to directly adopt this presumption when considering perceptual learning of dysarthric speech. The speech degradation that occurs in individuals with neurologic impairment is, by its nature, far from consistent. Speakers may deal with issues such as fluctuating muscle tone, inadequate respiratory support that worsens with fatigue, phonatory instability, and overarching deficits in articulatory movement coordination. Thus, although some acoustic features (e.g., hypernasality or breathiness) may be consistent and pervasive in a person's speech, others may vary widely (e.g., irregular articulatory breakdowns or variable speech rate). If we adopt the more general view of perceptual learning, we can hypothesize that those production features that are the most consistent and regular will be more "learnable." Subsequently, these features would be most salient for improving perceptual performance, relative to those aspects that are inconsistently expressed. By extension, dysarthrias with more consistent signal degradations (e.g., hypokinetic) would be expected to be more amenable to perceptual training than those with

more inherent variability (e.g., hyperkinetic). However, the role of acoustic consistency in perceptual learning remains largely untested. It may very well be that there is perceptual value in exposure to nonsystematic acoustic variation as well, even though the source of benefit could not be attributed to inducing a perceptual remapping. In this case, establishing "expectations of variability" may be the mechanism by which performance is enhanced. Recent work by Mattys and Liss (2008) has identified that words produced by a speaker with hypokinetic dysarthria were better recalled if played in the same voice, as opposed to a different voice, between the two successive blocks. This perceptual advantage of indexical consistency suggests that speakerspecific detail may inform recognition of dysarthric speech. Investigations have yet to document whether indexical information influences perceptual learning of dysarthric speech. It is imperative to establish "what is learnable" if perceptual learning is to be harnessed to build a theoretical account that supports, or otherwise, the development of listener-based treatment for the management of dysarthria.

To date, only a handful of studies have examined perceptual processing and changes to speech recognition for listeners familiarized with dysarthric speech. These are reported in Table 1.2 The majority of these studies have been clinically based and their findings largely equivocal. Although some reports have observed significant intelligibility gains for listeners familiarized with dysarthric speech (D'Innocenzo, Tjaden, &Greenman, 2006; Hustad &Cahill, 2003; Liss et al., 2002; Spitzer, Liss, Caviness, &Adler, 2000; Tjaden &Liss, 1995a, 1995b), others have not (Garcia &Cannito, 1996; Yorkston &Beukelman, 1983). Substantial variations in research designs limit the degree to which studies can be compared; however, they do provide valuable insight into variables that may influence the nature of perceptual learning with the dysarthric signal. In the following section, we summarize this body of research presented in Table 1 with regard to source(s) of learning and the variables that appear most salient in promoting improved recognition of dysarthric speech.

Learning Source

Traditionally, the dysarthrias are categorized by both type and severity, dependent on the presence of perceptual errors (segmental goodness) and patterns (e.g., speech rate and prosody, phonatory characteristics) and the degree to which these errors and patterns impact the integrity of the acoustic signal (Duffy, 2005). This conceptualization motivates the majority of studies of perceptual learning in dysarthria, wherein a wide variety of dysarthria types (flaccid, spastic, ataxic, hypokinetic, hyperkinetic, spastic-flaccid, spastic-hyperkinetic and spastic-ataxic) and severities (ranging from mild to severe) have been used. Furthermore, the few studies that have sought to identify a source of learning (i.e., "what is learnable?") have approached dysarthric speech signal characteristics in terms of segmental versus suprasegmental degradation.

To our knowledge, the first attempt to address "what is being learned" in a case of dysarthria was conducted by Tjaden and Liss (1995a). A nonnative English-speaking woman with cerebral palsy and a moderate-to-severe spastic-ataxic dysarthria provided the speech material. Normal hearing listeners transcribed her speech after first being familiarized with either her production of a read passage or with all of the words of the passage presented as a single read word list. It was expected that experience with the segmental and suprasegmental features in the read passage would be superior for perceptual learning than the single words, but ultimately both conditions benefitted intelligibility to the same degree beyond a control condition. Additional analysis confirmed that listeners learned the nonnative English regularities, such as substituting /l/ for /r/.

In subsequent work, Liss and colleagues attempted to develop dependent variables that would distinguish learning about segmental regularities from suprasegmental regularities. Liss et al. (2002) examined the lexical boundary error (LBE) patterns (errors that reflect a reliance on syllable stress contrasts to inform processes of lexical segmentation) of listeners familiarized with either ataxic or hypokinetic dysarthria. Although all listeners made the anticipated post-familiarization intelligibility gains, LBE findings revealed no significant difference in error patterns made by familiarized listeners when compared with same-signal transcriptions from nonfamiliarized listeners. It is possible that this result indicates that familiarization does not improve a listener's ability to perceive differences in syllable stress contrasts with ataxic or hypokinetic dysarthria. However, it is

also possible that the familiarization procedure used in Liss et al., just 18 phrases, was too brief to facilitate detectable changes to the processes of lexical segmentation.

In a post hoc exploration of these data, Spitzer et al. (2000) completed segmental error analysis of the listener transcripts of participants who received explicit familiarization using phrases produced by speakers with either ataxic or hypokinetic dysarthria. The authors observed changes to segmental error patterns for listener's familiarized with ataxic speech but not for those familiarized with hypokinetic speech. Listeners who heard and transcribed ataxic stimuli produced a higher proportion of target consonants in word substitutions and a lower number of substitution errors that were not phonemically related to the intended targets compared with listeners who simply transcribed the ataxic speech stimuli. Interestingly, this segmental level benefit was not enjoyed by listeners who heard and transcribed hypokinetic speech. Absence of segmental level changes for listeners familiarized with hypokinetic speech provides further support for the hypothesis that the source of learning may be dependent on type of dysarthria (Spitzer et al., 2000). However, the type of analysis used and, again, the fleeting familiarization procedure, must be considered. It is predicted that a more extensive familiarization procedure and a more elaborate multievel analysis of listener transcripts may reveal a more comprehensive picture of the cognitiveperceptual changes associated with perceptual learning of dysarthric speech. Nonetheless, present findings enable us to speculate that the source of learning is likely influenced by the characteristics of the signal to be learned.

Signal Characteristics

The importance of type and quality of signal characteristics is further supported by a number of findings in the literature. Hustad and Cahill (2003) observed immediate improvements in recognition of mildly dysarthric speech for listeners familiarized with just 10 phrases of the speech; however, at least 30 familiarization phrases were required for intelligibility gains to be realized with severely dysarthric speech. Consistent with these findings, Garcia and Cannito (1996) failed to report any intelligibility benefit for listeners who received a single 16-phrase familiarization experience with severe dysarthria. Thus, it could be hypothesized that learning to better understand severely degraded dysarthric speech may necessitate greater amounts of familiarization than that required to achieve learning of milder forms of dysarthria. When intelligibility scores of ataxic and hypokinetic speech stimuli were matched, Liss and colleagues (2002) found that perceptual benefits of familiarization were greatest for listeners who heard and transcribed phrases produced by the speakers with ataxic dysarthria. This suggests that the perceptual presentation of ataxic dysarthria may be more amenable to learning than that which characterizes hypokinetic dysarthria. Taken together, the small number of studies conducted thus far demonstrates that perceptual learning may be highly dependent on the characteristics of the signal to be learned. Although further investigation into the effect of signal type and severity on the intelligibility benefits afforded by a familiarization experience is warranted, existing literature reveals a likelihood that such a relationship exists.

Familiarization Conditions

To date, two types of familiarization conditions have been used in studies in which perceptual learning of dysarthric speech has been examined: passive familiarization (degraded signal only) and explicit familiarization (degraded signal and written transcripts of the target stimuli). A clear picture of how different conditions enhance learning outcomes when listeners are familiarized with dysarthric speech is yet to emerge (see Table 1). Some studies in which passive familiarization has been used have revealed intelligibility gains for familiarized listeners (Hustad &Cahill, 2003), whereas no perceptual benefit has been observed in other studies following a simple auditory experience with the degraded signal (Garcia &Cannito, 1996; Yorkston &Beukelman, 1983). Similarly, when explicit familiarization involving both the degraded signal and written information has beed used in studies, intelligibility gains have been documented in some (D'Innocenzo et al., 2006; Liss et al., 2002; Spitzer et al., 2000; Tjaden &Liss, 1995a) but not in others (Yorkston &Beukelman, 1983). To date, the one study in which intelligibility scores were directly compared following passive versus explicit exposure reported no

significant difference across the two familiarization conditions (Yorkston &Beukelman, 1983).

Amount of Familiarization

Conflicting findings regarding the benefit of different familiarization conditions are likely due, in part, to the varying amount of familiarization undertaken. For example, listeners who failed to exhibit intelligibility gains following passive familiarization were exposed to a short conversational sample (specific details not provided) of dysarthric speech (Garcia &Cannito, 1996). In contrast, passive familiarization to 40 phrases yielded significant perceptual gain for listeners (Hustad &Cahill, 2003). From this comparison alone, it appears that when familiarization is passive, a greater amount of training may be required for the learning response to be realized. Studies in which explicit familiarization procedures have been used indicate that amount of training may have less impact on the perceptual benefit of familiarization (see Table 1 for more details).

Listener Familiarity

Previously published studies in which intelligibility improvements for listeners familiarized with dysarthric speech have been reported have all used listeners naïve to this type of speech degradation (e.g., D'Innocenzo et al., 2006; Hustad &Cahill, 2003; Liss et al., 2002; Spitzer et al., 2000). The single study in which speech pathologists and student clinicians were used as listeners failed to observe intelligibility improvements when familiarized with dysarthric speech under either passive or explicit conditions (Yorkston &Beukelman, 1983). Thus, it could be speculated that the listeners in this study, presumed already familiar with dysarthric speech, had previously adapted to the degraded speech during unstructured interactions. Experimental studies on listeners familiarized with dysarthric speech have yet to investigate the role of listener familiarity in perceptual learning of dysarthric speech.

Developing a Perceptual Learning Approach to Management

Taken together, the small number of studies conducted thus far yield preliminary evidence that listeners can learn to better recognize neurologically degraded speech. Moreover, the studies provide insight into the possible learning sources that enable these intelligibility improvements to be realized. Improved word recognition for listeners familiarized with dysarthric speech reveals a potentially promising avenue for future intervention- that is, using a perceptual learning approach to address the intelligibility impairments that debilitate this population. Although such an approach may or may not afford clinical application to listeners already familiar with dysarthric speech, improving intelligibility for those unfamiliar with dysarthric speech, including family and friends of individuals with a recently acquired dysarthria (e.g., stroke, traumatic brain injury), holds significant value. Indeed, the importance of research into listener training was underscored almost a decade ago (Yorkston, Dowden, &Beukelman, 1992). In order to establish the efficacy of exploiting perceptual learning paradigms for rehabilitative gain in the management of dysarthria, a considerable amount of research is first required. In the subsequent section, we outline the initial steps required to develop a theoretical framework upon which future listener-targeted, perceptual learning approaches to the treatment of dysarthria can be developed. As some patterns and degrees of acoustic degradation are likely more amenable to learning than others, research in all four areas outlined below should be explored with dysarthrias of varying types and severities under comparable experimental conditions.

As a primary step, the establishment of strong empirical evidence supporting the existence of a perceptual learning effect resulting from experience with dysarthric speech is required. Although evidence of intelligibility improvements for listeners familiarized with dysarthric speech have been reported (see, e.g., D'Innocenzo et al., 2006; Spitzer et al., 2000), the absence of adequate experimental control has reduced the strength of existing findings. Research conducted thus far has attempted to assess the magnitude of perceptual learning effects by comparing intelligibility scores from listeners familiarized with dysarthric speech with nonfamiliarized listeners. In such cases, particularly where the training material affords similarities to the testing material, it is challenging to separate the perceptual improvements that result from familiarization with dysarthric speech from those that may arise simply from the familiarization experience (e.g., Hustad &Cahill, 2003; Liss et al., 2002). In order to

reliably attribute perceptual benefits to familiarization with dysarthric speech, research is required to include a control group, where listeners are familiarized with stimuli produced by neurologically intact speakers, age- and gender-matched to the speakers providing the dysarthric stimuli. Such comparisons would strengthen evidence of perceptual learning with dysarthric speech.

Once a perceptual learning effect has been established, a comprehensive picture of the cognitive-perceptual processes associated with improved recognition of the dysarthric signal is required. Common models of perceptual learning of speech assume an interactive integration of information, whereby bottom-up acoustic-phonetic information is supplemented with top-down linguistic and real-world information (Francis et al., 2007). From a theoretical vantage point, intelligibility improvements could arise from improved processing of any one, or combination, of the perceptual degradations that characterize dysarthria. To date, only two studies have begun to shed light on the possible cognitive-perceptual changes associated with intelligibility benefits following familiarization with dysarthric speech. These studies have examined source of learning from a segmental versus suprasegmental perspective and have proposed that the perceptual benefits associated with a familiarization experience may occur with improved processing of segmental information. However, evidence regarding the source of learning associated with improved recognition of dysarthric speech is limited, and present findings have not led to a clear answer. In order to provide a more complete picture of the source of learning associated with improved recognition of neurologically degraded speech, large-scale studies that consider the role of attentional mechanisms and resource allocation to linguistic (segmental and suprasegmental) and indexical features, with respect to both systematic and nonsystematic degradation, are required. Such knowledge is not only key to a theoretical framework of perceptual learning of the degraded signal but may further inform present models of perceptual processing with typical and atypical speech.

If high-level evidence regarding the perceptual benefit of familiarization with dysarthric speech is established and the source of such learning is identified, then research must seek to determine the conditions required to achieve this learning. As previously stated, a significant methodological variation across the existing research is found in the type of familiarization conditions used. There is evidence that learning may transpire automatically, as a result of passive familiarization to the degraded auditory productions (e.g., Hustad &Cahill, 2003). There is also evidence to suggest that more explicit familiarization involving supplementary written information may be required for perceptual benefits of familiarization to be realized (e.g., Liss et al., 2002). Existing research has yet to provide conclusive evidence on this matter. Accordingly, studies are needed to determine the conditions that promote improved recognition of dysarthric speech.

Clinically, the perceptual benefit of familiarization is only of functional value if improvements can persist over time. Therefore, research is also required to identify whether intelligibility improvements observed immediately following experience with dysarthric speech can remain stable over a period in which no further neurologically degraded speech input is received. Although studies of other forms of atypical speech have demonstrated that the intelligibility benefit following familiarization can continue following a significant time lapse (e.g., Lively, Pisoni, Yamada, Tohkura, &Yamada, 1994; McGettigan et al., 2008), the few studies in which perceptual learning has been examined with dysarthric speech have yet to investigate this phenomena. Bearing in mind the multiple segmental and suprasegmental distortions that characterize the dysarthric signal, improved recognition of dysarthric speech presumably involves a number of different processing levels and significant cognitive resources. Thus, investigation into the longevity of perceptual learning effects holds both clinical and theoretical significance.

Summary

The potential for perceptual learning of the dysarthric signal is considerable. If familiarization with dysarthric speech could facilitate improvements in a listener's ability to understand the neurologically degraded acoustic signal, then there is foundational evidence to support the use of perceptual learning paradigms in the development of a listener-based treatment program to address the intelligibility impairments. Primarily, a

perceptual learning rehabilitation approach would aim to increase intelligibility through improved signal processing for the trained listener. Although, ultimately, treatment that targets universal verbal interactions is the gold standard, any approach that improves communicative effectiveness affords significant clinical application. Listener training for the management of dysarthria may be particularly applicable in the following instances: when signal production does not improve with existing interventions; when speaker-oriented approaches are not recommended (e.g., in the case of flaccid dysarthria associated with myasthenia gravis); or when co-occurring physical deficits limit the utility of augmentative or alternative approaches (e.g., communication devices, gesture, etc). Moreover, treatment that targets perceptual processes may serve as an adjunct to speaker-orientated treatment to maximize performance outcomes with particular communication partners.

If we are to harness perceptual learning to build a theoretical account that supports the development of listener-based treatment for the management of dysarthria, a systematic programof study grounded in current models of perceptual processing is needed. Although a well-researched familiarization protocol with both familiar and unfamiliar listeners will ultimately be required, the initial stages of this research should establish strong empirical evidence of intelligibility improvements, investigate the source of learning, identify optimal learning conditions, and determine the longevity of learning, using listeners naïve to dysarthric speech. In this review, the notion of exploiting perceptual learning for rehabilitative gain has been framed within the context of dysarthria management, yet the scope of application is potentially much broader. Bearing in mind that the source of learning may be differentially influenced by the nature of the acoustic degradation, treatments that target perceptual processes may be extended to any situation in which intelligibility is compromised (e.g., foreign-accented speech, Deaf speech, speech processed through cochlear implants, or synthesized speech systems).

Acknowledgments

Primary support for this manuscript was provided by a University of Canterbury Doctoral Scholarship (awarded to the first author).We also gratefully acknowledge support from New Zealand Neurological Foundation Grant 0827-PG and Health Research Council of New Zealand Grant HRC09/251 (both awarded to the second author) as well as National Institute on Deafness and Other Communication Disorders Grant R01 DC 6859 (awarded to the third author).

Footnote

1Perceptual learning is reviewed with respect to experimental studies in which manipulation of the listener experience (familiarization/training) has been examined.

2Relevant studies were identified by electronic databases searches of PsycINFO, MEDLINE, CINAHL, and PubMED. The searches were composed of keywords (e.g., perceptual learning, familiarization, adaptation) paired with the term dysarthria. In addition to these electronic searches, hand searches of studies cited within an article were conducted. From this large search, those citations in which listeners were familiarized with dysarthric speech were abstracted by the first author in Table 1.

Abstract: Speech audiometry is an essential component of the audiological test battery, as it provides information concerning one's sensitivity to speech stimuli and the understanding of speech at supra-threshold levels. With regard to the history of materials for speech audiometry, different kinds of materials have been

developed by several investigators in English and non-English languages. Several such attempts have also been made to develop and standardize materials for speech audiometry in Indian languages. With reference to Telugu (South Indian Dravidian Language) no such material is available for measuring open-set speech recognition score in adults. Telugu is mother tongue of the majority of people of Andhra Pradesh (Southern State of India) which is divided into three regions. Although, the mother tongue of majority of people of Andhra Pradesh is Telugu, some of the most familiar and frequently used words in one region may not be familiar to people belonging to other regions due to dialectal variations. The purpose of this study is to develop speech material in Telugu which can be commonly used to assess speech recognition performance of individuals belonging to three regions. Four lists of bisyllabic words in Telugu were developed and equivalence analysis of difficulty between the word lists was evaluated for three groups (from three regions) of subjects (age range of 18-25 years) with normal hearing. Subsequently, performance intensity (PI) function for each list was also measured for the three groups. The results revealed that there was no significant difference ($p<0.05$) between scores obtained by three groups for each list and between four lists for each group. The four word lists developed were found to be equally difficult for all the groups. The performance-intensity (PI) function curve showed semi linear function, and the linear portion of the curve indicated an average linear slope showing 4.64%, 4.62%, 4.52% and 4.54% increase in word recognition score per dB for list 1, list 2, list 3 and list 4 respectively and were found be in accordance with the findings of earlier studies. The four lists thus developed were found to have sufficient reliability and validity in assessing speech recognition performance.

I. INTRODUCTION

Speech perception is defined as the process of decoding a message from a stream of sounds coming from the speaker (Borden &Harris, 1980). The study of speech perception is concerned with the listener's ability to perceive the acoustic waveforms produced by a speaker as a string of meaningful words and ideas (Goldinger, Pisonic &Logan, 1991). The components of speech perception and production are closely related and have been studied extensively for decades. Hearing is a vital sense that is necessary for the development and maintenance of acoustic communication skills. Hearing is the building block on which our intricate human communication system is constructed. Speech is one of the most important vehicles of human communication system. In order to hear and comprehend speech, it requires good auditory integrity. Individuals with hearing loss are bound to have difficulty in perception of speech. Therefore, it is the essential duty of audiologists to identify, evaluate and rehabilitate aurally handicapped individuals.

Aural rehabilitation refers to services and procedures for facilitating adequate receptive and expressive communication in individuals with hearing impairment (ASHA, 1984). Aural rehabilitation is designed to minimize the communication deficits caused by hearing loss. The first step in this process is a thorough evaluation of the audiological dimensions of the hearing loss. There are several clinical tests, which help the audiologist to make an accurate and effective diagnosis. The evaluation of an individual's hearing involves administering a battery of tests and these assessments collectively complement each other in defining the degree, type and configuration of hearing loss. Audiological evaluations also intend to provide information that describes the functional impact of hearing loss on communication. The principle tool used in the process of evaluating a patients auditory functioning is an audiometer. Audiometer is an electronic device that produces and delivers sounds as a stimulus to the patient and determines the intensity needed for a patient to hear those sounds. The sounds used to test a person's hearing must be clearly specified so that his hearing thresholds are both accurate and repeatable. The two most common sound stimuli used clinically to assess hearing are pure tones and speech. Each of them can provide valuable information concerning the integrity of the auditory system. Audiological assessment using non-speech signal such as pure-tones is known as pure-tone audiometry. On the other hand, audiological assessment using speech signal such as syllables, words, sentences etc. is known as speech audiometry.

Pure tone audiometry often thought of as the hearing test that involves presenting a series of pure-tones or beeps to the listener at specific frequencies to establish a person's hearing acuity. The smallest intensity of a sound (pure-tone) that a person needs to detect its presence is called his threshold for that sound. Clinically we define the threshold as the lowest intensity at which the patient responds to the sound at least 50% of the time. The hearing loss of an individual is usually defined as the average of pure-tone thresholds at 500 Hz, 1000 Hz and 2000 Hz in the better ear expressed in decibels (dB) with reference to normal thresholds. Pure-tone audiometry reveals the degree and type of hearing loss, and also facilitates the decision as to the need for further tests or medical interventions. The process of pure tone audiometry is uncomplicated and easily administered. "Identification of the stimulus by the listener presumes a relatively simple neural apparatus and the response usually raising the hand is not complex one" (Schill, 1985). Puretone audibility thresholds are an important part of many specialized procedures for testing auditory function as well as in evaluating hearing aids and other rehabilitation devices and in rehabilitation planning.

In spite of having such advantages, pure-tone audiometry alone has many limitations. Pure-tone audiometry does not provide all needed information for assessment of the auditory system. It serves the possibilities but not realities and helps in estimation only. Assessment of hearing using pure tones provide information regarding the sensitivity but not on the receptive auditory ability (Marshal &Bacon, 1981). The conventional pure tone procedures fail to provide any information about a person's ability to hear above the threshold. Pure tone audiometry can only assess the auditory system's ability to hear a simple stimulus and does not provide information about the individual's ability to understand speech. Ability to perceive pure tones does not require any psychic integration or synthesization thus the results are inadequate in the diagnosis and differential

diagnosis of various auditory disorders (Willeford, 1969; in Kholia, 2010, p. 2).

To find out the ability of a patient to hear speech involves testing him with speech stimuli, and this process is called speech audiometry. Carhart (1951) defined speech audiometry as the technique where in standardized samples of a language are represented through a calibrated system to measure some aspect of hearing ability. Speech audiometry means any method of assessing the state or ability of the auditory system of an individual, using speech stimuli or sounds as the response evoking stimuli (Lyregaard, 1976). The above two definitions are broadly similar and they emphasize that the purpose of speech audiometry i.e. to assess the ability of the auditory system to understand speech. According to James Jerger, speech audiometry is best friend in the clinic for audiological diagnosis (Kholia, 2010). Speech stimuli used in speech audiometry vary from consonants, phonetically balanced words, spondee words, digits, non-sense syllables, sentences and even continuous digit discourse. Speech sounds are more meaningful and reflect the critical activities of life and the comprehension of social communication. We live in an oral-aural society and hence the most measurable aspect of human auditory function should be the ability to understand speech. In summary speech tests are generally regarded as clinically more acceptable than pure-tone audiometry for identifying patients with poor auditory analytical capability, because they also involve the assessment of higher-level linguistic activities and the effects of contextual constraints in processing auditory information (Wang, Mannell, Newall, Zhang &Han, 2007).

II. BACKGROUND OF THE STUDY

A. Speech Recognition Score (SRS)

Speech recognition score (SRS) or word recognition score (WRS) or speech identification score (SIS) is a procedure of establishing the percentage of correctly perceived phonetically balanced monosyllabic words or consonant vowel combination presented at a comfortable supra-threshold level. Evaluating speech recognition score is a method where in the subject is presented with a series of stimuli and is asked to identify what he has heard and results are reported in terms of percentage on the basis of correctly repeated words presented to him. The phonetically balanced lists (PB lists) refer to the list of words consisting of a group of single words so selected that the frequency of occurrence of speech sounds within a group is same as the frequency of occurrence of the same sound in a language. Carhart (1965) recommended the use of monosyllabic words for discrimination test since they are meaningful to the patient and are non-redundant.

B. Clinical Functions of Speech Recognition Score

Gelfand (2007) has listed the following clinical functions of speech recognition score testing: 1) to describe the extent of hearing impairment in terms of how it affects speech understanding 2) to differentially diagnose auditory disorders by determining the anatomical site of lesion 3) for determining the needs for amplification and other forms of aural rehabilitation devices like cochlear implants, bone anchored hearing aids etc. 4) for making comparisons between various hearing aids, amplification approaches and other forms of aural rehabilitation devices 5) for verifying the benefits of hearing aid use and other forms of aural rehabilitation devices 6) for monitoring patient performance over time for either diagnostic or rehabilitative purpose.

C. Materials Available for Measuring Speech Recognition Score

With regard to the history of materials for speech audiometry testing, different kinds of materials have been developed by several investigators in English and used in clinics over a long period. The material available in English may not be appropriate for many of the world's other languages due to speaker's specific language or dialect. As it is difficult to test individuals whose native language is not English, there has been a spurt in the attempts to develop speech materials in non-English languages such as Spanish (Christensen, 1995), Italian (Bocca &Pelligrini, 1950 and Turrini, Cutugno, Maturi, Prosser, Leoni &Arslan, 1993), Portuguese (Harris, Goffi, Gygi &Merrill, 2001), Polish (Harris, Nielson, Mcpherson, Skarzynski &Eggett, 2004), Mandarin Chinese (Nissen, Harris, Jennings, Eggett &Buck, 2005), Russian (Harris, Nissen, Pola, Mcpherson, Tavartkiladze &Eggett, 2007) and Tongan (Seaver, 2008). Several such attempts have also been made to develop and standardize speech audiometric materials and tests in Indian languages including PB word list in English on

Indian population (Swarnalatha, 1972), PB word list in Hindi (De, 1973), PB word list in Tamil (Dayalan, 1976), PB words in Manipuri (Devi, 1985), PB word list in Kannada ((Yathiraj &Vijayalakshmi, 2005), PB word list in Mizo (Mangaiahi, 2009), PB word list in Rajasthani (Kholia, 2010). With reference to Telugu (South Indian Dravidian Language) no such material is available for measuring open-set speech recognition score in adults. Hence there is a need to develop such speech material and the current study aimed at developing word lists in Telugu for assessing speech recognition scores in adult subjects.

D. Telugu (a South Central Dravidian Language Spoken in South India)

Telugu is South Indian Dravidian language and has the third largest number of native speakers in India, and is 13th in the ethnologic list of most- spoken languages worldwide. It is the official language of Andhra Pradesh (state in south India), one of the largest states of India and the mother tongue of the majority of people of Andhra Pradesh. It is also spoken in such neighboring states as Karnataka, Tamilnadu, Orissa, Maharashtra and Chhattisgarh, and is one of the 22 scheduled languages of India. Niccolo Da Conti in 15th century called Telugu as the 'Italian of the East' as the words in Telugu end with a vowel sound similar to Italian. Telugu is mother tongue of the majority of people of Andhra Pradesh state. Andhra Pradesh is divided into three regions namely Telangana, Rayalaseema and Coastal Andhra. Although, the mother tongue of majority of people of Andhra Pradesh is Telugu, some of the most familiar and frequently used words in one region may not be familiar to people belonging to other regions due to dialectal variations. A number of studies on speech audiometry have indicated that the validity and reliability of speech recognition testing can be influenced by several factors, such as familiarity, words in common usage, normal sampling of speech sounds and so on. The word list developed by keeping in mind 'familiarity and commonly used' words with reference to particular region may not be useful to assess speech recognition performance in people belonging to other regions of Andhra Pradesh. Hence there is a need to develop material for assessing speech recognition score which includes words which are familiar and commonly used by people belonging to all the regions of Andhra Pradesh.

III. METHOD

Till date with reference to Telugu language no such material is available for measuring open-set speech recognition performance. The purpose of the study was to develop and evaluate word lists in Telugu for assessing speech recognition performance. In order to fulfill the aim of the study, the following method was adopted. The study was conducted in four phases:

Phase I: Development of word lists in Telugu as a test material for assessing speech recognition performance.

Phase II: Recording of the test material.

Phase III: Equivalence analysis of developed word lists.

Phase IV: Assessing performance-intensity (PI) function of normal subjects.

A. Phase I: Development of Word Lists in Telugu

The following steps were involved while developing the word lists in Telugu for assessing speech recognition performance: 1) Collection of words 2) Familiarity assessment of collected words 3) Subjective validation of words 4) Pilot study for objective validation of words 5) Construction of final word lists.

1. Collection of words in Telugu

The words were collected from different sources like periodicals, newspapers, magazines, journals, general books, phonetic books and spontaneous speech. This resulted in an accumulation of about 500 words in Telugu. The words collected were disyllabic in structure. These words were further subjected to familiarity assessment, subjective validation and objective validation in order to construct final word lists in Telugu for assessing speech recognition performance.

2. Assessment of familiarity of the collected words

The collected words were assessed for familiarity in order to ensure that the selected words were known to native speakers of Telugu and were commonly used by people belonging to different regions of Andhra Pradesh. To assess the familiarity of the selected words, a total of 90 subjects (age range of 18-25 years) from

different regions of Andhra Pradesh who are native speakers of Telugu language (Coastal Andhra, Rayalaseema &Telangana) were included. The subjects were further equally subdivided into three groups (30 subjects in each group) based on the above mentioned regions. A three point rating scale was used for familiarity rating as: most-familiar, familiar and unfamiliar. From the obtained results, the words with most-familiar and familiar rating were listed for each group (three regions). The obtained words of most-familiar and familiar rating were further assessed for homogeneity across individuals from the three regions. A hierarchical arrangement of the most-familiar and familiar rated words was done. The words with most-familiar and familiar response from the three different groups were considered for further assessment.

3. Subjective validation of test items

Validity refers to a degree to which a study accurately reflects or assesses the specific concept that the researcher is attempting to measure. Validity is the extent to which the concept one wishes to measure is actually being measured by a particular scale. To fulfill the purpose of validity of words in the test material, content validity was carried out to the words. Content validity is based on the extent to which a measurement reflects the specific intended domain of the content (Caramines, 1991). Content validity is based on logic and expertise. This type of validity is used because this technique helps the researcher to review how the essential test items can attribute the test measures. For the purpose of carrying out the content validity, the developed familiar words were given to six experts working in the field of Speech Language Pathology, Audiology and Linguistics. The experts were explained about the purpose of test procedure and asked to respond whether the words selected would fulfill the purpose. The responses of the experts were collected as agree, disagree and suggestions. Word wise validation of the material was done. A hierarchal arrangement of the agreed words was done. The only words which were agreed by all the experts were selected for further assessment.

4. Pilot study for objective validation of test items

A pilot study is a miniature version of a study that the researcher uses to test the validity of the collected words prior to the actual study. The pilot testing involves administering the test procedure using the collected words on a sample of normal subjects and analyzing the obtained data. This was carried out to ensure whether the words collected on the basis of familiarity assessment and expert validation can fulfill the goal of the speech recognition score testing. It is important that the test procedure be given in a situation that matches the actual circumstances in which test will be done. The pilot study was intended to identify the words which would be recognized or identified by a group of normal hearing subjects at an intensity level where it is expected to be recognized or identified correctly. It is generally expected that high speech recognition scores are obtained at levels of 30-40 dB SL relative to the SRT (Gold, Lubinsky &Shahar 1981; in Silman &Silverman, 1991, p.141). Hence a presentation level of 40 dB SL with reference to SRT is used for the pilot study.

a. Subjects

A total of 45 subjects in the age group of 18-25 years with normal hearing and no speech disorders served as subjects. All the children were native speakers of Telugu language. The subjects were further equally divided into three groups (15 subjects in each group) depending on their region of Andhra Pradesh. Group I: subjects belonging to Costal Andhra region, Group II: subjects belonging to Rayalaseema region and Group III: subjects belonging to Telangana region.

b. Audiometric testing

The audiometric assessments including otoscopic examination, pure-tone audiometry, speech audiometry and tympanometry were conducted to ensure that suitable subjects with normal hearing were selected for the experimental procedures. The pure-tone average threshold (PTA) and speech recognition threshold (SRT) was obtained for all the subjects using Maico MA 53 diagnostic clinical audiometer with TDH 39 headphones. Tympanometry was carried out using Madson Zodiac 901 middle-ear analyzer.

c. Administration procedure

The subjects were tested in a sound-treated audiometric room. The examiner presented the speech stimuli

using monitored live voice, ensuring that the deflection of the VU meter was zero. A distance of 6-9 inches was maintained between the microphone and the mouth of the tester. Each subject was given following instructions in Telugu "you will listen to the words presented through headphones. Listen carefully and when you hear a word repeat the word in a loud voice". Initially ten practice items were presented in order to familiarize the subjects about the test procedure. If the subjects felt tired during the test, a short break was given. All the words obtained after subjective validation were presented at presentation level of SRT+40 dB SL. The stimulus was presented through Maico MA 53 diagnostic clinical audiometer with TDH 39 headphones.

d. Selection of words for constructing final word lists

The words which were correctly recognized or identified by each group of subjects were arranged in a hierarchical order. The words which were correctly recognized or identified by the three groups of subjects were selected for preparing final lists of phonemically balanced bisyllabic words for assessing speech recognition performance. This has resulted in an accumulation of 320 words.

e. Preparation of final bisyllabic word lists

Classical Telugu consists of 35 consonants, 10 vowels and 2 diphthongs (Ramanarasimham, 1998). When it comes to spoken Telugu the lower mid vowel /æ / is used in it (Krishnamurti, 1998). Out of the total consonants 23 are considered as core and 12 are considered as non-core phonemes (Ramanarasimham, 1998). Although such a classification of core and non-core phonemes exists in Telugu, the final word lists were prepared based on the frequencies of occurrence of the phonemes in the Telugu corpus available in Centre for Applied Linguistics and Translation Studies Language Technology Lab, University of Hyderabad, India. The phonemes which have frequencies of occurrence of equal to or more than 0.5 were only considered while preparing the final word lists. The phonemes on which the test items were constructed were based on the frequencies of occurrence of phonemes in Telugu (Rao &Thenarasu, 2007). As the number of consonantal phonemes in each word list was coming to 49 and in order to balance the each word list with 50 phonemes (consonant), phoneme /l/ was repeated in the list 1 and phoneme /t/ was repeated in list 2, list 3 and list 4 as per the convenience. A total four final word lists and one practice word list were prepared for assessing speech recognition performance. All the words were disyllabic with the CVCV structure. However, words like /uru/ 'village', /et u/ 'which side' and /edi/ 'which one' which are VCV in structure were also included in the final word lists. Due to limited number of words with /s / in CVCV structure, the word /s apu/ 'shop' is included in list 2 and list 4. Each final word list consisted of 25 words (with a total of 100 words) and a trial list consisted of 10 words. After constructing the four final word lists, each final word list was again randomized into five times forming five different lists (with a total of 20 lists) for further assessment.

B. Phase II: Recording of the Test Material

The recording was done in a sound treated room and the noise levels were maintained as per the ANSI Guidelines S3.1-1991. Each randomized word list was spoken by a female native speaker of Telugu, and was recorded using 16 KHz sampling rate and 16 bit quantization using computerized speech lab (CSL) 4500 software. The signal was digitized at a sampling rate of 16 KHZ using a 12 bit analog to digital converter housed within the computer. Each word was saved as a separate file. The recorded material was then edited to carry out noise and hiss reduction. Amplitude normalization of the signals was done using adobe audition (version 3.0) software to maintain the constant amplitude across the words. The inter stimulus interval between the two words was set to 4 seconds. A calibration tone of 1 KHz was inserted before beginning of the word list to adjust the vu meter at zero. The material was then copied onto an audio compact disc using a compact disc writer.

C. Phase III: Assessing Equivalence Analysis of Word Lists

A formal study was carried out to evaluate the equivalence between four lists and comparing the performance of three groups for each list for further performance- intensity function assessment. In order to assess the equivalence between lists the following method has been formulated.

1. Subjects

A total of 90 subjects in the age group of 18 - 25 years with normal hearing and no speech disorders served as subjects. All the children were native speakers of Telugu language. The subjects were further equally divided into three groups (30 subjects in each group) depending on their region of Andhra Pradesh. Group I: subjects belonging to Costal Andhra region, Group II: subjects belonging to Rayalaseema region and Group II: subjects belonging to Telangana region.

2. Audiometric testing

The audiometric assessments including otoscopic examination, pure-tone audiometry, speech audiometry and tympanometry were conducted to ensure that suitable subjects with normal hearing were selected for the experimental procedures. The pure-tone average threshold (PTA) and speech recognition threshold (SRT) was obtained for all the subjects using Maico MA 53 diagnostic clinical audiometer with TDH 39 headphones. Tympanometry was carried out using Madson Zodiac 901 middle-ear analyzer.

3. Administration procedure

A total of 100 words equally divided into four final lists containing 25 words in each list (list 1, list 2, list 3 and list 4) were used as stimulus. Each word list was randomized in order for 5 times to form five different lists and a total of 20 different word lists (random 1, random 2, random 3, random 4 and random 5 of list 1, list 2, list 3 and list 4). This was done to avoid order and practice effect. The developed test material was played through a CD player, which was routed through Maico MA 53 diagnostic clinical audiometer and delivered through the TDH 39 headphones. The stimulus was presented at five presentation levels (5 dB SL, 15 dB SL, 25 dB SL, 35 dB SL and 45 dB SL with reference to SRT). At each presentation level a different randomized list was used. The order of list was also changed. All the subjects were tested monaurally with four lists and ear selection was done randomly. An open set response in the form of an oral response was obtained. If the subject felt tired during the test, a short break was given. The subjects were tested in a sound-treated audiometric room. Each subject was given following instructions in Telugu "you will listen to the disyllabic words presented through headphones. Listen carefully and when you hear a word repeat the word in a loud voice". Initially ten practice items were presented in order to familiarize the subjects about the test procedure. The responses of the subjects were marked as either 0 or 1. Each correct response was given a score of 1 and an incorrect response was given a score of 0. The raw score was then converted to percentage as follows:

...

D. Phase IV: Performance-Intensity (PI) Function Testing

Performance-intensity function is a graphical representation of the percentage of words correctly identified or recognized as a function of the intensity level of the words. The group mean and standard deviation values for each list at different presentation levels were calculated. These mean speech recognition scores at different presentation levels were used to obtain performance intensity function curve of each group for four lists. Various researchers have stated that performance of the subjects vary with the level of intensity of presentation of stimulus. Therefore, in order to find out the intensity level at which the performance could be maximum, the presentation level was increased in 10 dB steps starting from the 5 dB SL. Curve estimation and regression analysis were carried out in order to find out linearity function of the performance intensity function curve and to find out the average percentage (%) increase per dB in word recognition.

IV. ANALYSIS OF RESULTS

A. Equivalence Analysis of Word Lists

Speech recognition scores were calculated for each subject of three groups at each presentation level for four lists. Inter-list equivalence analysis was carried out by calculating the mean and standard deviation values of each group score for each list at different presentation levels. The mean and standard deviation values for each list at different presentation level for three groups are summarized in table 1. It has been found that with increase in presentation level, there was a corresponding increase in mean speech recognition scores in all the groups for four lists used. Each list showed normal distribution in all the groups. The data was subjected to

ANOVA in order to find out significant difference in speech scores of each group between four lists. The results indicated that there was no statistically significant difference between scores of each group between four lists ($p<0.05$). In addition to this the group score comparison was also carried out to find out any significant difference in groups mean score between four lists. The results indicated that there was no statistically significant difference in groups mean score between four lists ($p<0.05$). Finally the mean score comparison between three groups for each list was also carried out to find out significant difference in scores of each list between three groups. The results indicated that there was no statistically significant difference in mean score of each list between three groups ($p<0.05$). Hence it can be concluded that all the four lists are equally difficult for all the groups and could be used in testing the PI-PB function.

B. Performance-Intensity (PI) Function Testing

Performance-intensity function is a graphical representation of the percentage of words correctly identified or recognized as a function of the intensity level of the words. The group mean and standard deviation values for each list at different presentation levels are summarized in table 2. These mean speech recognition scores at different presentation levels were used to obtain performance intensity function curve of each list for three groups. Figure 1 shows group mean performance intensity function curve for list 1, list 2, list 3 and list 4. The mean word recognition scores increased as the presentation levels increased and the subjects reached 100% scores at SRT+35 dB SL for all the lists. This remained unchanged thereafter at higher intensity i.e. at SRT+45 dB SL. However, the normal range of recognition scores (90%-100%) was obtained at 25 dB SL with reference to SRT for all the lists. Clinically the most commonly used sensation levels are 25 to 40 dB SL. Twenty five dB SL corresponds to beginning of the plateau at which normal hearing subjects attains scores of 90% or better on most tests, and 40 dB sensation level represents a reasonably comfortable listening level for normal hearing subjects. The results revealed a narrow standard deviation for extreme presentation levels while broad standard deviation for low and mid presentation levels. When curve estimation and linear regression analysis were carried out, the performance intensity function curve represented a semi-linear function in all the groups. The lower segments of the curves are more linear as compared to less linear higher segments. Linear regression analysis showed that the linear portion of the function indicated an average linear slop showing 4.64%, 4.62%, 4.52% and 4.54% increase per dB in word recognition for list 1, list 2, list 3 and list 4 respectively.

V. DISCUSSION

Speech audiometry testing is generally regarded as clinically more acceptable than pure-tone audiometry for identifying individuals with poor auditory analytical capability, because they also involve the assessment of higher-level linguistic functions and the effects of contextual constraints in processing auditory information. Telugu is South Central Dravidian language spoken most commonly in Andhra Pradesh a southern state in India. With reference to Telugu, only a limited number of materials have been developed for use in speech audiometry. To date no speech material is available in Telugu to measure open set speech recognition scores in adults. Hence, the current study aimed at developing speech material for assessing speech recognition performance of adults in Telugu. A number of authors have indicated that the reliability and validity of speech audiometry testing can be influenced by factors such as the familiarity, phonetic balance of the words and type of stimulus used (Mackie &Dermody, 1982; Borden &Harris, 1980 and Nissen, Harris, Jennings, Eggett &Buck, 2005).

As mentioned earlier, Telugu is the mother tongue of the majority of people of Andhra Pradesh state which is divided into three regions. Although, the mother tongue of majority of people of Andhra Pradesh is Telugu, some of the most familiar and frequently used words in one region may not be familiar to people belong to other regions. The word list developed by keeping in mind 'familiarity and commonly used' words with reference to particular region may not be effective to assess speech recognition performance in people belonging to other regions of Andhra Pradesh. Hence there is a need of material for assessing speech recognition performance which includes words which are familiar and commonly used by people belonging to all the regions of Andhra

Pradesh. Hence, by considering 'familiarity' as an important factor in developing the word list, the authors in the current study carried out familiarity assessment among the subjects with different regional background and developed four lists of bisyllabic words.

The concept of phonetic balance played a major role in the development of many speech recognition tests. The phonetically (or rather phonemically) balanced (PB) word lists are a long established tool for the study of speech intelligibility. They generally contain monosyllabic words that have been selected in such a way that the lists reflect the statistical distribution of the phonemes in that dialect. However, phonetic balance has been found to have little practical impact on the outcomes of speech recognition tests, and its clinical relevance is questionable (Carhart, 1970; In Gelfand, 2007, p.274 and Aspinall, 1973; In Gelfand, 2007, p.274). Boothroyd (1968; in Wang et al. 2007, p.1-2) did not follow the concept of phonetic balance and developed the AB monosyllabic word lists with 10 words in each list, and described the lists as isophonemic, as the thirty most common phonemes appear in each list. Martin, Champlin &Perez (2000) reported that speech discrimination scores for subjects with hearing impairment or normal hearing did not seem to be affected by whether the word list had phonetic balance or not. Hence, in terms of its relevance to speech recognition testing, the issue of phonetic balance is still an area of dispute (Nissen, Harris, Jennings, Eggett &Buck, 2005). However, the authors in the current study felt that phonemic balance is important at least for consonants.

Vowels are produced without obstruction in the airflow and perceived better than consonants because they are voiced and relatively high in intensity. Vocal tract is relatively open for them producing prominent resonance for vowels. The first two formant frequencies (F1 &F2) are essential for the discrimination of the vowel sounds. Vowels are more accessible to auditory analysis by virtue of their longer duration and may hold longer duration in the auditory memory (Stevens, 2002). On the other hand, consonants are produced with the obstruction in the airflow. Consonants are classified according to whether they are voiced or unvoiced, by manner of production (stops, fricatives, nasals etc.) and by place of production (labial, alveolar, palatal etc.). Consonant sound identification is more dependent upon the ability to receive the higher frequency components. If these are inaudible, the place of consonant articulation cannot be determined, thus precluding identification. Although, most of the consonants contain the least power than vowels, these consonants are the ones which provide the major contributions of speech intelligibility. They are affected by loss of intensity rapidly than vowels. Hence, consonants are less accessible to auditory analysis due to their brevity and relatively low intensity, and held briefly in auditory memory (Stevens, 2002). Thus it could be inferred from the above information that perception of consonants is much more complex than vowel perception, due to the low intensity, more susceptible to degradation and varied classifications. This makes it a priority to consonantal aspect of phonemic balance in the word lists. Hence, the authors in the study considered that consonantal aspect of phonemic balance is reasonable while developing the word lists.

Another important aspect is the type of speech material used for assessing speech recognition scores. Monosyllabic words are generally used for assessing speech recognition scores, because monosyllabic words are minimum meaningful unit of a language and are non-redundant. Monosyllables are adequately available in languages like English and other Indian languages, because they are both vowel and consonant ending languages. But some are vowel ending languages where the occurrence of monosyllabic words will be minimal. In such languages it is difficult to construct phonetically balanced monosyllabic word lists because of the inadequate occurrence of meaningful monosyllables. In language like Italian, bisyllabic words are most frequently used as compared to monosyllabic words for developing speech material in evaluating intelligibility function (Turrini, Cutugno, Maturi, Prosser, Leoni &Arslan, 1993). Bocca &Pelligrini (1950) and Turrini, Cutugno, Maturi, Prosser, Leoni &Arslan (1993) developed disyllabic words as a material for speech audiometry. This could be attributed to the reason that, there are very few monosyllabic words in Italian, and most of them are function words (Pagliuca &Monaghan, 2010) since Italian is a vowel ending language. Similarly in Kannada (south Indian Dravidian language) disyllabic words are used to assess speech recognition scores (Yathiraj

&Vijayalakshmi, 2005) as Kannada is also a vowel ending language.

The authors in the current study also faced difficulty in collecting monosyllabic words for constructing test material in Telugu. There are very few monosyllabic words in Telugu as compared to bisyllabic words (Rao &Thenarasu 2007). Moreover, most of the monosyllabic words in Telugu do not convey meaning when they occur in isolation. These monosyllabic words gain meaning only when they occur in combination with some other word. This could be attributed to the reason that Telugu is yet another vowel ending language like Italian and Kannada. Hence, Niccolo Da Conti in 15th century called Telugu as the 'Italian of the East' as the words in Telugu and Italian end with a vowel sound. Disyllabic words are frequently occurring minimum meaningful units of Telugu language. Hence disyllabic words were used in constructing test material for assessing speech recognition performance in Telugu. In summary speech recognition scores are the percentage of correctly identified or recognized monosyllabic words, provided the language contains adequate number of meaningful monosyllabic words. However, languages which end with vowel do not contain adequate number of meaningful monosyllabic words and hence disyllabic words can be used since they are the most frequently occurring minimum meaningful units of that particular language. Hence it can be concluded that speech recognition score is the percentage (%) of correctly identified or recognized test words which are minimum meaningful units of a language and less redundant and presented at comfortable supra-threshold level.

A total four final word lists and one practice word list were prepared for assessing speech recognition performance. All the words were disyllabic with the CVCV structure. However, words like /uru/ 'village', /et u/ 'which side' and /edi/ 'which one' which are VCV in structure were also included in the final word lists. In Dravidian languages, especially in Telugu, the words beginning with front vowels /i/, /i/, /e/ and /e/ are preceded by the palatal glide /y/ when they occur in the initial position. Similarly, the words beginning with back vowels /u/, /u/, /o/ and /o/ are preceded by labial glide /w/ when they occur in initial position. Hence, the words like /uru/, /et u/ and /edi/ are considered as [wuru], [yet u] and [yedi] respectively in this study. In order to keep the phonemic balance and due to limited number of words with /s / in CVCV structure, the word /s apu/ 'shop' is included in list 2 and list 4. It is felt that this would not present problems, as there were a total of 100 disyllabic words in the lists (see appendix).

There are four different methods commonly used to determine the reliability of tests of speech recognition, including test-retest reliability, inter-list equivalence, split-half method and inter-item consistency reliability (Mackie &Dermody, 1982). In this study, the equivalence of difficulty between four lists of Telugu bisyllabic words was evaluated. The four lists developed in the study showed normal distribution and there was no statistically significant difference found between four lists for each group at each presentation level. When the data was further analyzed to identify significant difference in mean scores of each group, it was found that there was no significant difference found between three groups for each list. Hence, the four lists were found to have equal difficulty and these word lists can be used interchangeably for any group of subjects in clinical practice.

There are three categories of methods commonly used to determine the validity of tests of speech recognition, including construct validity, criterion related validity and content validity. Criterion-related validity indicates the validity of a test predicting an individual's behavior in specified situation (Anastasi, 1968). In this study performanceintensity function curve, which is the percentage correct identification of speech stimulus as a function of stimulus intensity, was measured. The standard deviation values reduced as the presentation level was increased in the mean performance-intensity function test. The results revealed a narrow standard deviation for extreme presentation levels while broad standard deviation for low and mid presentation levels. This indicates that at higher presentation levels the subjects' performance became less variable. This may occur because, as the presentation level increases, the relevant phonetic cues would become more reliably audible to these normally-hearing subjects. As the presentation level decreased the responses from the subjects became more variable. This may occur because phonetic cues would become less reliably audible and responses would increasingly depend upon guessing the words.

The group mean slope of the linear portion of the PI-PB function for Telugu bisyllabic words shows 4.64%, 4.62%, 4.52% and 4.54% increase per dB in word recognition for list 1, list 2, list 3 and list 4 respectively. Beattie, Edgerton &Svilhovec (1977) reported a mean slope of 4.2% per dB and 4.6% per dB for English materials, the NU-6 word lists and the CID W-22 word lists respectively and for Indian materials, the authors Dayalan (1976), Devi (1985) and Kholia (2010) reported a mean slop of 3.0% per dB, 5.4% per dB and 3.7% per dB for Tamil, Manipuri and Rajasthani PB word lists respectively. The normal range of speech recognition score (90%-100%) was obtained between 25 dB SL and 45 dB SL stimulus presentation levels for all the lists. It is generally expected that high speech recognition scores are obtained at levels of 30-40 dB SL relative to the SRT (Gold, Lubinsky &Shahar 1981; in Silman &Silverman, 1991, p.141). Although, there is no other speech recognition test for adults available in Telugu language, most of the findings of the study are in line with the findings of earlier researchers.

VI. CONCLUSION

Speech audiometry is an essential component of the audiological test battery, as it provides information concerning one's sensitivity to speech stimuli and the understanding of speech at supra-threshold levels. Speech perception skills must be assessed routinely using valid and reliable clinical assessment methods suitable for native speakers of language. The current study developed four bisyllabic word lists in Telugu for assessing speech recognition performance in adults. They were found to be equally difficult, reliable and valid test material in Telugu. To continue the studies on the developed speech material, the test material can be administered on hearing impaired population and other clinical population to check the applicability. This test material can be used in selecting appropriate rehabilitative options and also to measure the efficacy of different rehabilitative devices. The same test material can be used to further develop speech in noise (SPIN) test, time compressed speech test, filtered speech test and other special test for differential diagnosis of auditory disorders.

ACKNOWLEDGEMENT

The author would like to sincerely thank the following who provided constant help in conducting this study. Our students: Phaninder, Yamini, Madhu, Nagaraju, Divya, Priyanka, Soubhagya, Anil and Srinivas and our colleagues: Prof. Umamaheswara Rao, Centre for Applied Linguistics and Translation Studies, University of Hyderabad for providing the frequency lists of Telugu and Prof. Ramanarasimham, Department of Telugu, University of Hyderabad for providing information on Telugu.

Implant helps inner-ear damage

Author: Mann, Leslie

Publication info: Chicago Tribune [Chicago, Ill] 18 Jan 2012: 5.2.

Abstract: Device stimulates inner ear rather than turning up the volume Since her teens, Lesa Merlo, of Hinsdale, had learned to compensate as her hearing declined.

Full text: Since her teens, Lesa Merlo, of Hinsdale, had learned to compensate as her hearing declined. She used the television's closed-captioning feature. She read lips and paid attention to body language. Often, it meant only being able to do one thing at a time, explained the mother of three.

Now, thanks to an implant called Esteem, Merlo can multitask. "I can make dinner and supervise homework at the same time," she said. "I don't have to stop and look directly at the children. I can hear what they're saying behind my back."

Unlike a hearing aid, which amplifies sounds, Esteem is a prosthetic inner-ear stimulator. "When I wore a hearing aid, I turned it off when I got home because all the background noise was so agitating," said Merlo, 40. "But I keep (the Esteem) on."

A controller the size of a cellphone enables her to set her Esteem to different environments, such as "home," "restaurant" or "school."

Merlo's doctor, ear surgeon Sam Marzo of Loyola University Medical Center in Maywood, has performed 40 Esteem implants since he was trained by its manufacturer, Envoy Medical Corp. in St. Paul, Minn., in 2010. He is the only Chicago-area surgeon authorized to implant the device, said an Envoy representative. Esteem was approved by the Food and Drug Administration in March 2010. (For surgeons outside Chicago, visit envoymedical.com.)

"This really fills a need for adults with moderate to severe sensorineural hearing loss," Marzo said.

The condition is caused by damage to the inner ear or to nerves from the inner ear to the brain. For patients with profound hearing loss, a cochlear implant is a better option, he said.

"Esteem is great for people who have used hearing aids but are not happy with them," Marzo said. "Aids require a lot of upkeep and need frequent battery changes. And they amplify all the noise so it's hard to filter out background noise."

Implanting the Esteem is a three-hour outpatient procedure done under general anesthesia. About two months later, when internal swelling has subsided, the doctor turns on the device.

The implant is permanent. It contains a battery that must be replaced in about seven years.

Merlo had Esteem implanted in her left ear in September. In March, she plans to have one put in her right ear.

"There are little things that I probably heard when I was younger, before my hearing loss, but I don't remember them," she said. "Since I got the implant, they're new to me. Branches tapping the windows, the breathing of the horses when I ride, different instruments in my favorite songs."

Full text: By SONYA PADGETT
LAS VEGAS REVIEW-JOURNAL
There's an old joke in the auditory industry that illustrates the public relations problems - and the functional issues - related to hearing aids.
It starts with a man telling his friend, "I just got new hearing aids."
The friend says, "Oh? What kind are they?"
The man looks at his watch and answers: "It's 3 o'clock."
Funny if you have perfect hearing. Not so funny if you've been in that guy's shoes. And it's downright disappointing if you are Brent Edwards, vice president for research at Starkey Laboratories Inc.
Starkey, the largest maker of hearing devices in the United States, held its innovation expo at The Cosmopolitan of Las Vegas last week. More than 3,000 audiologists and other hearing experts from across the country gathered to talk about the latest in hearing aids and what's on the horizon.
There was a time when that joke wasn't far from the truth and you may have had better results using an ear trumpet than a hearing aid. But those days are gone, Edwards says. Still, that news hasn't filtered out into a public that could benefit from the latest hearing aid technology.
While hearing aids have grown more effective, Edwards says, the negative reputation lingers.
The good news is that hearing aids are smaller and better than ever. They're so small that they are almost undetectable when worn in the ear. They also can help people hear better, understand speech more clearly and mask sounds such as ringing or buzzing.
Wireless technology, the same that is used in Bluetooth devices, has enabled manufacturers to address two of the biggest problems people encounter when using hearing aids: talking on the phone and watching television, Edwards says. The wireless technology allows sound to be streamed right to the hearing aid.
"This has been an evolution," says Jerry Ruzicka , president of Starkey. "Hearing aids were always analog devices. About a decade ago we started introducing digital. After that, we were able to take the next step, which was introduce software that could (program) hearing aids. Now we've taken the next step, which is to put these radios in each hearing aid."
There also have been advances in directional microphones, which are inside hearing aids and amplify sound. One of the biggest obstacles for hearing-aid wearers is communicating in a noisy environment, Edwards says. "That's a huge challenge."
These new microphones add three decibels, which translates into almost a 45 percent improvement in a wearer's ability to understand words.
Despite these advances, the average age of a person who buys a hearing aid is 69, Edwards says.
One would think that age would decrease as baby boomers age. In fact, boomers have been a driving force behind some of the developments in high-tech hearing, experts say. But there's still a resistance to hearing aids that has been difficult to overcome.
Cost may be a problem. Most insurance companies don't cover the cost of the devices, which can range from $1,000 to $4,000 each.
Deeply ingrained stigmas may be at play, too, Edwards says. If people think they are perceived as weak for needing hearing aids, they may be less likely to wear them. Also, if they feel like the hearing aids don't help, they won't wear them.
"There's a fallacy that people expect hearing aids to give the same level of improvement that eyeglasses do to

vision," Edwards says.
And that's not true. There are two kinds of hearing loss: conductive, which is the ossification of the inner ear anatomy, and sensory neural. Hearing aids and surgery can almost perfectly overcome conductive hearing loss.

Most hearing loss is sensory neural, caused by noise or aging. A hearing aid can help restore some hearing in those cases, Edwards says, but it won't be perfect.
Hearing loss can affect a person's life in more ways than one, says Loleata Wigall , audiologist who attended the expo last week. She owns a private practice in Massachusetts.
People who are losing their hearing start withdrawing from life, Wigall says.
"They sometimes think other people are talking about them. They misunderstand conversations, thinking they got it right and they didn't," Wigall says. "This can cause conflict. I think it can really affect family relationships. It can cause problems between child and parent and spouses. And it can come into play at work, too."
Even though more physicians are referring patients to get hearing tests, the majority of those who come to see Wigall did so at the insistence of their families.
Research has shown that hearing loss causes increased mental effort and distress because the brain has to work harder to understand sounds. In 2005, Brandeis University researchers found that people who suffer a hearing loss may also have poor memories. The belief is that, though they hear the information, the brain becomes taxed because it has to work harder to figure out what is speech and what is noise, Edwards says.
"You get really tired because you're straining to hear," Wigall says. "I tell people all the time, 'Don't be surprised if you have more energy after you get hearing aids.' "
People start losing their hearing at age 21, Wigall says. Baby boomers are losing their hearing faster than their parents did, mainly because we live in a noisy world, she adds. Music concerts, vacuum cleaners, anything that is so loud you have to raise your voice to be heard, can damage your hearing.
Also, diabetics are at a higher risk of hearing loss because of poor circulation. People who have had certain diseases or even taken certain medications, such as antibiotics, can be at a higher risk of losing their hearing. That includes people who received chemotherapy, Wigall notes.
Now, she counsels people to prevent hearing loss. Carry earplugs and use them. Turn the radio and television down.
Most importantly, she says, don't be afraid to get your hearing checked.
"We take hearing for granted," she says. "Often, it's so gradual, you don't even notice you're not hearing. But the rest of your family notices."

Audiological and electrophysiological assessment of professional pop/rock musicians

Author: Samelli, Alessandra; Matas, Carla; Carvallo, Renata; Gomes, Raquel; de Beija, Carolina; Magliaro, Fernanda; Rabelo, Camila

Publication info: Noise & Health 14.56 (Jan 2012): 6-12.

Abstract: In the present study, we evaluated peripheral and central auditory pathways in professional musicians (with and without hearing loss) compared to non-musicians. The goal was to verify if music exposure could affect auditory pathways as a whole. This is a prospective study that compared the results obtained between three groups (musicians with and without hearing loss and non-musicians). Thirty-two male individuals participated and they were assessed by: Immittance measurements, pure-tone air conduction thresholds at all frequencies from 0.25 to 20 kHz, Transient Evoked Otoacoustic Emissions, Auditory Brainstem Response (ABR), and Cognitive Potential. The musicians showed worse hearing thresholds in both conventional and high frequency audiometry when compared to the non-musicians; the mean amplitude of Transient Evoked Otoacoustic Emissions was smaller in the musicians group, but the mean latencies of Auditory Brainstem Response and Cognitive Potential were diminished in the musicians when compared to the non-musicians. Our findings suggest that the population of musicians is at risk for developing music-induced hearing loss. However, the electrophysiological evaluation showed that latency waves of ABR and P300 were diminished in musicians, which may suggest that the auditory training to which these musicians are exposed acts as a facilitator of the acoustic signal transmission to the cortex.

Full text: Introduction

Exposure to noise of high intensity and for a long period increases the risk of permanent hearing damage. The degree of hearing loss it may cause depends on the frequency and intermittency of the exposure. [1],[2]

Even as the controversy over whether or not music causes permanent hearing loss remains, [1] many studies have presented evidence of a potential risk for hearing damage from music exposure. [1],[3],[4] This hearing loss has been referred to as a music-induced hearing loss. [5]

It is well known that the pathophysiological effects of noise act mainly on the cochlea, [6],[7],[8],[9] but some previous investigations have shown that the central components of the auditory pathways can also be affected by acoustic overstimulation. [10],[11],[12],[13]

Exposure to noise tends to cause structural and metabolic changes in the hair cells, which can subsequently degenerate. [1],[6],[7],[8],[9],[13] Additionally, it has been shown that noise exposure alters mitochondrial activity, leading to increased production of free radicals that cause changes in blood flow and neural activity that induce the death of hair cells by both necrosis and apoptosis. [9]

Once the cochlea is damaged, a sequence of events occurs in a pathophysiological cascade. In summary, decreasing cochlear input into the central auditory pathway may induce apoptosis in the neurons, which reduces cell density in the ventral cochlear nucleus. Next, the cell density and important structures of the central auditory pathway (central nucleus of the inferior colliculus, medial geniculate body, and primary auditory cortex) are also affected by overstimulation of the neurons and intense calcium influx. [13] These changes lead to toxic neurodegenerative processes and an enhanced neurotransmitter release that can induce glutamate excitotoxicity due to ionic homeostasis changes. [1],[13]

Despite the injuries that exposure to music may cause to the peripheral and central auditory pathway, clinical practice and even the research done on the subject in humans have been limited to audiological assessment. [10] However, audiological assessment is a poor indicator of the degree of damage caused to the auditory pathways. Hence, recent studies on music-induced hearing loss have adopted advanced audiological measurements (high frequency audiometry and otoacoustic emission) for the early identification of these damages, even before the changes can be detected by conventional audiometry. [1] Our study is the first in which a battery of assessments that include electrophysiological, eletroacoustic, and audiological assessments have been used to investigate the impact that exposure to music may have on whole auditory pathways.

The present study

In the present study, we evaluated peripheral and central auditory pathways in professional musicians (with and without hearing loss) compared to non-musicians. The goal was to verify if music exposure could affect auditory pathways as a whole.

Method

Participants

Professional Pop/Rock Musician Groups: The inclusion criteria adopted in this study were (a) being a professional musician, (b) being a member of a pop/rock band for more than five years, (c) having had exposure to intense sound levels from electrically amplified music for at least two hours weekly, (d) being male, (e) being between 18 and 45 years old, and (f) having an audiological threshold from 250 to 8000 Hz <40 dBNA. The exclusion criteria were (a) existing acoustic trauma, (b) exposure to noise (>80 dBA) during occupational activities from sources other than music, (c) a history of recurrent otitis media, (d) previous ear surgery, (e) conductive hearing loss and excessive ear cerumen, and (f) use of potentially ototoxic drugs.Non-musicians Group: The inclusion and exclusion criteria for the control subjects were the same, except for exposure to music considered at a professional level according to the criteria adopted for the musicians group.

Our study group of professional musicians contained 16 subjects with ages ranging between 21 and 41 years (mean, 27.10 years; SD, 6.02 years) and the control group contained 16 subjects with ages ranging between 20 to 43 years (mean, 26.87 years; SD, 7.40 years) (P value=0.936). The instruments considered in the musicians group were guitar (n=4) and drums (n=12). The mean average of weekly noise exposure to intense sound levels in the musicians group was approximately 23.1 hours over a mean period of approximately 16.3 years.

The musicians group, in turn, was classified in two subgroups: HLG - hearing loss musician group (0.25 kHz - 20 kHz), according to analysis criteria of British Society of Audiology [14] and Burguetti et al., [15] and MG - musicians without hearing loss in any frequencies (0.25 kHz - 20 kHz).

Procedures and Measures

Informed consent was obtained from each individual who participated in this study. The study was approved by the Ethics Committee of the University of São Paulo, Brazil.

All subjects were requested to complete a detailed questionnaire concerning their age, gender, education, medical history, occupational history, and the circumstances surrounding their musical activities, such as how long the subject played per day, how loud, how often, and what instruments, as well as whether or not they had used ear protection.

An audiometric assessment was conducted on all participants. Screening acoustic immittance measurements (GSI 38 Auto Tymp, Grason-Stadler, Inc., Madison, WI) and otoscopy were performed.

Pure-tone air conduction thresholds at all frequencies from 0.25 to 8 kHz and in the extended high frequencies of 9, 10, 12.5, 14, 16, 18, and 20 kHz were carried out with a GSI 61 Clinical Audiometer (Grason-Stadler, Inc., Madison, WI) using standard audiometric techniques in a sound-attenuated testing room.

Transient Evoked Otoacoustic Emissions (TEOAE) were recorded using an ILO 292 Plus OAE analyzer, v 6 (Otodynamics Ltd., Hatfield, UK), using ILO insert phones. The TEOAEs were recorded in a nonlinear mode. Under all conditions, the mean intensity of the clicks was 78 - 83 peSPL, and 200 sweeps were recorded for each ear. The response level was determined by measuring the signal-to-noise ratio with an analysis time window of 4 - 20 ms. The nonlinear transient click of 80-μ s duration was presented at a rate of 50 Hz, in alternating blocks. The individuals were tested in a sound booth, in a quiet room.

The electrophysiological tests (Auditory Brainstem Response - ABR, and Cognitive Potential - P300) were carried out in an electric- and sound-attenuated testing room. The electrophysiological assessment was done using a two-channel electroneuromyograph equipment (Biologic Traveler Electrodiagnostic Testing System; Biological Systems Corp., Mundelein, IL, USA). The individual was asked to remain with his eyes fixed on a figure positioned about five feet away during the recording of potentials, in order to control eye movement artifacts.

For the ABR, a rate of 19 clicks per second, with 0.1 μ s duration, were used with a filter slope of 12 db/octave, with the band pass filter 100-1500 Hz, and 2000 sweeps. The stimulus was 80 dBnHL. The ABR measurements were duplicated to ensure fidelity.

The oddball paradigm was used in the P300 recordings. This paradigm was based on distinguishing between a target stimulus repeated randomly (20% of the time) and the non-target stimuli, with frequent repetition (80% of the time). The subjects were asked to count the stimuli when they discriminated the target stimulus. A monaural auditory stimulus was presented. Frequencies were 1000 Hz for the frequent stimuli (non-target) and 1500 Hz for the rare (target) stimulus. The stimulus was 75 dBnHL. A rate of 1.1 tone-burst per second was used with the low filter setup in 30 Hz and the high filter in 1 Hz, and 300 sweeps.

The electrodes were positioned according to an international electrode system (IES), 10 - 20. [16] Electrode impedances were always less than 5 kΩ. Standard Bio-logic TDH49 headphones were used to deliver the sound stimuli for the electrophysiological tests.

Latency and amplitude of the waves were analyzed. The P300 were analyzed after subtracting the curves resulting from the rare and frequent stimulus (of the same ear), and were measured at the most positive point (amplitude), from 250 to 600 ms.

For the statistical analyses, the Kolmogorov-Smirnov test was applied to determine normality of the variable distribution. We used the Analysis of Variance (ANOVA) and Tukey's test for quantitative analysis and Chi-square (Fisher's exact test and Mantel-Haenszel) for qualitative analysis. The level of significance was set at 0.05. Significant values were designated with an asterisk (FNx01).

Results

There was no statistically significant difference between the right and left ears (P>0.05; ANOVA) for conventional and high frequency pure-tone audiometry, amplitudes of OAE, or the wave latencies of electrophysiological tests, for all individuals in all groups. Thus, both ears of the individuals in each group were grouped and 16 musician subject responses (32 ears) were compared with 16 non-musician subject responses (32 ears). The HLG was composed of 14 ears and the MG was composed of 18 ears.

Hearing thresholds in both conventional and high frequency audiometry

A statistical analysis performed for pure-tone thresholds revealed that values significantly differed between the three groups for 2 and 3 kHz, and for 12.5 to 18 kHz [Table 1]. The musicians groups (HLG and MG) exhibited higher thresholds than the controls, in general.

For pairwise comparison (Tukey's test), we observed the statistical significant difference for: 2 kHz NG×HLG (P=0.013); 3 kHz NG×HLG (P=0.049); 12.5 kHz NG×HLG (P=0.007); MG×HLG (P=0.001); 14 kHz NG×HLG (P=0.004); MG×HLG (P=0.001); 16 kHz NG×MG (P=0.017); NG×HLG (P=0.009); MG×HLG (P=0.001); 18 kHz NG×HLG (P=0.001); MG×HLG (P=0.001){Table 1}.

On audiometry, 7.15% of the HLG ears had hearing loss in at least one frequency (significant difference between groups). In the high-frequency audiometry, 100% of the HLG ears had hearing loss in at least one frequency (significant difference between groups) [Table 2].{Table 2}

Amplitudes of otoacoustic emissions

In transient evoked otoacoustic emissions, a statistically significant difference between the mean response (amplitude) of the three groups for all frequencies was observed [Table 3]. The HLG and MG had smaller TEOAE amplitudes when compared with the NG. For this comparison, we excluded the subjects with absent OEA.{Table 3}

For pairwise comparison (Tukey's test), we observed statistical significant difference for: 1 kHz NG×MG (P<0.001); NG×HLG (P<0.001); 1.5 kHz NG×MG (P<0.001); NG×HLG (P<0.001); 2 kHz NG×MG (P<0.001); NG×HLG (P<0.001); 3 kHz NG×MG (P<0.001); NG×HLG (P<0.001); 4 kHz NG×MG (P<0.001); NG×HLG (P<0.001); Response NG×MG (P<0.001); NG×HLG (P<0.001).

In HLG, 14.28% of the ears had absent TEOAE and 85.71% had TEOAE partially present, although a

statistically significant difference between the groups was observed only for TEOAE, which was partially present [Table 4].{Table 4}

Short and late latency responses

We compared the waves and interpeak latencies of ABR between the three groups [Table 5]. There was statistically no significant difference in any waves or interpeaks comparison between the groups.{Table 5}

For pairwise comparison (Tukey's test), we observed a statistically significant difference for: NG×MG (P=0.041).

There was a statistically significant difference between the groups [Table 6]; the MG had smaller mean latency of P300 when compared to NG and HLG.

There was a statistically significant difference for ABR alterations between groups, with more alterations in NG than in MG and HLG [Table 7]. There was statistically no significant difference between groups for the P300 (data not shown), because no P300 alterations (according to McPherson [18] normality) were observed in both groups.{Table 6}{Table 7}

Discussion

We found that musicians (HLG) had 7.15% of their ears with sensorineural hearing loss (as shown by conventional audiometry) and 100% of their ears with hearing loss in high frequencies. The values significantly differed between the three groups for 2 and 3 kHz, and for 12.5 to 18 kHz. Nevertheless, the mean values in the musicians group (MG and HLG) were worse than in the control group. This fact showed that the musicians already had some degree of peripheral damage, even though these individuals were still young.

These results agreed with other studies that found worse hearing thresholds when comparing pop/rock musicians with a control group [3] or those that found different prevalence of hearing loss among musicians from different musical genres (58% of the musicians; [20] 52.5% of the musicians; [21] 37% of the musicians; [22] 33 to 52% of the musicians, depending on the criteria of hearing loss used; [23] 49% of the musicians; [24] more than 50% of the musicians had a hearing loss of 15 dB(A) and more; [25] 42.9% of the musicians [26]). Previously, our group showed that depending on the hearing loss criteria used (different thresholds of cut off, averages of thresholds, uni-or bilateral hearing loss, etc.), [1] the prevalence of hearing loss could change, which might explain the differences observed in the previous studies.

Concerning TEOAE, the musician groups (MG and HLG) presented significantly smaller mean amplitudes for all frequencies compared to the non-musician groups. Moreover, if we considered the absent emissions and the partly present emissions together, the HLG showed 100% alteration, the MG showed 44.44% alteration, whereas, the NG showed no absent or partially present emissions.

Among the studies in which TEOAE were used to draw the audiological profile of musicians, the results varied considerably. A previous study [27] found 38% sensorineural hearing loss in high frequencies and 69% absent otoacoustic emissions in orchestral musicians. Another study [28] found 100% normal hearing, but 60% absent responses of TEOAE in rock musicians. A third study [29] observed that TEOAE was present in all evaluated singers, but with less robust responses when compared to the control group. A recent investigation [30] found nearly 21% hearing loss and 45.8% absent TEOAE in pop/rock musicians.

These values were higher than those observed in this study (12.5%, if were consider HLG and MG together). It should be noted that these studies evaluated parameters different from those evaluated in our study and did not consider the 'partially present' values, which in our study showed a high prevalence (100%). Despite these differences, our findings suggested worse function of outer hair cells (OHC) in MG and HLG, when compared with NG, suggesting cochlear damage in most of the musicians, even though this damage had not yet been seen in conventional and/or high frequency audiometry.

For the electrophysiological evaluation, we have found early responses to ABR and P300 waves in musicians. These professionals, with musical training and practice, increase the spontaneous attention to the sound and their sound discrimination abilities. [1] This fact suggests that musical training provides a better processing of

acoustic information by the central auditory nervous system. Some authors [31] have evaluated the ABR and cortical evoked responses of musicians and non-musicians and shown that musicians have earlier responses when compared to non-musicians, indicating rapid identification and perception of sound by musicians. The auditory training through the musical experience provides a neural synchrony to the auditory system as well as faster responses to the presence of sound, as has been concluded in another study, [32] which has analyzed the ABR of musicians to speech sounds.

Our results agree with those of the previous studies, although no significant differences for ABR waves were found between groups. Also, for qualitative analysis, we found that the MG and HLG had fewer individuals with alterations in ABR than the NG, a result that suggests a good integrity of the auditory brainstem response in this population.

With regard to the P300 results, although three groups showed mean values within normal limits, the MG and HLG showed a shorter latency than the NG. Some authors [33] assessed how musicians responded to pure tones, harmonics, and speech, by analyzing the components in N1, and P300 auditory evoked potentials of long latency, and compared these results with those obtained in the control group (non-musicians). They concluded that musicians regularly exposed to music showed shorter latencies for harmonic and speech stimuli, and for pure tone results they found no difference between the groups, although the musicians group had shorter latencies of the P300 wave, similar to what we found.

Thus, our findings do not support the hypothesis that the central components of the auditory pathways can also be affected by acoustic overstimulation. [10],[11],[12],[13] However, previous studies have dealt with the damage caused by noise and not the music itself. Thus, it is possible that music and noise do not act in the same way about the central auditory pathways, although both stimuli cause damage to the peripheral auditory pathways, as previously mentioned.

Therefore, alterations in otoacoustic emissions and high frequency audiometry presented by musicians with and without hearing loss showed that despite the fact that the central portion was not clearly affected by noise exposure, the peripheral portion showed that it was already affected, and these two tools could be used to predict the possible damage caused by exposure to very intense pressure levels sounds.

Musicians are different from factory workers in several areas that make the former slightly less susceptible to hearing loss. Music tends to be intermittent, with loud passages and quiet passages intermixed, while industrial noise tends to be continuous. Perhaps this intermittency makes the music slightly less damaging than an equal intensity of noise for a similar length of time. [34]

A study [35] showed that musicians who had played for less than 10 years did not develop hearing loss, whereas, 40% who had played between 10 and 19 years, and 66% who had played for more than 20 years, had developed hearing loss. However, another study [36] documented a measurable loss in the hearing function of workers in 328 construction industries in their first three years of work. Also, it is possible that a change in the circulation in the auditory pathway on a hormonal basis, if music is perceived as pleasant, makes music less damaging than noise. [34] It is well known that the impact of the perception of pleasant and unpleasant sounds may result in endocrine changes, including the production of stress hormones such as cortisol and ACTH, catecholamines, and others. [37] On account of these physiological reactions, the noise becomes detrimental to health in many ways, leading to sleep disturbance, cardiovascular disease, psychiatric symptoms, and psychosocial effects, including the discomfort with noise, reduction in performance/attention, and increased aggressive behavior. [38]

Thus, it is possible that compared to noise, music causes less harmful effects to the central auditory pathways, due to its spectral and temporal (intermittence) characteristics, as a function of hormonal changes. This function may be caused by sounds rated as pleasant or unpleasant, which may trigger negative reactions in the entire system that results in a cascade of adverse events.

Future studies with animals comparing different acoustic stimuli that resemble the characteristics of music

(spectral and temporal) are important for this hypothesis to be tested. A comparison with the effects of noise can be made by checking the effects on the peripheral and central pathways of different types of stimuli.

A limitation of our study is our small sample of musicians, which included guitarists and drummers only. This was done in an attempt to minimize the variety of different instruments and music exposure of professional musicians, as they may carry different audiological features.

An analysis of musicians showed that drummers had worse hearing thresholds and smaller TEOAE amplitudes when compared to guitar players. Drummer players present a bigger damage most likely because of the impact noise produced by the instrument. This finding has also been observed by others. [3]

Our study is the first to assess both the central and peripheral auditory pathway of professional musicians. This approach allowed us to find that music can cause damage to the peripheral auditory pathways. Additionally, music may act as a training tool for central auditory pathways, improving the processing of acoustic information to the cortex. Future studies in which more musicians playing different instruments are included will be enlightening.

However, we cannot rule out that central damage can also be caused by the music itself, when exposure occurs for long times. Thus, longitudinal studies of this kind are also needed to clarify these issues. As indicated by others, [23],[27],[39] hearing protection measures should always be taken with this group of professionals, including engineering control measures (acoustically, the sound source distance, decreased amplification, etc.), personal protection (use of protective earplugs for musicians, with uniform attenuation of frequencies), training in placement and cleaning earplugs, educational programs, audiological monitoring, and others. [23],[27],[39]

Conclusion

Our findings suggest that the population of musicians is at risk for developing music-induced hearing loss. However, the electrophysiological evaluation showed that latency waves of ABR and P300 diminished in musicians, which may suggest that the auditory training of musicians, who are exposed to sound in the profession, acts as a facilitator of the acoustic signal transmission to the cortex, that is, provides a better processing of acoustic information by the central auditory nervous system.

Don't pump up the volume if you really love your music

Publication info: Daily Post [Liverpool (UK)] 13 Dec 2011: 10.
ProQuest document link

Abstract: Abby Davies, an audiology specialist at the charity Hearing on Action Loss Cymru, which was previously the RNID, said: The World Health Organisation has predicted that by 2030 adult onset hearing loss will be in the top 10 of disease burdens in the UK, but it's not inevitable that everyone will get hearing loss as they age.

Full text: As a generation of young people seem glued to their headphones, Madeleine Brindley examines growing concern about potential future damage to their ears A QUICK glance around any train or bus carriage will reveal most young people are sporting headphones of some shape, style and colour.

The explosion in MP3 technology means these tiny players, which are capable of storing thousands of songs and albums, have become the electronic accessory of choice.

But there are increasing fears that this so-called iPod generation are at risk of hearing damage later in life because they're exposing their ears to too much loud music.

Statistics show a staggering 41% of over-50s and 71% of people over 70 have some degree of hearing loss as a result of damage to the tiny sensory cells in the inner ear.

It is estimated there are more than 10 million people throughout the UK with some form of hearing loss - this is equivalent to about one in six of the population. About a third are of working age.

By 2031, it is estimated there will be 14.5 million people with hearing loss in the UK.

Abby Davies, an audiology specialist at the charity Hearing on Action Loss Cymru, which was previously the RNID, said: "The World Health Organisation has predicted that by 2030 adult onset hearing loss will be in the top 10 of disease burdens in the UK, but it's not inevitable that everyone will get hearing loss as they age.

"Adult onset hearing loss is caused by damage or loss of the tiny sensory cells in the cochlear; the damage means they no longer respond to certain sounds and that's when you get hearing loss.
"It tends to be the cells which respond to high-pitched sounds which are damaged which is why people often mishear the beginning and end of words. It can mean you don't hear S, T, P or F - when you miss the beginning and ends of words it can be very difficult to work out what's being said.
"The volume may be OK but the clarity isn't. People with hearing loss often feel OK but sounds aren't very clear."
She added: "The damage tends to be caused by general wear and tear but there are things you can do to help prevent hearing loss, including protecting your hearing from noisy environments."
Concern is growing about the potential damage young people are doing to their hearing by listening to too loud music, particularly via their MP3 players.
Claire Kingston, campaigns and communication manager for Action on Hearing Loss Cymru, said: "When we've done research in the past, 90% of people questioned said they had, at some point, experienced tinnitus after a night out.
"Most of us will be familiar with that muffled feeling which fades after a while after being at a pub or club or watching a live band. That muffled feeling is temporary hearing loss.
"People who listen to very loud music at high volumes over a relatively long period of time are at risk of damaging their hearing permanently.
"Our protect your hearing campaign aims to raise awareness among the younger generation about the dangers of listening to loud music over a long period of time.
"We want to see this embedded as a public health campaign in the same way that people are warned about the risks of smoking or too much sun exposure.
"People are completely unaware of how much damage they could be doing simply by listening to their MP3 player."
It has been recognised that noise above 85 decibels is harmful to hearing - a typical nightclub registers at around 100 decibels, which is the same level as the maximum volume on some MP3 players, Ms Kingston said.

"Stop-and-search research we've done among young people across the UK, including in Wales, to measure the volume of MP3 players has found that more than 50% were listening at above 85 decibels.
"We're not telling anyone to stop listening to music," she added. "But we are saying that if they want to still be listening to music when they're older, they need to give their ears a break - don't stand next to speakers; wear earplugs or the right earphones.
"Some earphones will allow outside noise to filter through, so people crank up the volume to drown it out but noise-cancelling headphones are available and are really good as they are more effective at cutting off background noise."
DJ Judge Jules has backed the Action on Hearing Loss campaign, saying: "I expose myself to a lot of loud noises and enjoy myself all the time; the problem with loud noise is that it can cause irreversible ear damage - there's absolutely no way back when it's happened. It is, however, entirely preventable.
"Music is such a fundamental part of everyone's lives that if you lose the ability to enjoy it, it's everything."
And popstar and DJ Boy George said: "'I think it would just be awful to lose your hearing. I think it would be the most difficult thing to deal with.
"I think if you've never had hearing it is a different thing, but if you've had hearing and you lose it that must be very difficult to deal with. Same as anything, losing a limb, losing your sight."
Ms Davies said: "Hearing loss has a significant personal and social impact as the loss of communication has far-reaching consequences. "It can be very isolating and excluding; people with hearing loss are more likely to withdraw from interaction with large groups of people and it can be associated with high levels of depression."

Kay Coleman, a member of the Swansea Hard of Hearing Group, said having difficulty with hearing could be "embarrassing" and isolating for sufferers, especially in social situations.
Ms Coleman, a mother of one, was fitted with a hearing aid in one ear eight years ago; she now requires them in both ears. She said: "Because my two ears were affected, one very badly, I couldn't hear very well.
"For example, I had to turn the television up quite loud, because unless you have over-ear headphones you can't insert them in to your ears which is quite a dilemma.
"I do have a small digital radio and I would use it on my good ear and then that cut out. I used to use it on the bus.
"That can be a bit isolating, in a way, and it can be a bit embarrassing because you can't hear what other people are saying."
The former nurse and nursing tutor, who is now retired, said she often struggled to keep up with conversations in social situations and at conferences and meetings for Action on Hearing Loss, for whom she volunteers.
The pensioner said she wanted to learn to lip read but there are no teachers in the area.
She added: "I came home one Sunday from church and I had bought some pots to put seedlings in.
"My son was at home and he said something to me about seedlings, but I thought he was talking about the ceiling. It just didn't make sense to me."
HOW DO YOU GET A HEARING TEST? 'It takes, on average, a decade for people worried about their hearing to do something about it.
But Abby Davies, an Action on Hearing Loss audiology specialist, said the earlier people seek help the better they can adapt to hearing aids, if they are needed.
She said: "A lot of people with hearing loss think that they can hear OK and it's other people who aren't speaking clearly.
"What they don't understand is that if they can't hear clearly they already have some hearing loss. But people will cope and muddle through for lots of different reasons, which is why it can take 10 years."
Action for Hearing Loss has developed an online hearing check, which can also be carried out over the telephone, to help people who are worried about their hearing.
Hearing tests are available privately on the high street but people can also see their GP about hearing issues, which could result in a referral to a hospital.
Ms Davies said: "The first step is to see your GP who can then refer you for a full hearing test, which will involve an audiologist going through some questions and a history before the test begins.
"Patients put on a pair of headphones and their hearing is tested across different frequencies and pitches - patients are asked to respond to beeps at medium, high and low frequencies. The beeps will get quieter and quieter until the patient no longer responds and then they will go up again, this is to establish a person's hearing threshold.
"Individuals will each have different hearing loss but it tends to follow a similar pattern by being more severe in the high pitches.
"People can also self refer themselves to a private provider, which will test hearing in a similar way but they will have to pay for any hearing aids because it hasn't been done through the NHS."
To take the Action on Hearing Loss hearing check visit www.actiononhearingloss.org.uk or call 0844 800 3838
How loud is too loud? Loudness of a sound is measured in decibels (dB). Experts agree that exposure to noise at or above 85 dB (A) can damage hearing. Some examples of average decibel levels of common noises: 20 dB (A) A quiet room at night 60 dB (A) Ordinary spoken conversation 70 dB (A) City street 100 dB (A) Pneumatic drill; maximum volume on some MP3 players 110 dB (A) Night club 115 dB (A) Rock concert 120 dB (A) Aeroplane taking off Without sound-measuring equipment, it can be difficult to know how loud the sound really is. As a rule of thumb, if you have to raise your voice to speak to someone two metres away, the noise is loud enough to damage your hearing and you should take steps to protect yourself. If the sound ever hurts your ears,

leave immediately.
How long can I listen to music for? It depends on how loud the music is.
Decibels work as ratios so the louder the volume, the less time you can listen to it without damaging your hearing. For every 3 dB (A) increase in volume, the amount of time is halved before hearing damage occurs. If a nightclub has music playing at 100 dB (A), it is only possible to listen to it for 10 to 15 minutes before the exposure becomes damaging.
Won't my ears get used to loud music? In short, no. Loud music affects everyone's hearing. Some people may be more susceptible to damage than others but it is only possible to know your susceptibility once you have damaged your hearing. It is important to take steps to prevent any damage from occurring.
What might happen if I damage my hearing? If you've been exposed to loud music, you may experience ringing in your ears. This is usually temporary and tends to go after 24 hours at most. However, continued exposure to loud music can lead to the ringing, or tinnitus, to become permanent. This has been known to affect people's lives, their ability to sleep and concentrate. You may also experience premature hearing loss. While you may not notice this straight away, it could bring on hearing loss as a result of age much quicker.

STUDIES WARN HEARING LOSS IS PUBLIC HEALTH THREAT

Author: Cohn, Meredith

Publication info: The Baltimore Sun [Baltimore, Md] 04 Dec 2011: A.4.
ProQuest document link

Abstract: Hearing loss is more prevalent in those with hypertension and diabetes, and among white men compared with women and African-Americans. Hearing loss generally occurs when hair cells in the inner ear responsible for converting sound into signals that go to the brain die off over time and are not replaced.

Full text: One in five Americans has significant hearing loss, far more than previously thought, according to new research that has scientists warning of an impending public health threat.
Researchers at the Johns Hopkins University say a growing number of seniors in the United States are at risk of isolation from their hearing loss and could suffer physical and mental debilitation.
"People think hearing loss is an inconsequential part of getting older," said Dr. Frank Lin, an assistant professor in Hopkins' department of otolaryngology-head and neck, who led the study. "But hearing loss is associated with a greater risk of developing dementia, and having poorer cognitive and physical functioning."
The World Health Organization says significant hearing loss is when someone is unable to hear sounds of 25 decibels or less. Lin says words sound mumbled, especially when there is background noise.
The study found that about 30 million Americans, or close to 13 percent of the population, had such loss in both ears, and 48 million, or just over 20 percent, had loss in at least one ear. Previous estimates were closer to 21 million to 29 million.
This study, published in the Archives of Internal Medicine, used data from all ages and ethnicities collected in a continuing federal research program called the National Health and Nutritional Examination Surveys.
The data showed that the risk of hearing loss doubles in a person every decade, and because more people are

living longer, there are now more people with hearing loss. Hearing loss is more prevalent in those with hypertension and diabetes, and among white men compared with women and African-Americans. The female hormone estrogen and melatonin, which colors skin, seem to be protective, Lin said.

Hearing loss generally occurs when hair cells in the inner ear responsible for converting sound into signals that go to the brain die off over time and are not replaced. Damage isn't typically seen for years and losses aren't reversible, and the only preventive step for most people is to avoid long periods of loud noises. Lin suggested, for example, that young people stay away from the loudspeakers at concerts and stop using ear buds, which allow for louder sounds when they listen to music.

Lin said only an estimated 20 percent of those who suffer hearing loss seek treatment. Others don't recognize or acknowledge a problem, especially if the loss comes gradually. People hear some sounds and fill in the gaps by asking speakers to repeat themselves, turning up the television, or reading lips and using other signals.

That's what Bob Ward did. The 66-year-old Annapolis man believes his hearing loss resulted from military service in Vietnam. About 15 years ago, he went for hearing aids.

He has since been through several pairs of increasing strength. They took some getting used to because they don't filter background noise well, but he said they helped until recently. He was finding it hard to communicate at home and at work at Pitney Bowes, where he is a director of applied technology.

"I didn't notice at first, but my wife and family noticed that I'd become rather withdrawn," he said. "I wasn't participating because I couldn't hear, and pretty soon people wouldn't even try and include me in conversation. It has a real psychological effect. I started to feel isolated."

Ward said he avoided coffee shops because he was afraid he'd be asked a question. He even began researching jobs he could do without hearing.

One day he was visiting his grandchildren's school in Washington, where about half the kids are deaf and have cochlear implants, which are surgically implanted electronic hearing devices for the more severely hearing-impaired. He was inspired to head to Hopkins to see if he would be a candidate.

And now that he's had one implant, he's begun to recognize long-ago familiar sounds, such as the clanking of his dogs' tags.

"I can have conversations that I wasn't having before," he said. "I see other people who can't hear and they give up on things. I see how it can become mentally and then physically debilitating."

Plenty of people acknowledge ignoring the problem. More than 60 percent of members of AARP reported difficulty hearing in noisy situations in a new poll by the group and the American Speech-Language-Hearing Association.

Yet only 43 percent have gone for a test, even though hearing troubles have affected relationships for many. Close to two-thirds don't believe their problem warrants treatment, and about the same percentage say lack of insurance coverage and cost are reasons not to be treated. (Hearing aids cost $2,000 to $4,000.)

That frustrates Linda S. Remensnyder, an Illinois audiologist who has consulted with Lin and has become an advocate for the hearing-impaired. She says many of her older patients have become withdrawn and debilitated by the time they get to her.

She said some diseases and treatments cause hearing loss, along with age, but she believes hearing loss also makes their physical and mental health worse.

Remensnyder has joined other audiologists and the American Academy of Audiology, the Hearing Loss Association of America and AARP to encourage regular screenings, use of hearing aids and installation of hearing loops in public places such as theaters, shops and churches. The loops magnetically transmit sounds to a wireless receiver in hearing aids, filtering outside noise.

"Patients come in here and tell me that they've stopped going to activities," she said. "We not only have to provide hearing aids but make sure venues are audible. It's an incredible issue, and if we don't get it addressed, we'll be paying for it. Maybe we can defer the onset of dementia."

Other scientists, including Dr. George Gates, a hearing expert at the University of Washington in Seattle, say they're not so sure hearing loss causes dementia. Gates says his research shows that dementia may cause hearing loss, and he is an advocate for more testing.

"What we've found is, long before anyone gets a diagnosis of dementia, their ability to hear noise is severely affected, so a hearing test may reveal people at risk of dementia long before any other test," said Gates. He added that there is no cure for dementia, but early interventions may slow the progression.

He agreed with Lin that improving hearing can stave off depression, which he said can lead to other mental and physical maladies. "There absolutely is a public health threat from hearing loss," he said.

Lin, also an assistant professor in the epidemiology department in Hopkins' Bloomberg School of Public Health, plans to continue looking at the link to physical and mental health.

He's studying the cognitive abilities in those older than 50 who have hearing loss. He's also planning a larger study that will test the cognitive and physical abilities of people with hearing loss over years. One set will get free hearing aids, intensive instruction on using them and loop systems in some public areas. The other set will just be observed (they can buy a hearing aid themselves if they want).

"No one would think of not treating their high blood pressure, but hearing loss is still perceived as not that bad for you," Lin said. "If 30 million have hearing loss and less than one in five people do anything about it, and studies show that hearing loss is associated with adverse outcomes, think of how huge a public health threat that is."

Damage isn't typically seen for years and losses aren't reversible, and the only preventive step for most people is to avoid long periods of loud noises. Lin suggested, for example, that young people avoid the speakers at concerts and stop using ear buds that cause them to listen to music more loudly.

Lin said only an estimated 20 percent seek treatment. Others don't recognize or acknowledge a problem, especially if the loss comes gradually. People hear some sounds and fill gaps by asking speakers to repeat themselves, turning up the television and reading lips and other signals.

That's what Bob Ward did. The 66-year-old Annapolis man believes his hearing loss results from military service in Vietnam. About 15 years ago, he went for hearing aids.

He's since been through several pairs of increasing strength. They took some getting used to because they don't filter background noise well, but he said they helped until recently. He was finding it hard to communicate at home and at work at Pitney Bowes, where he is a director of applied technology.

"I didn't notice at first, but my wife and family noticed that I'd become rather withdrawn," he said. "I wasn't participating because I couldn't hear and pretty soon people wouldn't even try and include me in conversation. It has a real psychological effect. I started to feel isolated."

Ward said he avoided coffee shops because he was afraid they'd ask him a question. He even began researching jobs he could do without hearing.

One day he was visiting his grandchildren's school in Washington, where about half the kids are deaf and have cochlear implants, surgically implanted electronic hearing devices for the more severely hearing impaired. He was inspired to head to Hopkins to see if would be a candidate.

And now that he's had one implant, he's begun to recognize long-ago familiar sounds, such as the clanking of his dogs' tags.

"I can have conversations that I wasn't having before," he said. "I see other people who can't hear and they give up on things. I see how it can become mentally and then physically debilitating."

And plenty of people admit to ignoring the problem. More than 60 percent of members of AARP reported difficulty hearing in noisy situations in a new poll by the group and the American Speech-Language-Hearing Association.

Yet only 43 percent have gone for a test even though hearing troubles have affected relationships for many. Close to two-thirds don't believe their problem warrants treatment, and about the same percentage say lack of insurance coverage and cost are reasons not to be treated. (Hearing aids cost $2,000 to $4,000.)

That frustrates Linda S. Remensnyder, an Illinois audiologist who has consulted with Lin and has become an

advocate for the hearing-impaired. She says many of her older patients have become withdrawn and debilitated by the time they get to her.
She said some diseases and treatments cause hearing loss, along with age, but she believes the hearing loss makes their physical and mental health worse.
Remensnyder has joined other audiologists and the American Academy of Audiology, the Hearing Loss Association of America and AARP to encourage regular screenings, use of hearing aids and installation of hearing loops in public places such as theaters, shops and churches. The loops magnetically transmit sounds to a wireless receiver in hearing aids, filtering outside noise.
"Patients come in here and tell me that they've stopped going to activities," she said. "We not only have to provide hearing aids but make sure venues are audible. It's an incredible issue, and if we don't get it addressed we'll be paying for it. Maybe we can defer the onset of dementia."
Other scientists, including Dr. George Gates, a hearing expert at the University of Washington in Seattle, say they're not so sure hearing loss causes dementia. Gates says his research shows that dementia may cause hearing loss, and he is an advocate for more testing.
"What we've found is long before anyone gets a diagnosis of dementia, their ability to hear noise is severely affected, so a hearing test may reveal people at risk of dementia long before any other test," said Gates. He added that there is no cure for dementia, but early interventions may slow the progression.
He agreed with Lin that improving hearing can stave off depression, which he said can lead to other mental and physical maladies. "There absolutely is a public health threat from hearing loss," he said.
Lin, also an assistant professor in the epidemiology department in Hopkins' Bloomberg School of Public Health, plans to continue looking at the link to physical and mental health.
He's studying the cognitive abilities in those over 50 with hearing loss. He's also planning a larger study that will test the cognitive and physical abilities of people with hearing loss over years. One set will get free hearing aids, intensive instruction on using them and loop systems in some public areas. The other set will just be observed (they can buy a hearing aid themselves if they want).
"No one would think of not treating their high blood pressure, but hearing loss is still perceived as not that bad for you," Lin said. "If 30 million have hearing loss and less than one in five people do anything about it, and studies show that hearing loss is associated with adverse outcomes, think of how huge a public health threat that is."

Gabapentin for Tinnitus: A Systematic Review

Author: Aazh, Hashir; El Refaie, Amr; Humphriss, Rachel

Publication info: American Journal of Audiology (Online) 20.2 (Dec 1, 2011): 151-8.
ProQuest document link

Abstract: The main aim of this study was to assess the effect of gabapentin on tinnitus via a systematic review. An electronic search of literature as well as a hand search were conducted. Only double-blind randomized

controlled trials (RCTs) that met all of the inclusion criteria were included in this review. The Cochrane Collaboration tool for risk of bias assessment was used to investigate the validity of the included studies. Meta-analysis was not appropriate due to inadequate details in reporting the data in the included studies. Hence, qualitative synthesis and interpretation of the data were carried out. Two studies that met the inclusion criteria were included in the review. Fourteen studies were excluded. There were substantive within-study clinical heterogeneities with regard to the baseline tinnitus handicap scores, duration of tinnitus, and severity of hearing loss in the included double-blind RCTs. The authors of both studies reported that gabapentin was not superior to placebo in their primary outcomes. However, following the assessment of risk of bias and within-study clinical heterogeneities, this review concludes that there is insufficient evidence regarding the effect of gabapentin on tinnitus.

Purpose: The main aim of this study was to assess the effect of gabapentin on tinnitus via a systematic review.
Method: An electronic search of literature as well as a hand search were conducted. Only double-blind randomized controlled trials (RCTs) that met all of the inclusion criteria were included in this review. The Cochrane Collaboration tool for risk of bias assessment was used to investigate the validity of the included studies. Meta-analysis was not appropriate due to inadequate details in reporting the data in the included studies. Hence, qualitative synthesis and interpretation of the data were carried out.
Results: Two studies that met the inclusion criteria were included in the review. Fourteen studies were excluded. There were substantive within-study clinical heterogeneities with regard to the baseline tinnitus handicap scores, duration of tinnitus, and severity of hearing loss in the included double-blind RCTs.
Conclusion: The authors of both studies reported that gabapentin was not superior to placebo in their primary outcomes. However, following the assessment of risk of bias and within-study clinical heterogeneities, this review concludes that there is insufficient evidence regarding the effect of gabapentin on tinnitus.
Key Words: tinnitus, gabapentin, systematic review, hearing impairment

Tinnitus is the sensation of sound in the ears or head without actual acoustic stimulation. Tinnitus is most commonly associated with hearing loss (Brunnberg, Lindén-Boström, &Berglund, 2008; Dias &Cordeiro, 2008; Hiller &Goebel, 2006; Mrena, Ylikoski, Mäkitie, Pirvola, &Ylikoski, 2007; Nondahl et al., 2002; Ratnayake, Jayarajan, &Bartlett, 2009). There is not a one-to-one relationship between tinnitus and hearing loss; many people with normal hearing have tinnitus, and many people with hearing loss do not experience tinnitus. Nevertheless, the relationship between tinnitus and hearing loss has widely been acknowledged (Bauer, Turner, Caspary, Myers, &Brozoski, 2008; Moffat et al., 2009; Moore, Vinay, &Sandhya, 2010; Nelson &Chen, 2004; Nicolas-Puel et al., 2002; Ochi, Ohashi, &Kenmochi, 2003; Parra &Pearlmutter, 2007; Surr, Montgomery, &Mueller, 1985; Temmel, Kierner, Steurer, Riedl, &Innitzer, 1999).

Development in the field of neurobiology in recent decades has enabled researchers to look for the cause of tinnitus by focusing on chemical transmission at synapses in the peripheral and central auditory nervous system. Gamma amino butyric acid (GABA) is the major inhibitory neurotransmitter throughout the central nervous system and is also expressed in the inner ear (Watanabe, Maemura, Kanbara, Tamayama, &Hayasaki, 2002). When GABA binds to the GABAA receptor, it opens the associated chloride (Cl-) channels and allows flow of Cl- into the neuron. Thus, GABA hyperpolarizes the neuronal membrane and makes the cell less reactive to the excitatory neurotransmitters.

A reduction in GABA levels in the inferior colliculus was documented following noise-induced hearing loss in rats (Milbrandt, Holder, Wilson, Salvi, &Caspary, 2000). Tinnitus has been hypothesized to be the result of spontaneous hyperactivity at one or multiple levels in the auditory pathway, and this means that reduction in GABA levels could theoretically result in increased spontaneous activity in the auditory pathway and contribute

to the sensation of tinnitus. Reduction in GABA was also found following salicylate-induced hearing loss (Bauer, Brozoski, Holder, &Caspary, 2000).

Gabapentin is an anticonvulsant that is thought to increase the synthesis of GABA from glutamate and increase the concentration of GABA in the brain (Taylor et al., 1998). The side effects of gabapentin are relatively less than for other GABAergic drugs. Shulman, Strashun, Seibyl, Daftary, and Goldstein (2000) reported a significant decrease in GABAA receptor density in the medial temporal cortex in six patients with severe disabling tinnitus and hearing loss. Following this observation, they suggested the use of gabapentin for patients with severe disabling tinnitus. Zapp (2001) reported that 500 mg/day of gabapentin helped a patient to be free of tinnitus approximately 23 days/month. Shulman, Strashun, and Goldstein (2002) reported an improvement in tinnitus in 19 out of 21 patients with severe disabling central tinnitus who took a combination of gabapentin and clonazepam. In an experimental study on rats, Bauer and Brozoski (2001) reported that gabapentin reduced tinnitus induced by acoustic trauma without affecting hearing or general psychological performance.

Despite the evidence for the efficacy of gabapentin in animal studies and human case studies (Bauer &Brozoski, 2001; Shulman et al., 2002), there have been conflicting results among the controlled trials. Randomized controlled trials (RCTs) are the design of choice for examining the efficacy of a given treatment, because nonrandomized studies may exaggerate the effects of the intervention by up to 40% (Schulz, 1995). Although several independent RCT studies have been conducted to assess the efficacy of gabapentin on tinnitus, incorporating their results into practice by clinicians has been limited for the following reasons: (a) There have been conflicting findings among different RCT studies on gabapentin and tinnitus; (b) there have been variations in the quality of the RCT studies on gabapentin and tinnitus, and thus their outcomes should be interpreted in light of their methodological limitations; and (c) there has been no systematic review of the literature to consider the totality of available evidence and increase the efficient access to evidence through synthesis of results from multiple studies (Green, 2005).

The aim of this study was to assess the effect of gabapentin on tinnitus via a systematic review.

Method

Study Selection Criteria

Studies were included in this review if they were doubleblind RCTs that investigated the effects of gabapentin on tinnitus. Given the susceptibility to several types of bias (e.g., selection bias and placebo effect), studies with other designs (e.g., nonrandomized, before-and-after comparisons, case reports, and clinical observations) were excluded from this review. This is consistent with guidelines produced by the Cochrane Collaboration which strongly recommend that only RCTs be included in a systematic review (Higgins &Altman, 2008).

Participants included patients experiencing tinnitus. Studies in which patients in the experimental intervention group received orally administered gabapentin (brand name Neurontin) and patients in the control group received a matched placebo were included.

The dosage and duration of treatment were not restricted for the following reasons:

1. The dosage for gabapentin is individualized and should be based on the patient's report of tinnitus or adverse reactions (Shulman, 2008).
2. Although it has been suggested that the most effective dose for tinnitus is between 1,800 and 2,400 mg/day, there is no set dose or duration for this drug (Bauer &Brozoski, 2006).
3. To avoid significant side effects, patients should be placed on an escalating dosage scale.
4. Gabapentin bioavailability is not dose proportional. This means that as the dose is increased, bioavailability decreases. Bioavailability of gabapentin is approximately 60%, 47%, 34%, 33%, and 27% following 900, 1,200, 2,400, 3,600, and 4,800 mg/day given in three divided doses, respectively (Pfizer, 2009). Another criterion for inclusion is for the studies to employ psychometrically validated tinnitus questionnaires as outcome measures.

Search and Identification of Studies

Electronic search. A search of literature was conducted utilizing the following resources: AMED (Allied and

Complementary Medicine Database; 1985 to October 2009); British Nursing Index (1985 to October 2009); CINAHL (Cumulative Index to Nursing and Allied Health Literature; 1981 to October 2009); Embase (1980 to October 2009); Health Business Elite; Medline (1950 to October 2009); PsycInfo (1985 to October 2009); HMIC (Health Management Information Consortium); the Cochrane Ear, Nose and Throat Disorders Group Trials Register; CENTRAL (the Cochrane Central Register of Controlled Trials; The Cochrane Library, current issue); ISRCTN (the International Standard Randomized Controlled Trial Number register of clinical trials); and ClinicalTrials.gov, which is a registry of federally and privately supported clinical trials conducted in the United States and around the world.

The search strategy used the terms tinnitus AND (gabapentin OR neurontin) in titles and abstracts. To maximize sensitivity, no filters were employed in the search.

Hand search of journals and grey literature. The hand search was conducted on the following books: Andersson, Baguley, McKenna, and McFerran (2005); Henry, Trune, Robb, and Jastreboff (2007); Jastreboff and Hazell (2004); Luxon, Furman, Martini, and Stephens (2003); and Sataloff, Dentchev, and Hawkshaw (2007).

In addition, the authors of the published trials on gabapentin and tinnitus were contacted to find any unpublished studies that had not been identified by the search of published literature.

Data Collection and Analysis

Study identification. The titles and abstracts of the articles retrieved using the search strategy were reviewed. Articles that failed to meet the inclusion criteria were not reviewed (see Table 1 for the details of the inclusion criteria). The full text of articles that could not be excluded based on their titles and abstracts was retrieved and reviewed by the first author. Only studies that met all of the inclusion criteria were included in the review.

Quality assessment. The Cochrane Collaboration tool for assessing risk of bias (Higgins &Altman, 2008) was used for quality assessment in the present systematic review. The quality assessment was conducted by the first author and reviewed by the second and third authors. The Cochrane Collaboration tool for assessing risk of bias is a domainbased evaluation in which critical assessments are made separately for (a) sequence generation, (b) allocation concealment, (c) blinding, (d) incomplete outcome data, (e) selective outcome reporting, and (f) other sources of bias. All of the items included in this tool are related to risk of bias and internal validity. The application of this tool involves the following steps:

1. For each domain, there is one entry for describing what was reported to have happened in the study.
2. The second part of the tool involves assigning a judgment relating to the risk of bias for that entry. This is achieved by answering prespecified questions that are about the adequacy of the study in relation to the entry. The judgment yes indicates low risk of bias, no indicates high risk of bias, and unclear indicates unclear or unknown risk of bias (Higgins &Altman, 2008).

Results

The Search Process

Figure 1 summarizes the search and retrieval process for articles to include in this systematic review. The search process identified 16 articles. Two studies that met the inclusion criteria were included in the review. Fourteen studies were excluded. Table 2 shows the characteristics of the excluded articles and the reasons for exclusion.

Description of the Included Studies

Witsell, Hannley, Stinnet, and Tucci (2007). This was a double-blind RCT of gabapentin versus placebo. Seventynine patients met the inclusion criteria and were enrolled (53 gabapentin and 26 in placebo group). No statistically significant difference in decline in the Tinnitus Handicap Inventory (THI; Newman, Jacobson, &Spitzer, 1996) scores was detected between gabapentin and placebo groups at the corresponding intervals. There were no statistically significant changes in the Profile of Mood States (McNair, Lorr, &Droppleman, 1992) by treatment group at the end of Week 4 or any other measured intervals. Using a 10-point Likert scale, patients

reported whether their tinnitus was the same, better, or worse at the end of Week 4. Eighteen patients in the gabapentin group reported improvement, whereas only one in the placebo group noted improvement.
Piccirillo, Finnell, Vlahiotis, Chole, and Spitznagel (2007). This was a double-blind RCT of gabapentin for tinnitus. A total of 135 subjects were enrolled in the study. The change in the THI score from baseline to Week 8 for the gabapentin group was 11.3 (SD = 16.4); for the placebo group, the change was 11.0 (SD = 16.4). The difference between the groups was not statistically significant. At the end of Week 8, participants were asked to describe their overall degree of life disturbance due to tinnitus, their overall impression of change in tinnitus, and whether they would recommend the product they received to a friend. There were no significant differences in responses to these three questions between subjects in the two treatment arms. Finally, there were no considerable differences in the change in Beck Depression Inventory, Brief Symptom Inventory, and Epworth Sleepiness Scale Score following the therapy between the gabapentin and placebo groups (D. Kallogjeri, personal communication, March 8, 2010).

Quality Assessment (Risk of Bias in Included Studies)

Witsell et al. (2007). As shown in Table 3, following the assessment of risk of bias, this study was judged to be at high risk of attrition bias and reporting bias. This seriously weakened confidence in the study's results. The reasons for attrition in this study were not reported (except for only one patient). If the reasons for attrition were reported and were balanced across the groups, then the review author could have assessed whether the important bias should be expected. However, incomplete reporting of reasons for missing outcomes prevented the review author from making such assessment. In addition, the authors reported that 10 more patients were lost to follow-up. However, they did not clarify whether the missing data were distributed equally between the groups. Therefore, the final number of participants who completed the trial in each group was not clear.
In this study, the mean THI scores and their standard deviations were not reported clearly. Given the extent of the inadequate details in reporting the data, it was impossible for the review author to compute the standard deviations and other data necessary for including this study in a meta-analysis. An unsuccessful attempt was made to contact the corresponding investigator to request the missing data.
Piccirillo et al. (2007). As shown in Table 4, following the assessment of risk of bias, this study was judged to be at low risk of bias. Selection bias is unlikely to have seriously altered their results because their participants were sequentially randomized in a double-blind fashion according to a computer-generated random code. In addition, allocation of gabapentin and placebo was adequately concealed, as the research pharmacist maintained the randomization schedule and prepared the gabapentin and placebo capsules for the entire study. Plausible performance bias is unlikely to have seriously altered their results because the knowledge of the allocated intervention was adequately prevented during the study through blinding of the participants and the researchers. Finally, this study was judged to have low risk of attrition bias and reporting bias.

Discussion

The present study was designed to assess the effect of gabapentin on tinnitus by conducting a systematic review of the available research literature. As discussed earlier, doubleblind RCT is the study design that has the least likelihood of introducing any biases that can influence the results. In addition, given the subjective nature of tinnitus, there is always a high risk of placebo effect in all kind of tinnitus therapies. Therefore, it was decided to only include doubleblind RCTs in this review. Two double-blind RCTs regarding the effect of gabapentin on tinnitus were included (Piccirillo et al., 2007; Witsell et al., 2007).
The primary outcome measure of the included studies was the change in the THI scores. Using this outcome measure, both studies concluded that gabapentin was not superior to placebo. Hence, the result of this systematic review suggests that there is insufficient evidence supporting the effectiveness of gabapentin for tinnitus. Although the initial intention was to perform a meta-analysis of the results, it became apparent that this might prove unsatisfactory due to methodological limitations and the extent of the inadequate details in reporting the data in the included studies.

There are five issues that need consideration in interpreting this finding:

1. Overall quality and applicability of evidence. Although the final conclusion of the included studies was not in favor of gabapentin therapy for tinnitus, their results should be interpreted in light of their methodological limitations. Following the risk of bias assessment, the study by Witsell et al. (2007) was judged to be at high risk of attrition bias and high risk of reporting bias. This seriously weakens confidence in their results.

2. Pretreatment THI scores. The pretreatment THI scores across the gabapentin and placebo groups were relatively low in both of the included studies, making it more difficult to detect a between-group difference. This also contradicts the recommendation by Shulman et al. (2000, 2002) of using gabapentin therapy for patients with "severe disabling" tinnitus. Witsell et al. (2007) did not define any threshold for individual THI score in their inclusion criteria. The mean pretreatment THI score for patients in the gabapentin group was 37.8 (SD = 23). This means that given the wide intersubject variability, as shown by the large standard deviation, they probably included patients with a variety of tinnitus handicap ranging from no handicap to severe handicap. In the second study (Piccirillo et al., 2007), 23 patients in the gabapentin group and 18 patients in the placebo group had a THI score less than 38.

3. Large intersubject variability in tinnitus duration. There was a large intersubject variability in tinnitus duration (the length of time that a person hears tinnitus) among the subjects included in these two double-blind RCTs. In the study by Witsell et al. (2007), the inclusion criterion for tinnitus duration was tinnitus lasting more than 3 months. In the study by Piccirillo et al. (2007), the inclusion criterion associated with tinnitus duration was tinnitus lasting more than 6 months. The distribution of tinnitus duration in Piccirillo et al. (2007) ranged from 1 to 55 years. The subgroup analysis using two-factor repeated-measures analyses of variance did not show any correlation between duration of tinnitus and efficacy of gabapentin. However, lack of significant correlation in the subgroup analyses should be interpreted with caution, as the statistical power to detect a real difference is usually diminished when many subgroups are examined.

Although the relation between tinnitus duration and the extent of cortical reorganization is vague, many scientists suggest that on top of the modifications of the tonotopic map which occur immediately after peripheral damage, there are changes in the auditory cortex that take place over time (e.g., long-term synaptic potentiation or axonal sprouting; Bauer, 2004; Noreña &Eggermont, 2003; Noreña, Tomita, &Eggermont, 2003). Schlee, Hartmann, Langguth, and Weisz (2009) reported that people whose tinnitus lasted less than 4 years had marked changes in magneto-encephalography activity over the temporal cortex on the left side. However people whose tinnitus lasted longer than 4 years presented changes across a more widespread network of brain areas. This may have some clinical implications. For instance, it is possible that larger cortical reorganization subsequent to a longlasting tinnitus may be more difficult to modulate by treatment with gabapentin in comparison with less extensive cortical reorganization associated with a recent tinnitus. Therefore, lack of statistically significant improvement following gabapentin therapy in the included studies may in fact be related to the large intersubject variability in tinnitus duration.

4. Large intersubject variability in hearing levels. Loss of inhibition in the auditory cortex and down regulation of GABA is expected to happen following a peripheral deafferentation. In the animal studies that supported the effectiveness of gabapentin, tinnitus coexisted with hearing impairment that was caused directly by acoustic trauma. In addition, Bauer and Brozoski (2006) reported that gabapentin was effective in reducing tinnitus loudness and annoyance in some individuals with acoustic trauma-induced hearing loss presenting an audiogram notch between 3 and 6 kHz. Therefore, restoring GABA activity via gabapentin may be effective only in a subpopulation of tinnitus patients exhibiting some forms of hearing impairment. However, the majority of participants in Witsell et al. (2007) and Piccirillo et al. (2007) had normal hearing or mild hearing loss. This might have contributed to the lack of therapeutic effect of gabapentin on tinnitus that was reported in these studies.

5. Insensitive outcome measures. The outcome measures used in the included studies may not be sensitive enough or responsive to the prospective changes in tinnitus following a drug therapy. The primary outcome

measure at both studies included in this review was the change in the THI scores. The THI is a 25-item self-report questionnaire that assesses the impact of the tinnitus on the sufferer's life (i.e., tinnitus handicap). However, tinnitus handicap is not directly related to the severity or loudness of tinnitus (Budd &Pugh, 1996; Delb, D'Amelio, Schonecke, &Iro, 1999). This may explain the conflicting results reported by Witsell et al. (2007). In their study, there was no significant difference in the change in overall THI scores between the gabapentin and placebo groups. However, 18 patients in the gabapentin group reported improvement in their tinnitus, whereas only one in the placebo group noted improvement. This observation led Witsell et al. (2007) to conclude that the THI might not be sensitive or responsive enough to detect a measurable improvement in tinnitus levels. Piccirillo et al. (2007) also reported that the change in THI score in response to gabapentin in normal hearing subjects was not supported by other outcome measures such as the global rating of response or satisfaction with care. This observation led them to conclude that "the response to gabapentin, as measured by the THI score, does not reflect a true effect" (p. 397).

Implication for Practice

This systematic review of the literature from 1950 to October 2009 revealed that there are two double-blind RCT studies regarding the effect of gabapentin on tinnitus. The authors of both studies (Piccirillo et al., 2007; Witsell et al., 2007) reported that gabapentin was not superior to placebo in improving THI scores. As a result, it was concluded that there is insufficient evidence that gabapentin is effective for tinnitus.

Implication for Research

To accurately evaluate the effect of gabapentin on tinnitus, further studies with placebo-controlled RCT design are required. An important point to consider is the possibility that restoring GABA activity via gabapentin may be effective only in a subpopulation of tinnitus patients exhibiting some forms of hearing impairment. The efficacy of gabapentin in people with tinnitus with a duration of less than 4 years or even in people with recent tinnitus (duration less than 3 months) should also be addressed. While the link between tinnitus duration and cortical reorganization is debatable, it is possible that larger cortical reorganization may be more difficult to modulate by treatment with gabapentin in comparison with less extensive cortical reorganization. The effect of gabapentin on tinnitus itself and not on tinnitus handicap should be further investigated, though it will be harder to prove. A potential reduction in tinnitus loudness following gabapentin therapy may not necessarily have an effect on tinnitus handicap. There is little correlation between tinnitus loudness and the impact of tinnitus on daily life as measured by the THI (Ward &Baumann, 2009). Therefore, it is recommended that clinical trials should include a number of validated tinnitus questionnaires to assess the effect of interventions on tinnitus. In future studies, priority should be given to develop and use the outcome measurement tools that are responsive to the changes in tinnitus which may occur following a drug therapy.

Conclusions

Two double-blind RCTs were included in this systematic review of literature. The primary outcome measure used in the included studies was the change in the THI scores. The authors of both studies found that gabapentin was not superior to placebo in their primary outcomes. Following the assessment of risk of bias, the study by Witsell et al. (2007) was judged to be at high risk of attrition bias and reporting bias, and the study by Piccirillo et al. (2007) was judged to have low risk bias. Therefore, there is insufficient evidence supporting the effectiveness of gabapentin for tinnitus. This result should not be misinterpreted as evidence for the "ineffectiveness" of gabapentin for tinnitus.

Acknowledgments

This study was part of the first author's master of science (MSc) dissertation at the University of Bristol. We would like to thank Shahrzad Aazh, Helen Pryce, Pete Roberts, Deepak Prasher, and James Lockley for their support throughout the MSc program. We thank Jay F. Piccirillo for providing additional data concerning the Piccirillo et al. (2007) RCT on the effect of gabapentin on tinnitus. Finally, we thank Brian C. J. Moore for his valuable comments on an earlier version of this article.

Audiovisual Cues and Perceptual Learning of Spectrally Distorted Speech

Author: Pilling, Michael; Thomas, Sharon

Publication info: Language and Speech 54 (Dec 2011): 487-97.

Abstract: Two experiments investigate the effectiveness of audiovisual (AV) speech cues (cues derived from both seeing and hearing a talker speak) in facilitating perceptual learning of spectrally distorted speech. Speech was distorted through an eight channel noise-vocoder which shifted the spectral envelope of the speech signal to simulate the properties of a cochlear implant with a 6 mm place mismatch. Experiment 1 found that participants showed significantly greater improvement in perceiving noise-vocoded speech when training gave AV cues than when it gave auditory cues alone. Experiment 2 compared training with AV cues with training which gave written feedback. These two methods did not significantly differ in the pattern of training they produced. Suggestions are made about the types of circumstances in which the two training methods might be found to differ in facilitating auditory perceptual learning of speech. [PUBLICATION ABSTRACT]

Abstract

Two experiments investigate the effectiveness of audiovisual (AV) speech cues (cues derived from both seeing and hearing a talker speak) in facilitating perceptual learning of spectrally distorted speech. Speech was distorted through an eight channel noise-vocoder which shifted the spectral envelope of the speech signal to simulate the properties of a cochlear implant with a 6 mm place mismatch. Experiment 1 found that participants showed significantly greater improvement in perceiving noise-vocoded speech when training gave AV cues than when it gave auditory cues alone. Experiment 2 compared training with AV cues with training which gave written feedback. These two methods did not significantly differ in the pattern of training they produced. Suggestions are made about the types of circumstances in which the two training methods might be found to differ in facilitating auditory perceptual learning of speech.

Keywords

audiovisual, perceptual learning, speech

1 Introduction

As we speak we produce movements in our jaw, lips, and tongue that are easily perceptible to the eye. This visual speech information gives useful sensory cues that help decode the speech that we hear, particularly in terms of features such as place of articulation, rounding, and stress (Summerfield, 1987; Dohen et al., 2004; Munhall et al., 2004). As a consequence of this, audiovisual (AV) speech, speech where a talker is both seen and heard, tends to be more perceptible than speech where the talker can only be heard. The advantages in perceiving AV speech over unimodal auditory speech are most apparent when the heard speech is either impoverished or distorted in some way (Erber, 1975; MacLeod &Summerfield, 1987; Gagné et al., 1994; Helfer &Freyman, 2005). However, advantages for AV speech presentation have been documented even under ideal listening conditions (e.g., Davis &Kim, 2004).

The visual cues in AV speech influence how speech is perceived. Such effects are demonstrated by the McGurk effect (McGurk &MacDonald, 1976; Munhall et al., 1996). In this phenomenon certain incongruent auditory and visual speech tokens, e.g., auditory /ba/; visual /ga/, when presented simultaneously, result in a percept which is a fusion of the two modalities, e.g., /ta/. Evidence suggests that this integration of visual and auditory speech cues occurs at a relatively early stage of perceptual processing (Green, 1997; Schwartz et al., 2004), and that it is largely obligatory (Soto-Faraco et al., 2004).

AV cues can also play a role in speech learning. In infants AV cues have been shown to facilitate discrimination of auditory speech contrasts (Teinonen et al., 2008). In adult populations AV cues have been shown to facilitate learning of phonetic contrasts in L2 learners of English when the contrast is one which was absent in the native language and where the contrast produces visually salient movements for English speakers (Hazan et al., 2005;

see also Hardison, 2003). Another area of perceptual learning in which AV cues might play a role is in learning to comprehend speech which has altered characteristics. Noise-vocoded speech is one particular form of altered speech which is of particular scientific interest. This is speech which has properties which reflect those of natural speech when heard through a cochlear implant device (Dorman et al., 1998). The noise-vocoding process retains the coarser spectral and temporal properties of speech while removing its finer spectro-temporal structure. For normal hearing listeners the intelligibility of this speech is partly determined by the number of frequency bands used in its production (Shannon et al., 1995). These individual bands can be considered analogous to the independent electrode channels in an implant device. If at least eight bands are used the speech can be intelligible almost immediately, even to a naïve listener. If only four or fewer bands are used then initial speech intelligibility can be rather low, but is usually improved by training (Davies et al., 2005; Hervais-Adelman et al., 2008; Rota et al., 2008).

The implant electrodes of a cochlear implant device can be inserted only part way into the cochlea. This means that the band limits of the speech-processor analysis filter driving the electrode tend to be mismatched to the characteristic frequency of the primary auditory nerve fibers which are stimulated by the electrode (see Shannon et al., 1998). The spectral envelope of noise-vocoded speech can also be shifted to simulate this basalward shift of excitation that is thought to be common with cochlear implants. The change in timbre resulting from this additional transformation of the speech signal has a generally negative effect on perceptibility. Negative effects are found on the initial intelligibility of upward shifted speech even if it is constructed using a sufficient number of bands for the unshifted speech to be readily intelligible (Dorman et al., 1997; Shannon et al., 1998; Stacey &Summerfield, 2007). However, as with unshifted speech, perceptibility is often dramatically improved when training is given (Rosen et al., 1999; Fu &Galvin, 2003; Fu et al., 2006; Stacey &Summerfield, 2007, 2008).

Rosen et al. (1999) investigated learning of this shifted noise-vocoded speech in a study which gave participants access to AV cues during training. In this study participants were trained using a connected discourse tracking task in which they attempted to repeat segments of spoken text in communication with a talker in a separate booth who could be seen (through a glass screen) but whose speech was only heard through a noise-vocoding circuit. This training was effective in improving purely auditory recognition of the altered speech: Before training participants could identify less than one percent of the keywords by ear alone in an initial test block of sentences; after twelve sessions of training they could identify nearly forty percent of the keywords. Though these effects are impressive the main object of the study was not to assess the value of AV cues in auditory learning. As a consequence of this no control training condition was given from which the specific benefit of AV cues could be determined. The current paper aims to determine the effectiveness of AV cues in driving auditory learning of spectrally altered speech. This is done by comparing training with AV cues against training conditions which are auditory only (AO) in nature. The effectiveness of training in promoting learning of spectrally distorted speech is measured by the change in performance on AO test blocks given before and after training. Experiment 1 compared the effectiveness of three training conditions: AV, AO, and AO-Natural. AV training consisted of exposure to spectrally distorted auditory speech accompanied by a video of the face of the talker producing the original speech. AO training consisted of exposure to spectrally distorted auditory speech without the video. Finally, AO-Natural training consisted of exposure to auditory presentations of natural (i.e., undistorted) speech, also without the video.

2 Experiment 1

2.1 Method

2.1.1 Participants. Forty-two participants were recruited from the student population of the University of Nottingham. Participants were paid £10 for their time. All were English native speakers. All had normal hearing (pure-tone detection threshold levels of more than 25 dB in a range of 250 to 8000 Hz) and normal, or corrected-to-normal, vision (20/20 acuity on a Snellen test). None had formerly taken part in any study involving

either perceptual learning or exposure to spectrally distorted speech.

2.1.2 Stimuli and equipment. A single male talker with a southern British accent was video recorded uttering the sentences of the BKB sentence battery (Bench et al., 1979). BKB sentences have a simple vocabulary and their use in measuring speech perceptibility is well established. Sentences contain 3 to 4 keywords (e.g., the orange is quite sweet; rain falls from the clouds). Recordings were made in a sound attenuated room. The talker was recorded using a Sony DSR200AP digital camcorder. Video was recorded at a sample rate of 25 frames-per-second and audio at 48 kHz. The camcorder was placed 1.5 m from the talker's face. The talker's face was filmed from the front with a white screen as background. Three lamps were positioned to illuminate the face in a way in which shadowing did not occur. Auditory speech was captured by a microphone attached below the talker's face and out of sight of the camera. The talker began each sentence from a neutral facial expression with both lips held together. Recordings were edited offline into separate clips of each sentence using video editing software (Final Cut Pro 4, Apple Inc., CA). During editing a 1000 ms still frame was placed at the beginning and end of each clip. This still frame was given a 500 ms fade in/out from black. The audio track was cleaned of any background noise using the noise removal algorithm in Audacity software V1.2.6 (Mazzoni et al., 2006). Routines written in Matlab were used to produce the noise-vocoding and spectral shifting of the auditory speech. The technique used was similar to that described by Rosen et al. (1999). The auditory signal was first filtered through eight sixth-order elliptical IIR input filters. Filtered waveforms were half-wave-rectified and low-pass filtered (160 Hz). Envelopes were then multiplied by low-pass filtered (10 kHz) white noise. The signal from each of the channels was then filtered by eight sixth-order elliptical IIR output filters with central frequencies which had been shifted upwards to simulate a 6 mm basilar membrane displacement. The range and central frequencies of the individual input and output frequencies are given in Table 1. The eight channels were then summed into a single digital waveform. The output auditory waveform was resynchronized with the video recording to create the AV stimulus materials for the experiment. Resynchronization of the output waveform was done by manually matching the start and end points of this waveform with that of the original recorded auditory waveform in the video file. This was done within the video editing software earlier described. After synchronization was completed the original clean auditory waveform was deleted from the video file to leave the noise-vocoded auditory waveform. This version of the audiovisual file was then converted to Apple QuickTime format for use in the experiment. The experiment was performed on a G4 Apple Macintosh computer. Video was displayed on a Macintosh plasma VDU. Sound was presented through a separate loudspeaker connected to the computer via an amplifier. Software routines written in SuperCard (V. 4.1.1, Solutions Etcetera, CA) controlled all aspects of trial randomization, stimulus presentation, and recording of typed responses. Participants typed in responses using a standard Macintosh computer keyboard. These were recorded onto the computer's hard-disk. For all participants, an initial highly intelligible noise-vocoded sentence (24 frequency bands and no frequency shift) was given as an initial practice trial. This was done to familiarize participants with the task and to ensure that the instructions were understood correctly.

2.1.3 Procedure. Experiment 1 consisted of three trial blocks, Pretraining, Training, and Posttraining. All blocks contained 76 sentences. Sentences were allocated to blocks pseudorandomly with the constraint that no sentence appeared in more than one block and that blocks all had an equal number of keywords (235). Within each block no sentence was ever repeated. Randomization of the sentence materials was done separately for each participant. All participants performed the same Pretraining and Posttraining blocks which functioned as test blocks. Participants were randomly assigned in equal numbers to one of three training groups: AV, AO, AO-Natural. For test and training blocks participants were required to listen to the speech (while also looking at the screen in the AV training condition) and type as much of each sentence as was understood into the computer using the keyboard. Participants were encouraged to guess if unsure. If they did not understand anything from a particular sentence they were told to type "I don't know". Participants pressed the return key to record their responses into the computer. The pressing of this key instigated the next trial after a 1000 ms blank interval. No

feedback was given on any trial. A five minute break was given between successive blocks.

2.2 Results and discussion

A loose-keyword scoring method (Bench et al., 1979) was used to determine performance in each block. In this method each correct keyword receives a single point, irrespective of the order that words are reported in and morphological errors are accepted as correct. The total number of keywords correct was calculated for each participant using the above criteria. Mean scores in each block are given in Table 2. These are given separately for each of the three training groups. The fourth column of this table shows the mean improvement for the three training groups calculated by subtracting the performance in the Pretraining block from that of the Posttraining block.

For the training blocks analysis showed that the number of correctly reported keywords was significantly higher in the AV condition than the AO training condition, $t(26) = 5.54$, $p < .001$; however AV training block performance was still lower than performance in the AO-Natural training block, $t(26) = 5.33$, $p < .001$. A one-way ANOVA was used to look at test block performance. This ANOVA compared the mean test improvement scores (i.e., Posttest minus Pretest) for the three training groups. This showed a significant effect of training group, $F(2, 39) = 10.7$, $p < .001$. Post-hoc testing (Studentized Newman-Keuls) indicated that this effect was the result of the AV trained group showing greater improvement across the test blocks than either the AO and AO-Natural training groups ($p < .05$); the AO and AO-Natural training groups did not differ statistically in the level of improvement produced after training ($p > .05$).

Thus, Experiment 1 showed that AV training was more effective than AO training in promoting learning of spectrally altered speech. It suggested that exposure to AV speech can drive learning at an auditory perceptual level. Experiment 2 further explored this AV training effect.

3 Experiment 2

In Experiment 1 training was evaluated only across performance on two test blocks presented before and after a single block of training. The results from this experiment therefore give little indication of the time course that training might take. Experiment 2 gave shorter but more frequent alternating training and test blocks throughout the experiment. This allowed a more continuous monitoring of the effect of training on the auditory learning of speech. Experiment 2 also had a second purpose. Previous studies have demonstrated that perceptual learning of speech can be facilitated by presenting written feedback alongside auditory speech (Davis et al., 2005; Stacey &Summerfield, 2007, 2008). Written feedback seems to benefit auditory perceptual learning because of the lexical cues it provides: no effect of written feedback is found when training uses non-word speech (Davis et al., 2005; cf. Hervais-Adelman et al., 2008).

Experiment 2 compared the AV training effect identified in Experiment 1 with training using written feedback (AO+Text). The AV and AO+Text training groups were both compared against an AO training group given as a baseline training condition. As in Experiment 1 the AO training group received only auditory speech on training blocks. The effectiveness of training was measured by changes in test block performance over the course of the experiment. Test blocks were presented as AO for all three training groups.

3.1 Method

3.1.1 Participants. Forty-five students of the University of Nottingham were selected using the same inclusion criteria as Experiment 1. Participants all received a payment of £10. No participant had taken part in Experiment 1. Participants were allocated in equal numbers to one of the three training groups using a randomization procedure.

3.1.2 Stimuli. Stimuli were recordings of BKB sentences. Recordings were of the same origin as Experiment 1: 285 recorded sentences were used, 145 of these sentences were allocated as test trial stimuli and 140 of the sentences were used as training stimuli.

3.1.3 Procedure. Training and test blocks each contained five sentences. As in Experiment 1 randomization of sentences into the test blocks was done separately for each participant. This was done with the constraint that

no sentence was presented twice to a participant and that the five sentences in each test block always contained 15 keywords. The AO and AV training trials were the same as described for Experiment 1. The AO+Text training consisted of presentations of the distorted speech simultaneously with the text of the sentence being displayed on screen. Text was presented in uppercase at 45 point in Helvetica Neue font. This text scrolled across the computer screen word by word moving from right to left. The presentation of the words was at a rate which approximated that in the recorded speech of the talker. The first block was a test block. After this alternating training and test blocks were given. The last block was also a test block. In all 28 training and 29 test blocks were given. On all trials participants were instructed to type as much as they could decipher from the presented sentence into the computer.1 They were encouraged to guess if unsure and told to type "I don't know" on trials where they were unable to guess anything of the sentence content. No break was given between any blocks though participants were informed that they could have a break at any point in the experiment by delaying pressing the return key after typing in their response to a trial. A practice sentence was given to the participant before starting the experiment as described in Experiment 1.

3.2 Results and discussion

The same loose-keyword scoring method was used as in Experiment 1. Table 3 gives the mean overall number of keywords correctly identified in each test block for the three training groups. Figure 1 shows a plot of the number of keywords recognized for individual test blocks for the three training groups.

The three groups did not initially statistically differ from one another in terms of performance on the first test block, $F(2, 42) = 2.76$, $MSE = 1.29$, $p > .05$. Performance in subsequent test blocks was analyzed by organizing the test blocks into four separate bins. The first bin contained test blocks 2-8, the second contained blocks 9-15, the third blocks 16-22, and the fourth blocks 23-29. These were then entered into a two-way mixed ANOVA, with training condition as a three-level independent factor (AO, AV, AO+Text), and training duration as a four-level related factor (bin 1, bin 2, bin 3, bin 4). There was a significant main effect of training condition, $F(2, 42) = 7.14$, $MSE = 26.30$, $p < .01$, and a significant linear main effect of training duration, $F(1, 42) = 40.63$, $MSE = 3.42$, $p < .001$. There was no significant interaction between the main effects $F(2, 42) = 0.52$, $MSE = 3.42$, $p > .05$. Post-hoc testing (Studentized Newman-Keuls) of the training condition main effect revealed that test performance with AO-distorted training was significantly poorer than with AV-distorted or AO+Text training. However, AV and AO+Text trained groups did not differ from each other statistically in test performance in this analysis ($p > .05$).

The absence of a significant interaction between the main effects suggests that differences in performance between the training groups occurred during the initial training blocks and that these differences were then maintained across the rest of the experiment. This interpretation is supported by observation of the plots of the individual test trials in Figure 1. It can be seen that, for all three training groups, the most rapid performance increases occur in the initial test blocks and begin to asymptote in later test blocks.

4 General discussion

Experiments 1 and 2 both demonstrate the effectiveness of AV training in facilitating perceptual learning of spectrally altered speech. One question concerns how this facilitation occurs. When the auditory system first encounters spectrally altered speech it presumably has some difficulty in identifying its phonetic structure: The features of the incoming speech will differ somewhat from those of stored phonetic representations. Visual speech cues may assist in this process. Visual speech contains perceptually salient cues about the phonetic structure of auditory speech, cues which tend to anticipate their occurrence in the auditory signal (Grant et al., 1998; Hazen, 2006). It has been suggested that these cues can operate by constraining the phonetic categorization of speech, for instance if speech is being articulated on the lips this indicates that a given sound is a bilabial consonant such as /p/, /b/ or /m/ (see van Wassenhove et al., 2005). By constraining the phonetic interpretation of the auditory signal in this way visual cues might simultaneously provide guidance to auditory learning mechanisms in adjusting to the characteristics of the speech. This additional guidance is likely to make

learning more successful than when the perceiver must rely on auditory cues alone. Experiment 2 also showed that AO training with written feedback produced greater learning than observed with AO speech alone, replicating several earlier findings (e.g., Davis et al., 2005; Stacey &Summerfield, 2007). This form of training was equally as successful as AV training in facilitating perceptual learning of the given speech. The two forms of training are similar in as much as they both give additional visually presented cues to disambiguate the altered speech. At a phenomenal level both methods produce an immediate improvement in the perceived clarity of the speech heard on training trials (an effect with written feedback described as "pop-out", Davis et al., 2005). However, while written feedback is thought to give top-down lexical information, visual speech is more likely to give cues which are largely bottom-up and sensory in nature. Our experiment suggests that, under the specific conditions of our experiment at least, top-down lexical guidance is as effective as guidance from visual sensory cues in facilitating auditory learning.

This similarity in the effectiveness of the two training methods is likely to be coincidental and is unlikely to hold under all circumstances. The time course of perceptual learning for noise-vocoded speech tends to be longer when the speech is created from fewer than the eight bands used in the current study. With four band noise-vocoded speech, Rosen et al. (1999) found that learning continued to some degree over sessions spanning a number of days. The two training methods may be found to differ if the auditory speech is constructed from fewer bands under conditions where learning is more protracted. It is known that AV cues benefit speech perception across a wide range of auditory conditions, even where only minimal auditory speech cues are available (e.g., Erber, 1975; Saldaña et al., 1996). It is quite possible that written feedback is more limited in the range in which it is able to guide speech perception mechanisms. To test this, further research is needed to assess the relative effectiveness of the two training methods over a varied range of noise-vocoded speech conditions. There are other factors which may be of differential importance to the two training methods. Compared to written feedback the effectiveness of AV training is likely to be more dependent on the characteristics of the talker used. It is known that talkers vary considerably in the visual intelligibility of the speech they produce (Kricos &Lesner, 1982; Lesner, 1988; Demorest &Bernstein, 1992; Daly et al., 1996). Relative to written feedback training, AV training will probably be less effective with a talker with low visual speech intelligibility. Finally, the choice of speech materials themselves might influence the relative effectiveness of the two training methods. Written feedback training depends on the lexicality of the training speech materials, no training effect occurs when the items are non-words (Davies et al., 2005). If, as suggested above, AV training depends only on sensory cues then facilitation should be found even with non-word speech materials. AV training should drive perceptual learning just as well with non-word speech materials as with speech consisting of meaningful sentences.

Further research is clearly required to understand the different circumstances in which AV speech and written text are effective. What can be concluded from the current study is that AV speech cues, at least under some circumstances, are as effective as written feedback in driving perceptual learning. Practical suggestions can be made about how this form of training might be incorporated in a clinical context. Children who are prelingually deafened often have poor reading skills, possibly as a result of a less comprehensive understanding of grapheme-phoneme relations (e.g., James et al., 2008). However, such children when fitted with implants still derive considerable immediate benefits from access to AV cues when listening to speech (Bergeson et al., 2005). Such individuals may therefore find greater benefit from training which utilizes AV cues than training which is reliant on the presentation of text or on auditory presentations alone. Research is needed which evaluates the usefulness of AV training in comparison to other methods in the context of cochlear implant rehabilitation.

5 Conclusion

AV training was shown to reliably facilitate learning of spectrally distorted speech. It is suggested that this effect is driven by bottom-up sensory guidance of auditory learning mechanisms. Under the circumstances tested AV

training was at least as effective as training giving written feedback. Further research in both normal hearing and clinical populations is needed to determine the conditions under which the two methods are most useful in facilitating learning of this speech.

Acknowledgements

Some of these data were presented at the BSA meeting Cambridge, UK, 14-15 September (2006) and at AVSP (Hilvarenbeek, Netherlands, 2007). The first author is now at Oxford Brookes University, Headington, Oxford, UK. The comments of Andrew Faulkner and one anonymous referee on previous versions of this paper are gratefully acknowledged.

Footnote

Note

1 For the training trials of the AO+Text condition this was a trivial task because participants were being presented with the sentence contents in the form of the presented text. However, by giving this task it ensured that they did attend to the written cues as they were presented on each training trial.

SUMMARY: NMFS has received an application from the U.S. Marine Corps (USMC) requesting authorization to take marine mammals incidental to various training exercises at Marine Corps Air Station (MCAS) Cherry Point Range Complex, North Carolina. The USMC's activities are considered military readiness activities pursuant to the Marine Mammal Protection Act (MMPA), as amended by the National Defense Authorization Act (NDAA) for Fiscal Year 2004. Pursuant to the MMPA, NMFS is requesting comments on its proposal to issue an incidental harassment authorization (IHA) to the USMC to take bottlenose dolphins (Tursiops truncatus), by Level B harassment only, from specified activities.

SUMMARY: NMFS has received an application from the U.S. Marine Corps (USMC) requesting authorization to take marine mammals incidental to various training exercises at Marine Corps Air Station (MCAS) Cherry Point Range Complex, North Carolina. The USMC's activities are considered military readiness activities pursuant to the Marine Mammal Protection Act (MMPA), as amended by the National Defense Authorization Act (NDAA) for Fiscal Year 2004. Pursuant to the MMPA, NMFS is requesting comments on its proposal to issue an incidental harassment authorization (IHA) to the USMC to take bottlenose dolphins (Tursiops truncatus), by Level B harassment only, from specified activities.

DATES: Comments and information must be received no later than December 19, 2011.

ADDRESSES: Comments on the application should be addressed to Michael Payne, Chief, Permits and Conservation Division, Office of Protected Resources, National Marine Fisheries Service, 1315 East-West Highway, Silver Spring, MD 20910-3225. The mailbox address for providing email comments is ITP.Laws@noaa.gov. NMFS is not responsible for email comments sent to addresses other than the one provided here. Comments sent via email, including all attachments, must not exceed a 10-megabyte file size.

Instructions: All comments received are a part of the public record and may be posted to http://www.nmfs.noaa.gov/pr/permits/incidental.htm without change. All Personal Identifying Information (for example, name, address, etc.) voluntarily submitted by the commenter may be publicly accessible. Do not submit Confidential Business Information or otherwise sensitive or protected information.

A copy of the application containing a list of the references used in this document may be obtained by writing to the address specified above, telephoning the contact listed below (see FOR FURTHER INFORMATION CONTACT), or visiting the Internet at: http://www.nmfs.noaa.gov/pr/permits/incidental.htm. The following associated document is also available at the same Internet address: Environmental Assessment MCAS Cherry Point Range Operations (USMC 2009). Documents cited in this notice may also be viewed, by appointment, during regular business hours, at the aforementioned address.

FOR FURTHER INFORMATION CONTACT: Ben Laws, Office of Protected Resources, NMFS, (301) 427-8401.

SUPPLEMENTARY INFORMATION:

Background

Sections 101(a)(5)(A) of the MMPA (16 U.S.C. 1361 et seq.) direct the Secretary of Commerce to allow, upon request, the incidental, but not intentional, taking of marine mammals by U.S. citizens who engage in a specified activity (other than commercial fishing) if certain findings are made and regulations are issued or, if the taking is limited to harassment, notice of a proposed authorization is provided to the public for review.

Authorization for incidental takings may be granted if NMFS finds that the taking will have a negligible impact on the species or stock(s), will not have an unmitigable adverse impact on the availability of the species or stock(s) for certain subsistence uses, and if the permissible methods of taking and requirements pertaining to the mitigation, monitoring and reporting of such taking are set forth. NMFS has defined "negligible impact" in 50 CFR 216.103 as: "An impact resulting from the specified activity that cannot be reasonably expected to, and is

not reasonably likely to, adversely affect the species or stock through effects on annual rates of recruitment or survival."

Section 101(a)(5)(D) of the MMPA established an expedited process by which citizens of the United States can apply for an authorization to incidentally take small numbers of marine mammals by harassment. Section 101(a)(5)(D) establishes a 45-day time limit for NMFS review of an application followed by a 30-day public notice and comment period on any proposed authorizations for the incidental harassment of marine mammals. Within 45 days of the close of the comment period, NMFS must either issue or deny the authorization.

The NDAA (Pub. L. 108-136) removed the "small numbers" and "specified geographical region" limitations and amended the definition of "harassment" as it applies to a "military readiness activity" to read as follows (Section 3(18)(B) of the MMPA):

(i) Any act that injures or has the significant potential to injure a marine mammal or marine mammal stock in the wild [Level A Harassment]; or (ii) Any act that disturbs or is likely to disturb a marine mammal or marine mammal stock in the wild by causing disruption of natural behavioral patterns, including, but not limited to, migration, surfacing, nursing, breeding, feeding, or sheltering, to a point where such behavioral patterns are abandoned or significantly altered [Level B Harassment].

Summary of Request

On September 22, 2011, NMFS received an application from the USMC requesting an IHA for the harassment of Atlantic bottlenose dolphins (Tursiops truncatus) incidental to air-to-surface and surface-to-surface training exercises conducted around two bombing targets (BTs) within southern Pamlico Sound, North Carolina, at MCAS Cherry Point. NMFS first issued an IHA to the USMC for the same activities that was valid for a period of one year, beginning December 1, 2011 (75 FR 72807; November 26, 2010).

Weapon delivery training would occur at two BTs: Brant Island Target (BT-9) and Piney Island Bombing Range (BT-11). Training at BT-9 would involve air-to-surface (from aircraft to in-water targets) and surface-to-surface (from vessels to in-water targets) warfare training, including bombing, strafing, special (laser systems) weapons; surface fires using non-explosive and explosive ordnance; and mine laying exercises (inert). Training at BT-11 would involve air- to-surface exercises to provide training in the delivery of conventional (non-explosive) and special (laser systems) weapons. Surface-to-surface training by small military watercraft would also be executed here. The types of ordnances proposed for use at BT-9 and BT-11 include small arms, large arms, bombs, rockets, missiles, and pyrotechnics. All munitions used at BT-11 are inert, practice rounds. No live firing occurs at BT-11. Training for any activity may occur year-round. Active sonar is not a component of these specified training exercises; therefore, discussion of marine mammal harassment from active sonar operations is not included within this notice.

Description of the Specified Activity

The USMC is requesting authorization to harass bottlenose dolphins from ammunition firing conducted at two BTs within MCAS Cherry Point. The authorization would be valid for a period of one year from the date of issuance. The BTs are located at the convergence of the Neuse River and Pamlico Sound, North Carolina. BT-9 is a water-based target located approximately 52 km (28 nautical miles [nm]) northeast of MCAS Cherry Point. The BT-9 target area ranges in depth from 1.2 m to 6.1 m, with the shallow areas concentrated along the Brandt Island Shoal (which runs down the middle of the restricted area in a northwest to southeast orientation). The target itself consists of three ship hulls grounded on Brant Island Shoals, located approximately 4.8 km (3 miles [mi]) southeast of Goose Creek Island. Inert (non-explosive) ordnance up to 454 kilograms (kg) (1,000 lbs) and live (explosive) ordnance up to 45.4 kg (100 lbs) TNT equivalent, including ordnance released during strafing, are authorized for use at this target range. The target is defined by a 6 statute-mile (SM) diameter prohibited area designated by the U.S. Army Corps of Engineers, Wilmington District (33 CFR 334.420). Non-military vessels are not permitted within the prohibited area, which is delineated by large signs located on pilings surrounding the perimeter of the BT. BT-9 also provides a mining exercise area; however, all mine exercises

are simulation only and do not involve detonations. BT-9 standard operating procedures limit live ordnance deliveries to a maximum explosive weight of 100 lbs TNT equivalent. The USMC estimates that it would conduct approximately 1,539 aircraft-based and 165 vessel-based sorties, annually, at BT-9. The standard sortie consists of two aircraft per bombing run or an average of two and maximum of six vessels.

BT-11 is a 50.6 square kilometers (sq km) (19.5 square miles [sq mi]) complex of land- and water-based targets on Piney Island. The BT-11 target area ranges in depth from 0.3 m along the shoreline to 3.1 m in the center of Rattan Bay (BA 2001). The in-water stationary targets of BT-11 consist of a barge and patrol (PT) boat located in roughly the center of Rattan Bay. The barge target is approximately 135 ft by 40 ft in dimension. The PT boat is approximately 110 ft by 35 ft in dimension. Water depths in the center of Rattan Bay are estimated as 2.4 to 3 m (8 to 10 ft) with bottom depths ranging from 0.3 to 1.5 m (1 to 5 ft) adjacent to the shoreline of Piney Island. A shallow ledge, with substrate expected to be hard-packed to hard bottom, surrounds Piney Island. No live firing occurs at BT-11; all munitions used are inert, non-explosive practice rounds. Only 36 percent of all munitions fired at BT-11 occur over water; the remaining munitions are fired to land based targets on Piney Island. The USMC estimates that it would conduct approximately 6,727 aircraft-based and 51 vessel-based sorties, annually, at BT-11.

All inert and live-fire exercises at MCAS Cherry Point ranges are conducted so that all ammunition and other ordnances strike and/or fall on the land or water based target or within the existing danger zones or water restricted areas. A danger zone is a defined water area that is closed to the public on an intermittent or full-time basis for use by military forces for hazardous operations such as target practice and ordnance firing. A water restricted area is a defined water area where public access is prohibited or limited in order to provide security for Government property and/or to protect the public from the risks of injury or damage that could occur from the government's use of that area (33 CFR 334.2). Surface danger zones are designated areas of rocket firing, target practice, or other hazardous operations (33 CFR 334.420). The surface danger zone (prohibited area) for BT-9 is a 4.8 km radius centered on the south side of Brant Island Shoal. The surface danger zone for BT-11 is a 2.9 km radius centered on a barge target in Rattan Bay.

According to the application, the USMC is requesting take of marine mammals incidental to specified activities at MCAS Cherry Point Range Complex, located within Pamlico Sound, North Carolina. These activities include gunnery; mine laying; bombing; or rocket exercises and are classified into two categories here based on delivery method: (1) Surface-to-surface gunnery and (2) air-to-surface bombing. Exercises may occur year round, day or night (approximately 15 percent of training occurs at night).

Surface-to-Surface Gunnery Exercises

Surface-to-surface fires are fires from boats at sea to targets at sea. These can be direct (targets are within sight) or indirect (targets are not within sight). Gunnery exercise employing only direct fire is the only category of surface-to-surface activity currently conducted within the MCAS Cherry Point BTs. An average of two and maximum of six small boats (24-85 ft), or fleet of boats, typically operated by Special Boat Team personnel, use a machine gun to attack and disable or destroy a surface target that simulates another ship, boat, swimmer, floating mine or near shore land targets. Vessels travel between 0-20 kts with an average of two vessels actually conducting surface-to-surface firing activities. Typical munitions are 7.62 millimeter (mm) or .50 caliber (cal) machine guns; and/or 40 mm Grenade machine guns. This exercise is usually a live-fire exercise, but at times blanks may be used so that the boat crews can practice their ship handling skills. The goal of training is to hit the targets; however, some munitions may bounce off the targets and land in the water or miss the target entirely. Additionally, G911 Concussion hand grenades (inert and live) are used; however, these are not aimed at targets, as the goal is to learn how to throw them into the water.

The estimated amount of munitions expended at BT-9 and BT-11 during this training can be found in Table 1 below. Historically, boat sorties have been conducted at BT-9 and BT-11 year round with equal distribution of training effort throughout the seasons. Live fires constitute approximately 90 percent of all surface-to-surface

gunnery events. The majority of sorties originated and practiced at BT-9 as no live fire is conducted at BT-11. The USMC has indicated a comparable number of sorties would occur throughout the IHA timeframe. There is no specific schedule associated with the use of ranges by the small boat teams. However, exercises tend to be scheduled for 5-day blocks with exercises at various times throughout that timeframe. There is no specific time of year or month training occurs as variables such as deployment status, range availability, and completion of crew specific training requirements influence schedules.

A number of different types of boats are used during surface-to-surface exercises depending on the unit using the boat and their mission and include versions of Small Unit River Craft, Combat Rubber Raiding Craft, Rigid Hull Inflatable Boats, Patrol Craft. They are inboard or outboard, diesel or gasoline engines with either propeller or water jet propulsion. Boat crews approach, at a maximum of 20 kts, and engage targets simulating other boats, swimmers, floating mines, or near shore land targets with 7.62 mm or .50 cal machine guns; 40 mm grenade machine guns; or M3A2 Concussion hand grenades (approximately 200, 800, 10, and 10 rounds respectively). Vessels typically travel in linear paths and do not operate erratically. Other vessels may be located within the BTs; however, these are support craft and do not participate in munitions expenditures. The purpose of the support craft is to remotely control High Speed Maneuvering Surface Targets (HSMSTs) or to conduct maintenance on electronic equipment located in the towers at BT-9. Support craft are typically anchored or tied to marker pilings during HSMST operations or tied to equipment towers. When underway, vessels do not typically travel faster than 12-18 kts or in an erratic manner.

Air-to-Surface

Air-to-surface training involves ordnance delivered from aircraft and aimed at targets on the water's surface or on land in the case of BT-11. A description of the types of targets used at MCAS Cherry Point is provided in the section on BTs above. There are four types of air-to-surface activities conducted within the MCAS Cherry Point BTs: Mine laying; bombing; gunnery or rocket exercises which are carried out via fixed wing or rotary wing aircraft.

Mine Laying Exercises

Mine Warfare (MIW) includes the strategic, operational, and tactical use of mines and mine countermine measures. MIW is divided into two basic subdivisions: (a) The laying of mines to degrade the enemy's capabilities to wage land, air, and maritime warfare, and (b) the countering of enemy-laid mines to permit friendly maneuver or use of selected land or sea areas (DoN, 2007). MCAS Cherry Point would only engage in mine laying exercises as described below. No detonations of any mine device are involved with this training. During mine laying, a fixed-wing or maritime patrol aircraft (P-3 or P-8) typically drops a series of about four inert mine shapes in an offensive or defensive pattern, making multiple passes along a pre-determined flight azimuth, and dropping one or more shapes each time. Mine simulation shapes include MK76, MK80 series, and BDU practice bombs ranging from 25 to 2,000 pounds in weight, There is an attempt to fly undetected to the area where the mines are laid with either a low or high altitude tactic flight. The shapes are scored for accuracy as they enter the water and the aircrew is later debriefed on their performance. The training shapes are inert (no detonations occur) and expendable. Mine laying operations are regularly conducted in the water in the vicinity of BT-9.

Bombing Exercises

The purpose of bombing exercises is to train pilots in destroying or disabling enemy ships or boats. During training, fixed wing or rotary wing aircraft deliver bombs against surface maritime targets at BT-9 or BT-11, day or night, using either unguided or precision-guided munitions. Unguided munitions include MK-76 and BDU-45 inert training bombs, and MK-80 series of inert bombs (no cluster munitions authorized). Precision-guided munitions consist of laser-guided bombs (inert) and laser-guided training rounds (inert). Typically, two aircraft approach the target (principally BT-9) from an altitude of approximately 914 m (3,000 ft) up to 4,572 m (15,000 ft) and, when on an established range, the aircraft adhere to designated ingress and egress routes. Typical bomb release altitude is 914 m (3,000 ft) for unguided munitions or above 4,572 m (15,000 ft) and in excess of 1.8 km (1 nm) for precision-guided munitions. However, the lowest minimum altitude for ordnance delivery (inert bombs) would be 152 m (500 ft).

Onboard laser designators or laser designators from a support aircraft or ground support personnel are used to illuminate certified targets for use when using laser guided weapons. Due to target maintenance issues, live bombs have not been dropped at the BT-9 targets for the past few years although these munitions are authorized for use. For the effective IHA timeframe, no live bombs would be utilized. Live rockets and grenades; however, have been expended at BT-9.

Air-to-Surface bombing exercises have the potential to occur on a daily basis. The standard sortie consists of two aircraft per bombing run. The frequency of these exercises is dependent on squadron level training requirements, deployment status, and range availability; therefore, there is no set pattern or specific time of year or month when this training occurs. Normal operating hours for the range are 0800-2300, Monday through Friday; however, the range is available for use 365 days per year.

Rocket Exercises

Rocket exercises are carried out similar to bombing exercises. Fixed- and rotary-wing aircraft crews launch

rockets at surface maritime targets, day and night, to train for destroying or disabling enemy ships or boats. These operations employ 2.75-inch and 5-inch rockets.

The average number of rockets delivered per sortie is approximately 14. As with the bombing exercise, there is no set level or pattern of amount of sorties conducted.

Gunnery Exercises

During gunnery training, fixed- and rotary-wing aircraft expend smaller munitions targeted at the BTs with the purpose of hitting them. However, some small arms may land in the water. Rotary wing exercises involve either CH-53, UH-1, CH-46, MV-22, or H-60 rotary-wing aircraft with mounted 7.62 mm or .50 cal machine guns. Each gunner expends approximately 800 rounds of 7.62 mm and 200 rounds of .50 cal ammunition in each exercise. These may be live or inert.

Fixed wing gunnery exercises involve the flight of two aircraft that begin to descend to the target from an altitude of approximately 914 meters (m) (3,000 feet [ft]) while still several miles away. Within a distance of 1,219 m (4,000 ft) from the target, each aircraft fires a burst of approximately 30 rounds before reaching an altitude of 305 m (1,000 ft), then breaks off and repositions for another strafing run until each aircraft expends its exercise ordnance allowance of approximately 250 rounds. In total, about 8-12 passes are made by each aircraft per exercise. Typically these fixed wing exercise events involve an F/A-18 and AH-1 with Vulcan M61A1/A2, 20 mm cannon; AV-8 with GAU-12, 25 mm cannon.

Munition Descriptions

A complete list of the ordnance authorized for use at BT-9 and BT-11 can be found in Tables 2 and 3, respectively. There are several varieties and net explosive weights (for live munition used at BT-9) can vary according to the variety. All practice bombs are inert and used to simulate the same ballistic properties of service type bombs. They are manufactured as either solid cast metal bodies or thin sheet metal containers. Since practice bombs contain no explosive filler, a practice bomb signal cartridge (smoke) is used for visual observation of weapon target impact. Practice bombs provide a low cost training device for pilot and ground handling crews. Due to the relatively small amount of explosive material in practice bombs (small signal charge), the availability of ranges for training is greatly increased.

When a high explosive detonates, it is converted almost instantly into a gas at very high pressure and temperature. Under the pressure of the gases thus generated, the weapon case expands and breaks into fragments. The air surrounding the casing is compressed and shock (blast) wave is transmitted into it. Typical initial values for a high-explosive weapon are 200 kilobars of pressure (1 bar = 1 atmosphere) and 5,000 degrees Celsius. There are five types of explosive sources used at BT-9: 2.75" Rocket High Explosives, 5" Rocket High Explosives, 30 mm High Explosives, 40 mm High Explosives, and G911 grenades. No live munitions are used at BT-11.

Description of Marine Mammals in the Area of the Specified Activity

Forty marine mammal species occur within the nearshore and offshore waters of North Carolina; however, the majority of these species are solely oceanic in distribution. Only one marine mammal species, the bottlenose dolphin, has been repeatedly sighted in Pamlico Sound, while an additional species, the endangered West Indian manatee (Trichechus manatus), has been sighted rarely (Lefebvre et al., 2001; DoN 2003). The U.S. Fish and Wildlife Service oversees management of the manatee; therefore, authorization to harass manatees would not be included in any NMFS' authorization and will not be discussed further.

No sightings of the endangered North Atlantic right whale (Eubalaena glacialis) or other large whales have been observed within Pamlico Sound or in vicinity of the BTs (Kenney 2006). No suitable habitat exists for these species in the shallow Pamlico Sound or BT vicinity; therefore, whales would not be affected by the specified activities and will not be discussed further. Other dolphins, such as Atlantic spotted (Stenella frontalis) and common dolphins (Delphinus delphis), are oceanic in distribution and do not venture into the shallow, brackish waters of southern Pamlico Sound. Therefore, the specified activity has the potential to affect one marine mammal species under NMFS' jurisdiction: the bottlenose dolphin.

Coastal (or nearshore) and offshore stocks of bottlenose dolphins in the Western North Atlantic can be distinguished by genetics, diet, blood characteristics, and outward appearance (Duffield et al., 1983; Hersh and Duffield, 1990; Mead and Potter, 1995; Curry and Smith, 1997). Initially, a single stock of coastal morphotype bottlenose dolphins was thought to migrate seasonally between New Jersey (summer months) and central Florida based on seasonal patterns in strandings during a large scale mortality event occurring during 1987-1988 (Scott et al., 1988). However, re-analysis of stranding data (McLellan et al., 2003) and extensive analysis of genetic, photo-identification, satellite telemetry, and stable isotope studies demonstrate a complex mosaic of coastal bottlenose dolphin stocks (NMFS 2001) which may be migratory or resident (they do not migrate and occur within an area year round). Four out of the seven designated coastal stocks may occur in North Carolina waters at some part of the year: The Northern Migratory stock (NM; winter); the Southern Migratory stock (SM; winter); the Northern North Carolina Estuarine stock (NNCE; resident, year round); and the more recently identified Southern North Carolina Estuarine stock (SNCE; resident, year round). Stable isotope depleted oxygen signature (hypoxic conditions routinely develops during summer in North Carolina waters) (Cortese, 2000), satellite telemetry, and photo-identification (NMFS, 2001) support stock structure analysis. Dolphins encountered at the BTs likely belong to the NNCE and SNCE stock; however, this may not always be the case. NMFS' 2010 stock assessment report provides further detail on stock delineation. All stocks discussed here are considered depleted (and thus strategic) under the MMPA (Waring et al., 2010).

NMFS provides abundance estimates for the four aforementioned migratory and resident coastal stocks in its 2010 stock assessment report. The best available abundance estimate for the NNCE stock is the combined abundance from estuarine (Read et al., 2003) and coastal (aerial survey data dating from 2002) waters. This combined estimate is 1,387 (Waring et al., 2010). Similarly, the best available abundance estimate for the SNCE stock is the combined abundance from estuarine and coastal waters. This combined estimate is 2,595 (Waring et al., 2010). The best abundance estimate for the NM stock, resulting from 2002 aerial surveys, is 9,604 (Waring et al., 2010). Using the same information, the resulting best abundance estimate for the SM stock is 12,482 (Waring et al., 2010).

From July 2004 through April 2006, the NMFS' SEFSC conducted 41 aerial surveys to document the seasonal distribution and estimated density of sea turtles and dolphins within Core Sound and portions of Pamlico Sound, and coastal waters extending one mile offshore (Goodman et al., 2007). Pamlico Sound was divided into two survey areas: western (encompassing BT-9 and BT-11) and eastern (including Core Sound and the eastern portion of restricted air space R-5306). In total, 281 dolphins were sighted in the western range. To account for animals likely missed during sightings (i.e., those below the surface), Goodman et al. (2007) estimate that, in reality, 415 dolphins were present. Densities for bottlenose dolphins in the western part of Pamlico Sound were calculated to be 0.0272/km ^{2} in winter; 0.2158/km^2 in autumn; 0.0371/km^2 in summer; and 0.0946/km^2 in summer (Goodman et al., 2007). Dolphins were sighted throughout the entire range when mean sea surface temperature (SST) was 7.60 [degrees] C to 30.82 [degrees] C, with fewer dolphins sighted as water temperatures increased. Like in Mayer (2003), dolphins were found in higher numbers around BT-11, a range where no live firing occurs.

In 2000, Duke University Marine Lab (DUML), conducted a boat-based mark-recapture survey throughout the estuaries, bays and sounds of North Carolina (Read et al., 2003). This summer survey yielded a dolphin density of 0.183/km^2 (0.071 mi^2) based on an estimate of 919 dolphins for the northern inshore waters divided by an estimated 5,015 km^2 (1,936 mi^2) survey area. Additionally, from July 2002-June 2003, the USMC supported DUML to conduct dolphin surveys specifically in and around BT-9 and BT-11. During these surveys, one sighting in the restricted area surrounding BT-9 and two sightings in proximity to BT-11 were observed, as well as seven sightings in waters adjacent to the BTs. In total, 276 bottlenose dolphins were sighted ranging in group size from two to 70 animals with mean dolphin density in BT-11 more than twice as large as the density of any of the other areas; however, the daily densities were not significantly different (Maher, 2003). Estimated dolphin

density at BT-9 and BT-11 based on these surveys were calculated to be 0.11 dolphins/km ^{2} , and 1.23 dolphins/km^2 , respectively, based on boat surveys conducted from July 2002 through June 2003 (excluding April, May, Sept. and Jan.). However, the USMC choose to estimate take of dolphins based on the higher density reported from the summer 2000 surveys (0.183/km^2). Although the aerial surveys were conducted year round and therefore provide for seasonal density estimates, the average year-round density from the aerial surveys is 0.0936, lower than the 0.183/km^2 density chosen to calculate take for purposes of this MMPA authorization. Additionally, Goodman et al. (2007) acknowledged that boat based density estimates may be more accurate than the uncorrected estimates derived from the aerial surveys.

In Pamlico Sound, bottlenose dolphins concentrate in shallow water habitats along shorelines, and few, if any, individuals are present in the central portions of the sounds (Gannon, 2003; Read et al., 2003a, 2003b). The dolphins utilize shallow habitats, such as tributary creeks and the edges of the Neuse River, where the bottom depth is less than 3.5 m (Gannon, 2003). Fine-scale distribution of dolphins seems to relate to the presence of topography or vertical structure, such as the steeply-sloping bottom near the shore and oyster reefs, which may be used to facilitate prey capture (Gannon, 2003). Results of a passive acoustic monitoring effort conducted from 2006-2007 by Duke University researchers validated this information. Vocalizations of dolphins in the BT-11 vicinity were higher in August and September than vocalization detection at BT-9, an open water area (Read et al., 2007). Additionally, detected vocalizations of dolphins were more frequent at night for the BT-9 area and during early morning hours at BT-11.

Unlike migrating whales which display strong temporal foraging and mating/birthing periods, many bottlenose dolphins in Pamlico Sound are residents and mate year round. However, dolphins in the southeast U.S. do display some reproductive seasonality. Based on neonate stranding records, sighting data, and births by known females, the populations of dolphins that frequent the North Carolina estuarine waters have calving peaks in spring but calving continues throughout the summer and is followed by a smaller number of fall births (Thayer et al., 2003).

Bottlenose dolphins can typically hear within a broad frequency range of 0.04 to 160 kHz (Au, 1993; Turl, 1993). Electrophysiological experiments suggest that the bottlenose dolphin brain has a dual analysis system: one specialized for ultrasonic clicks and another for lower-frequency sounds, such as whistles (Ridgway, 2000). Scientists have reported a range of highest sensitivity between 25 and 70 kHz, with peaks in sensitivity at 25 and 50 kHz (Nachtigall et al., 2000). Recent research on the same individuals indicates that auditory thresholds obtained by electrophysiological methods correlate well with those obtained in behavior studies, except at some lower (10 kHz) and higher (80 and 100 kHz) frequencies (Finneran and Houser, 2006).

Sounds emitted by bottlenose dolphins have been classified into two broad categories: pulsed sounds (including clicks and burst-pulses) and narrow-band continuous sounds (whistles), which usually are frequency modulated. Clicks have a dominant frequency range of 110 to 130 kiloHertz (kHz) and a source level of 218 to 228 dB re 1 [mu]Pa (peak-to-peak) (Au, 1993) and 3.4 to 14.5 kHz at 125 to 173 dB re 1 [mu]Pa (peak-to-peak) (Ketten, 1998). Whistles are primarily associated with communication and can serve to identify specific individuals (i.e., signature whistles) (Caldwell and Caldwell, 1965; Janik et al., 2006). Up to 52 percent of whistles produced by bottlenose dolphin groups with mother-calf pairs can be classified as signature whistles (Cook et al., 2004). Sound production is also influenced by group type (single or multiple individuals), habitat, and behavior (Nowacek, 2005). Bray calls (low-frequency vocalizations; majority of energy below 4 kHz), for example, are used when capturing fish, specifically sea trout (Salmo trutta) and Atlantic salmon (Salmo salar), in some regions (i.e., Moray Firth, Scotland) (Janik, 2000). Additionally, whistle production has been observed to increase while feeding (Acevedo-Gutierrez and Stienessen, 2004; Cook et al., 2004).

Potential Effects on Marine Mammals

As mentioned previously, with respect to military readiness activities, Section 3(18)(B) of the MMPA defines "harassment" as: (i) Any act that injures or has the significant potential to injure a marine mammal or marine

mammal stock in the wild [Level A Harassment]; or (ii) any act that disturbs or is likely to disturb a marine mammal or marine mammal stock in the wild by causing disruption of natural behavioral patterns, including, but not limited to, migration, surfacing, nursing, breeding, feeding, or sheltering, to a point where such behavioral patterns are abandoned or significantly altered [Level B Harassment].

The USMC has concluded that harassment to marine mammals may occur incidental to munitions firing noise and pressure at the BTs. These military readiness activities would result in increased noise levels, explosions, and munition debris within bottlenose dolphin habitat. NMFS also considered the potential for harassment from vessel and aircraft operation. NMFS' analysis of potential impacts from these factors, including consideration of the USMC's analysis in its application, is outlined below.

Anthropogenic Sound

Marine mammals respond to various types of anthropogenic sounds introduced in the ocean environment. Responses are highly variable and depend on a suite of internal and external factors which in turn results in varying degrees of significance (NRC, 2003; Southall et al., 2007). Internal factors include: (1) Individual hearing sensitivity, activity pattern, and motivational and behavioral state (e.g., feeding, traveling) at the time it receives the stimulus; (2) past exposure of the animal to the noise, which may lead to habituation or sensitization; (3) individual noise tolerance; and (4) demographic factors such as age, sex, and presence of dependent offspring. External factors include: (1) Non-acoustic characteristics of the sound source (e.g., if it is moving or stationary); (2) environmental variables (e.g., substrate) which influence sound transmission; and (3) habitat characteristics and location (e.g., open ocean vs. confined area). To determine whether an animal perceives the sound, the received level, frequency, and duration of the sound are compared to ambient noise levels and the species' hearing sensitivity range. That is, if the frequency of an introduced sound is outside of the species' frequency hearing range, it cannot be heard. Similarly, if the frequency is on the upper or lower end of the species hearing range, the sound must be louder in order to be heard.

Marine mammal responses to anthropogenic noise are typically subtle and can include visible and acoustic reactions such as avoidance, altered dive patterns and cessation of pre-exposure activities and vocalization reactions such as increasing or decreasing call rates or shifting call frequency. Responses can also be unobservable, such as stress hormone production and auditory trauma or fatigue. It is not always known how these behavioral and physiological responses relate to significant effects (e.g., long-term effects or individual/population consequences); however, individuals and populations can be monitored to provide some insight into the consequences of exposing marine mammals to noise. For example, Haviland-Howell et al. (2007) compared sighting rates of bottlenose dolphins within the Wilmington, NC stretch of the Atlantic Intracoastal Waterway (ICW) on weekends, when recreational vessel traffic was high, to weekdays, when vessel traffic was relatively minimal. The authors found that dolphins were less often sighted in the ICW during times of increased boat traffic (i.e., on weekends) and theorized that because vessel noise falls within the frequencies of dolphin communication whistles and primary energy of most fish vocalizations, the continuous vessel traffic along that stretch of the ICW could result in social and foraging impacts. However, the extent to which these impacts affect individual health and population structure is unknown.

A full assessment of marine mammal responses and disturbances when exposed to anthropogenic sound can be found in NMFS' proposed rulemaking for the Navy Cherry Point Range Complex (74 FR 11057, March 16, 2009). That rulemaking was made final on June 15, 2009 (74 FR 28370). In summary, sound exposure may result in physiological impacts, stress responses, and behavioral responses which could affect proximate or ultimate life functions. Proximate life history functions are the functions that the animal is engaged in at the time of acoustic exposure. The ultimate life functions are those that enable an animal to contribute to the population (or stock, or species, etc.).

I. Physiology-Hearing Threshold Shift

In mammals, high-intensity sound may rupture the eardrum, damage the small bones in the middle ear, or over

stimulate the electromechanical hair cells that convert the fluid motions caused by sound into neural impulses that are sent to the brain. Lower level exposures may cause a loss of hearing sensitivity, termed a threshold shift (TS) (Miller, 1974). Incidence of TS may be either permanent, referred to as permanent threshold shift (PTS), or temporary, referred to as temporary threshold shift (TTS). The amplitude, duration, frequency, and temporal pattern, and energy distribution of sound exposure all affect the amount of associated TS and the frequency range in which it occurs. As amplitude and duration of sound exposure increase, generally, so does the amount of TS and recovery time. Human non-impulsive noise exposure guidelines are based on exposures of equal energy (the same SEL) producing equal amounts of hearing impairment regardless of how the sound energy is distributed in time (NIOSH 1998). Until recently, previous marine mammal TTS studies have also generally supported this equal energy relationship (Southall et al., 2007). Three newer studies, two by Mooney et al. (2009a, 2009b) on a single bottlenose dolphin either exposed to playbacks of Navy MFAS or octave-band noise (4-8 kHz) and one by Kastak et al. (2007) on a single California sea lion exposed to airborne octave-band noise (centered at 2.5 kHz), concluded that for all noise exposure situations the equal energy relationship may not be the best indicator to predict TTS onset levels. Generally, with sound exposures of equal energy, those that were quieter (lower sound pressure level [SPL]) with longer duration were found to induce TTS onset more than those of louder (higher SPL) and shorter duration (more similar to noise from AS Cherry Point exercises). For intermittent sounds, less TS will occur than from a continuous exposure with the same energy (some recovery will occur between exposures) (Kryter et al., 1966; Ward, 1997). Additionally, though TTS is temporary, very prolonged exposure to sound strong enough to elicit TTS, or shorter-term exposure to sound levels well above the TTS threshold, can cause PTS, at least in terrestrial mammals (Kryter, 1985). However, these studies highlight the inherent complexity of predicting TTS onset in marine mammals, as well as the importance of considering exposure duration when assessing potential impacts.

PTS consists of non-recoverable physical damage to the sound receptors in the ear, which can include total or partial deafness, or an impaired ability to hear sounds in specific frequency ranges; PTS is considered Level A harassment. TTS is recoverable and is considered to result from temporary, non-injurious impacts to hearing-related tissues; TTS is considered Level B harassment.

Permanent Threshold Shift

Auditory trauma represents direct mechanical injury to hearing related structures, including tympanic membrane rupture, disarticulation of the middle ear ossicles, and trauma to the inner ear structures such as the organ of Corti and the associated hair cells. Auditory trauma is irreversible and considered to be an injury that could result in PTS. PTS results from exposure to intense sounds that cause a permanent loss of inner or outer cochlear hair cells or exceed the elastic limits of certain tissues and membranes in the middle and inner ears and result in changes in the chemical composition of the inner ear fluids. In some cases, there can be total or partial deafness across all frequencies, whereas in other cases, the animal has an impaired ability to hear sounds in specific frequency ranges. There is no empirical data for onset of PTS in any marine mammal, and therefore, PTS- onset must be estimated from TTS-onset measurements and from the rate of TTS growth with increasing exposure levels above the level eliciting TTS-onset. PTS is presumed to be likely if the hearing threshold is reduced by >/= 40 dB (i.e., 40 dB of TTS). Relationships between TTS and PTS thresholds have not been studied in marine mammals, but are assumed to be similar to those in humans and other terrestrial mammals.

Temporary Threshold Shift

TTS is the mildest form of hearing impairment that can occur during exposure to a loud sound (Kryter, 1985). Southall et al. (2007) indicate that although PTS is a tissue injury, TTS is not because the reduced hearing sensitivity following exposure to intense sound results primarily from fatigue, not loss, of cochlear hair cells and supporting structures and is reversible. Accordingly, NMFS classifies TTS as Level B Harassment, not Level A Harassment (injury); however, NMFS does not consider the onset of TTS to be the lowest level at which Level B

Harassment may occur (see III. Behavior section below).

Southall et al. (2007) considers a 6 dB TTS (i.e., baseline hearing thresholds are elevated by 6 dB) sufficient to be recognized as an unequivocal deviation and thus a sufficient definition of TTS onset. TTS in bottlenose dolphin hearing have been experimentally induced. For example, Finneran et al. (2002) exposed a trained captive bottlenose dolphin to a seismic watergun simulator with a single acoustic pulse. No TTS was observed in the dolphin at the highest exposure condition (peak: 207 kPa [30psi]; peak-to-peak: 228 dB re: 1 microPa; SEL: 188 dB re 1 microPa ^{2} -s). Schludt et al. (2000) demonstrated temporary shifts in masked hearing thresholds in five bottlenose dolphins occurring generally between 192 and 201 dB rms (192 and 201 dB SEL) after exposure to intense, non-pulse, 1-s tones at, 3kHz, 10kHz, and 20 kHz. TTS onset occurred at mean sound exposure level of 195 dB rms (195 dB SEL). At 0.4 kHz, no subjects exhibited threshold shifts after SPL exposures of 193dB re: 1 microPa (192 dB re: 1 microPa ^{2} -s). In the same study, at 75 kHz, one dolphin exhibited a TTS after exposure at 182 dB SPL re: 1 microPa but not at higher exposure levels. Another dolphin experienced no threshold shift after exposure to maximum SPL levels of 193 dB re: 1 microPa at the same frequency. Frequencies of explosives used at MCAS Cherry Point range from 1-25 kHz; the range where dolphin TTS onset occurred at 195 dB rms in the Schludt et al. (2000) study.

Preliminary research indicates that TTS and recovery after noise exposure are frequency dependent and that an inverse relationship exists between exposure time and sound pressure level associated with exposure (Mooney et al., 2005; Mooney, 2006). For example, Nachtigall et al. (2003) measured TTS in a bottlenose dolphin and found an average 11 dB shift following a 30 minute net exposure to OBN at a 7.5 kHz center frequency (max SPL of 179 dB re: 1 microPa; SEL: 212-214 dB re: 1 microPa ^{2} -s). No TTS was observed after exposure to the same duration and frequency noise with maximum SPLs of 165 and 171 dB re: 1 microPa. After 50 minutes of exposure to the same 7.5 kHz frequency OBN, Natchigall et al. (2004) measured a 4-8 dB shift (max SPL: 160dB re 1microPa; SEL: 193-195 dB re:1 microPa ^{2} -s). Finneran et al. (2005) concluded that a sound exposure level of 195 dB re 1 [mu]Pa2-s is a reasonable threshold for the onset of TTS in bottlenose dolphins exposed to mid-frequency tones.

II. Stress Response

An acoustic source is considered a potential stressor if, by its action on the animal, via auditory or non-auditory means, it may produce a stress response in the animal. Here, the stress response will refer to an increase in energetic expenditure that results from exposure to the stressor and which is predominantly characterized by either the stimulation of the sympathetic nervous system (SNS) or the hypothalamic-pituitary-adrenal (HPA) axis (Reeder and Kramer, 2005). The SNS response to a stressor is immediate and acute and is characterized by the release of the catecholamine neurohormones norepinephrine and epinephrine (i.e., adrenaline). These hormones produce elevations in the heart and respiration rate, increase awareness, and increase the availability of glucose and lipids for energy. The HPA response is ultimately defined by increases in the secretion of the glucocorticoid steroid hormones, predominantly cortisol in mammals. The presence and magnitude of a stress response in an animal depends on a number of factors. These include the animal's life history stage (e.g., neonate, juvenile, adult), the environmental conditions, reproductive or developmental state, and experience with the stressor. Not only will these factors be subject to individual variation, but they will also vary within an individual over time. The stress response may or may not result in a behavioral change, depending on the characteristics of the exposed animal. However, provided a stress response occurs, we assume that some contribution is made to the animal's allostatic load. Any immediate effect of exposure that produces an injury is assumed to also produce a stress response and contribute to the allostatic load. Allostasis is the ability of an animal to maintain stability through change by adjusting its physiology in response to both predictable and unpredictable events (McEwen and Wingfield, 2003). If the acoustic source does not produce tissue effects, is not perceived by the animal, or does not produce a stress response by any other means, we assume that the exposure does not contribute to the allostatic load. Additionally, without a stress response or

auditory masking, it is assumed that there can be no behavioral change.

III. Behavior

Changes in marine mammal behavior in response to anthropogenic noise may include altered travel directions, increased swimming speeds, changes in dive, surfacing, respiration and feeding patterns, and changes in vocalizations. As described above, lower level physiological stress responses could also co-occur with altered behavior; however, stress responses are more difficult to detect and fewer data exist relative to specific received levels of sound.

Acoustic Masking

Anthropogenic noise can interfere with, or mask, detection of acoustic signals such as communication calls, echolocation, and environmental sounds important to marine mammals. Southall et al. (2007) defines auditory masking as the partial or complete reduction in the audibility of signals due to the presence of interfering noise with the degree of masking depending on the spectral, temporal, and spatial relationships between signals and masking noise, as well as the respective received levels. Masking of sender communication space can be considered as the amount of change in a sender's communication space caused by the presence of other sounds, relative to a pre-industrial ambient noise condition (Clark et al., in press). Unlike auditory fatigue, which always results in a stress response because the sensory tissues are being stimulated beyond their normal physiological range, masking may or may not result in a stress response, depending on the degree and duration of the masking effect. Masking may also result in a unique circumstance where an animal's ability to detect other sounds is compromised without the animal's knowledge. This could conceivably result in sensory impairment and subsequent behavior change; in this case, the change in behavior is the lack of a response that would normally be made if sensory impairment did not occur. For this reason, masking also may lead directly to behavior change without first causing a stress response. Projecting noise into the marine environment which causes acoustic masking is considered Level B harassment as it can disrupt natural behavioral patterns by interrupting or limiting the marine mammal's receipt or transmittal of important information or environmental cues. To compensate for masking, marine mammals, including bottlenose dolphins, are known to increase their levels of vocalization as a function of background noise by increasing call repetition and amplitude, shifting calls higher frequencies, and/or changing the structure of call content (Lesage et al., 1999; Scheifele et al., 2005; McIwem, 2006).

While it may occur temporarily, NMFS does not expect auditory masking to result in detrimental impacts to an individual's or population's survival, fitness, or reproductive success. Dolphins are not confined to the BT ranges; allowing for movement out of area to avoid masking impacts. The USMC would also conduct visual sweeps of the area before any training exercise and implement training delay mitigation measures if a dolphin is sighted within designated zones (see Proposed Mitigation Measures section below). As discussed previously, the USMC has been working with DUML to collect baseline information on dolphins in Pamlico Sound, specifically dolphin abundance and habitat use around the BTs. The USMC has also recently accepted a DUML proposal to investigate methods of dolphin acoustic detection around the BTs. NMFS would encourage the USMC to expand acoustic investigations to include the impacts of training exercises on vocalization properties (e.g., call content, duration, frequency) and masking (e.g., communication and foraging impairment) of the affected population of dolphins in Pamlico Sound.

Assessment of Marine Mammal Impacts From Explosive Ordnances

MCAS Cherry Point plans to use five types of explosive sources during its training exercises: 2.75" Rocket High Explosives, 5" Rocket High Explosives, 30 mm High Explosives, 40 mm High Explosives, and G911 grenades. The underwater explosions from these weapons would send a shock wave and blast noise through the water, release gaseous by-products, create an oscillating bubble, and cause a plume of water to shoot up from the water surface. The shock wave and blast noise are of most concern to marine animals. In general, potential impacts from explosive detonations can range from brief effects (such as short term behavioral disturbance),

tactile perception, physical discomfort, slight injury of the internal organs and the auditory system, to death of the animal (Yelverton et al., 1973; O'Keeffe and Young, 1984; DoN, 2001).

Explosives produce significant acoustic energy across several frequency decades of bandwidth (i.e., broadband). Propagation loss is sufficiently sensitive to frequency as to require model estimates at several frequencies over such a wide band. The effects of an underwater explosion on a marine mammal depend on many factors, including the size, type, and depth of both the animal and the explosive charge; the depth of the water column; and the standoff distance between the charge and the animal, as well as the sound propagation properties of the environment. The net explosive weight (or NEW) of an explosive is the weight of TNT required to produce an equivalent explosive power. The detonation depth of an explosive is particularly important due to a propagation effect known as surface-image interference. For sources located near the sea surface, a distinct interference pattern arises from the coherent sum of the two paths that differ only by a single reflection from the pressure-release surface. As the source depth and/or the source frequency decreases, these two paths increasingly, destructively interfere with each other, reaching total cancellation at the surface (barring surface-reflection scattering loss). USMC conservatively estimates that all explosives would detonate at a 1.2 m (3.9 ft) water depth. This is the worst case scenario as the purpose of training is to hit the target, resulting in an in-air explosion.

The firing sequence for some of the munitions consists of a number of rapid bursts, often lasting a second or less. The maximum firing time is 10-15 second bursts. Due to the tight spacing in time, each burst can be treated as a single detonation. For the energy metrics, the impact area of a burst is computed using a source energy spectrum that is the source spectrum for a single detonation scaled by the number of rounds in a burst. For the pressure metrics, the impact area for a burst is the same as the impact area of a single round. For all metrics, the cumulative impact area of an event consisting of a certain number of bursts is merely the product of the impact area of a single burst and the number of bursts, as would be the case if the bursts are sufficiently spaced in time or location as to insure that each burst is affecting a different set of marine wildlife.

Physical damage of tissues resulting from a shock wave (from an explosive detonation) is classified as an injury. Blast effects are greatest at the gas-liquid interface (Landsberg, 2000) and gas containing organs, particularly the lungs and gastrointestinal tract, are especially susceptible to damage (Goertner, 1982; Hill 1978; Yelverton et al., 1973). Nasal sacs, larynx, pharynx, trachea, and lungs may be damaged by compression/expansion caused by the oscillations of the blast gas bubble (Reidenberg and Laitman, 2003). Severe damage (from the shock wave) to the ears can include tympanic membrane rupture, fracture of the ossicles, damage to the cochlea, hemorrhage, and cerebrospinal fluid leakage into the middle ear.

Non-lethal injury includes slight injury to internal organs and the auditory system; however, delayed lethality can be a result of individual or cumulative sublethal injuries (DoN, 2001). Immediate lethal injury would be a result of massive combined trauma to internal organs as a direct result of proximity to the point of detonation (DoN, 2001). Exposure to distance explosions could result only in behavioral changes. Masked underwater hearing thresholds in two bottlenose dolphins and one beluga whale have been measured before and after exposure to impulsive underwater sounds with waveforms resembling distant signatures of underwater explosions (Finneran et al., 2000). The authors found no temporary shifts in masked-hearing thresholds (MTTSs), defined as a 6-dB or larger increase in threshold over pre-exposure levels, had been observed at the highest impulse level generated (500 kg at 1.7 km, peak pressure 70 kPa); however, disruptions of the animals' trained behaviors began to occur at exposures corresponding to 5 kg at 9.3 km and 5 kg at 1.5 km for the dolphins and 500 kg at 1.9 km for the beluga whale.

Generally, the higher the level of impulse and pressure level exposure, the more severe the impact to an individual. While, in general, dolphins could sustain injury or mortality if within very close proximity to in-water explosion, monitoring and mitigation measures employed by the USMC before and during training exercises, as would be required under any ITA issued, are designed to avoid any firing if a marine mammal is sighted within

designated BT zones (see Proposed Mitigation and Monitoring section below). No marine mammal injury or death has been attributed to the specified activities described in the application. As such, and due to implementation of the proposed mitigation and monitoring measures, bottlenose dolphin injury or mortality is not anticipated nor would any be authorized.

Inert Ordnances

The potential risk to marine mammals from non-explosive ordnance entails two possible sources of impacts: Elevated sound levels or the ordnance physically hitting an animal. The latter is discussed below in the Munition Presence section below. The USMC provided information that the noise fields generated in water by the firing of non-explosive ordnance indicate that the energy radiated is about 1 to 2 percent of the total kinetic energy of the impact. This energy level (and likely peak pressure levels) is well below the TTS-energy threshold, even at 1-m from the impact and is not expected to be audible to marine mammals. As such, the noise generated by the in-water impact of non-explosive ordnance will not result in take of marine mammals.

Training Debris

In addition to behavioral and physiological impacts from live fire and ammunition testing, NMFS has preliminarily analyzed impacts from presence of munition debris in the water, as described in the USMC's application and 2009 EA. These impacts include falling debris, ingestion of expended ordnance, and entanglement in parachute debris.

Ingestion of marine debris by marine mammals can cause digestive tract blockages or damage the digestive system (Gorzelany, 1998; Stamper et al., 2006). Debris could be either the expended ordnance or non-munition related products such as chaff and self protection flares. Expended ordnance would be small and sink to the bottom. Chaff is composed of either aluminum foil or aluminum-coated glass fibers designed to act as a visual smoke screen; hiding the aircraft from enemy radar. Chaff also serves as a decoy for radar detection, allowing aircraft to maneuver or egress from the area. The foil type currently used is no longer manufactured, although it remains in the inventory and is used primarily by B-52 bombers. Both types of chaff are cut into dipoles ranging in length from 0.3 to over 2.0 inches. The aluminum foil dipoles are 0.45 mils (0.00045 inches) thick and 6 to 8 mils wide. The glass fiber dipoles are generally 1 mil (25.4 microns) in diameter, including the aluminum coating. Chaff is packed into about 4-ounce bundles. The major components of chaff are silica, aluminum, and stearic acid; all naturally prevalent in the environment.

Based on the dispersion characteristics of chaff, concentrations around the BTs would be low. For example, Hullar et al. (1999) calculated that a 4.97-mile by 7.46-mile area (37.1 km^2) would be affected by deployment of a single cartridge containing 150 grams of chaff; however, concentration would only be about 5.4 grams per square nautical mile. This corresponds to fewer than 179,000 fibers per square nautical mile or fewer than 0.005 fibers per square foot.

Self-protection flares are deployed to mislead or confuse heat-sensitive or heat-seeking anti-aircraft systems. The flares are magnesium pellets that, when ignited, burn for a short period of time (less than 10 seconds) at 2,000 degrees Fahrenheit. Air-deployed LUU-2 high-intensity illumination flares are used to illuminate targets, enhancing a pilot's ability to see targets while using Night Vision Goggles. The LUU-2B Flare has a light output rating of 1.8 x 10(6) candlepower and at 1,000 feet altitude illuminates a circle on the ground of 500 meters. The LUU-2 is housed in a pod or canister and is deployed by ejection. The mechanism has a timer on it that deploys the parachute and ignites the flare candle. The flare candle burns magnesium at high temperature, emitting an intense bright white light. The LUU-2 has a burn time of approximately 5 minutes while suspended from a parachute. The pyrotechnic candle consumes the flare housing, reducing flare weight, which in turn slows the rate of fall during the last 2 minutes of burn time. At candle burnout an explosive bolt is fired, releasing one parachute support cable, which causes the parachute to collapse.

Ingestion of debris by dolphins is not likely, as dolphins typically eat fish and other moving prey items. NMFS solicited information on evidence of debris ingestion from two marine mammal veterinarians who have

performed many necropsies on the protected species of North Carolina's waters. In their experience, no necropsies of bottlenose dolphins have revealed evidence of munition, parachute, or chaff ingestion (pers. comm., Drs. C. Harms and D. Rostein, November 14, 2009). However, it was noted evidence of chaff ingestion would be difficult to detect. In the chance that dolphins do ingest chaff, the filaments are so fine they would likely pass through the digestive system without complication. However, if the chaff is durable enough, it might act as a linear foreign body. In such case, the intestines bunch up on the line restricting movement of the line resulting in an obstruction. The peristalsis on an immovable thin line can cause intestinal lacerations and perforations (pers. comm., C. Harms, November 14, 2009. This is a well known complication in cats when they ingest thread and which occurs occasionally with sea turtles ingesting fishing line. The longevity of chaff filaments, based upon dispersion rates, is unclear. Chaff exposed to synthetic seawater and aqueous environments in the pH range of 4-10 exhibited varying levels of degradation suggesting a short lifespan for the outer aluminum coating (Farrell and Siciliano, 1998). The underlying filament is a flexible silica core and composed of primarily silica dioxide. While no studies have been conducted to evaluate the effects of chaff ingestion on marine mammals, the effects are expected to be negligible based upon chaff concentration in the environment, size of fibers, and available toxicity data on fiberglass and aluminum. Given that the size of chaff fibers are no more than 2 inches long, tidal flushing reduces concentration in the environment, and chaff degradation rate, the chance of chaff ingestions is unlikely; however, if swallowed, impacts would be negligible.

Given that there is no evidence that dolphins ingest military debris; dolphins in the Sound forage on moving prey suspended in the water column while expended munition would sink; the property and dispersion characteristics of chaff make potential for ingestion discountable; and that Pamlico Sound is a tidal body of water with continuing flushing, NMFS has preliminarily determined that the presence of training debris would not have an effect on dolphins in Pamlico Sound.

Although sometimes large, expended parachutes (e.g., those from the flares) are flimsy and structurally simple and NMFS has determined that the probability of entanglement with a dolphin is low. There are no known reports of live or stranded dolphins entangled in parachute gear; fishing gear is usually the culprit of reported entanglements. The NMFS' Marine Mammal Stranding Network (Network) has established protocol for reporting marine mammals in peril. Should any injured, stranded or entangled marine mammal be observed by USMC personnel during training exercises, the sighting would be reported to the Network within 24 hours of the observation.

Vessel and Aircraft Presence

The marine mammals most vulnerable to vessel strikes are slow-moving and/or spend extended periods of time at the surface in order to restore oxygen levels within their tissues after deep dives (e.g., right whales, fin whales, sperm whales). Smaller marine mammals such as bottlenose dolphins (the only marine mammal that would be encountered at the BTs) are agile and move more quickly through the water, making them less susceptible to ship strikes. NMFS is not aware of any vessel strikes of bottlenose dolphins in Pamlico Sound. Therefore, NMFS does not anticipate that USMC vessels engaged in the specified activity would strike any marine mammals and no take from ship strike would be authorized in the proposed IHA.

Behaviorally, marine mammals may or may not respond to the operation of vessels and associated noise. Responses to vessels vary widely among marine mammals in general, but also among different species of small cetaceans. Responses may include attraction to the vessel (Richardson et al., 1995); altering travel patterns to avoid vessels (Constantine, 2001; Nowacek et al., 2001; Lusseau, 2003, 2006); relocating to other areas (Allen and Read, 2000); cessation of feeding, resting, and social interaction (Baker et al., 1983; Bauer and Herman, 1986; Hall, 1982; Krieger and Wing, 1984; Lusseau, 2003; Constantine et al., 2004); abandoning feeding, resting, and nursing areas (Jurasz and Jurasz 1979; Dean et al., 1985; Glockner-Ferrari and Ferrari 1985, 1990; Lusseau, 2005; Norris et al., 1985; Salden, 1988; Forest, 2001; Morton and Symonds, 2002; Courbis, 2004; Bejder, 2006); stress (Romano et al., 2004); and changes in acoustic behavior (Van Parijs and

Corkeron, 2001). However, in some studies marine mammals display no reaction to vessels (Watkins, 1986; Nowacek et al., 2003) and many odontocetes show considerable tolerance to vessel traffic (Richardson et al., 1995). Dolphins may actually reduce the energetic cost of traveling by riding the bow or stern waves of vessels (Williams et al., 1992; Richardson et al., 1995).

Dolphins within Pamlico Sound are continually exposed to recreational, commercial, and military vessels. Richardson et al. (1995) addresses in detail three responses that marine mammals may experience when exposed to anthropogenic activities: Tolerance; habituation; and sensitization. More recent publications provide variations on these themes rather than new data (NRC 2003). Marine mammals are often seen in regions with much human activity; thus, certain individuals or populations exhibit some tolerance of anthropogenic noise and other stimuli. Animals will tolerate a stimulus they might otherwise avoid if the benefits in terms of feeding, mating, migrating to traditional habitats, or other factors outweigh the negative aspects of the stimulus (NRC, 2003). In many cases, tolerance develops as a result of habituation. The NRC (2003) defines habituation as a gradual waning of behavioral responsiveness over time as animals learn that a repeated or ongoing stimulus lacks significant consequences for the animals. Contrarily, sensitization occurs when an animal links a stimulus with some degree of negative consequence and as a result increases responsiveness to that human activity over time (Richardson et al., 1995). For example, seals and whales are known to avoid previously encountered vessels involved in subsistence hunts (Walker, 1949; Ash 1962; Terhune, 1985) and bottlenose dolphins that had previously been captured and released from a 7.3 m boat involved in health studies were documented to flee when that boat approached closer than 400 m, whereas dolphins that had not been involved in the capture did not display signs of avoidance of the vessel (Irvine et al., 1981). Because dolphins in Pamlico Sound are continually exposed to vessel traffic that does not present immediate danger to them, it is likely animals are both tolerant and habituated to vessels.

The specified activities also involve aircraft, which marine mammals are known to react (Richardson et al., 1995). Aircraft produce noise at frequencies that are well within the frequency range of cetacean hearing and also produce visual signals such as the aircraft itself and its shadow (Richardson et al., 1995, Richardson &Wuersig, 1997). A major difference between aircraft noise and noise caused by other anthropogenic sources is that the sound is generated in the air, transmitted through the water surface and then propagates underwater to the receiver, diminishing the received levels to significantly below what is heard above the water's surface. Sound transmission from air to water is greatest in a sound cone 26 degrees directly under the aircraft. Reactions of odontocetes to aircraft have been reported less often than those of pinnipeds. Responses to aircraft include diving, slapping the water with pectoral fins or tail fluke, or swimming away from the track of the aircraft (Richardson et al., 1995). The nature and degree of the response, or the lack thereof, are dependent upon nature of the flight (e.g., type of aircraft, altitude, straight vs. circular flight pattern). Wuersig et al. (1998) assessed the responses of cetaceans to aerial surveys in the northcentral and western Gulf of Mexico using a DeHavilland Twin Otter fixed-wing airplane. The plane flew at an altitude of 229 m at 204 km/hr. A minimum of 305 m straight line distance from the cetaceans was maintained. Water depth was 100-1000m. Bottlenose dolphins most commonly responded by diving (48 percent), while 14 percent responded by moving away. Other species (e.g., beluga whale, sperm whale) show considerable variation in reactions to aircraft but diving or swimming away from the aircraft are the most common reactions to low flights (less than 500 m).

Anticipated Effects on Habitat

Detonations of live ordnance would result in temporary modification to water properties. As described above, an underwater explosion from these weapon would send a shock wave and blast noise through the water, release gaseous by-products, create an oscillating bubble, and cause a plume of water to shoot up from the water surface. However, these would be temporary and not expected to last more than a few seconds. Because dolphins are not expected to be in the area during live firing, due to monitoring and mitigation measure implementation, they would not be subject to any short term habitat alterations.

Similarly, no long term impacts with regard to hazardous constituents are expected to occur. MCAS Cherry Point has an active Range Environmental Vulnerability Assessment (REVA) program in place to monitor impacts to habitat from its activities. One goal of REVA is to determine the horizontal and vertical concentration profiles of heavy metals, explosives constituents, perchlorate nutrients, and dissolved salts in the sediment and seawater surrounding BT-9 and BT-11. The preliminary results of the sampling indicate that explosive constituents (e.g., trinitrotoluene (TNT), cyclotrimethylenetrinitramine (RDX), and hexahydro-trinitro-triazine (HMX), as described in Hazardous Constituents [Subchapter 3.2.7.2] of the MCAS Cherry Point Range Operations EA, were not detected in any sediment or water sample surrounding the BTs. Metals were not present above toxicity screening values. Perchlorate was detected in a few sediment samples above the detection limit (0.21 ppm), but below the reporting limit (0.6 ppm). The ongoing REVA would continue to evaluate potential munitions constituent migration from operational range areas to off-range areas and MCAS Cherry Point.

Summary of Previous Monitoring

USMC complied with the mitigation and monitoring required under the previous authorization. In accordance with the 2010-11 IHA, USMC submitted a final monitoring report, which described the activities conducted and observations made. USMC did not record observations of any marine mammals during training exercises. The only recorded observations--which were of bottlenose dolphins--were on two occasions by maintenance vessels engaged in target maintenance. No marine mammals were observed during range sweeps, air to ground activities, surface to surface activities (small boats), or ad hoc via range cameras. Table 6 details the number of sorties conducted, by air and water, at each target. The number of sorties conducted does not relate to the total amount of munitions expended, as the training requirements for the specific military unit conducting the sortie determine the munitions loading for the air platform or watercraft during each sortie. In addition, munitions expenditures may be determined by the loading specifications of the specific aircraft and vessels used in the training exercise.

(water-to-water)		
Total_____	1,777_____	4,356

The total amount of ordnance expended at BT-9 and BT-11 under the 2010-11 IHA was 878,625 and 693,612 respectively (Table 7). These amounts represent 98 and 62 percent of the estimated annual maximum ordnance expenditures. The amounts of ordnance expended at the BTs account for all use of the targets. There are five types of explosive sources used at BT-9: 2.75" Rocket High Explosives, 5" Rocket High Explosives, 30 mm High Explosives, 40 mm High Explosives, and G911 grenades. No explosive munitions are used at BT-11.

Proposed Mitigation

In order to issue an incidental take authorization (ITA) under Section 101(a)(5)(D) of the MMPA, NMFS must set forth the "permissible methods of taking pursuant to such activity, and other means of effecting the least practicable adverse impact on such species or stock and its habitat, paying particular attention to rookeries, mating grounds, and areas of similar significance." The NDAA of 2004 amended the MMPA as it relates to military-readiness activities and the ITA process such that "least practicable adverse impact" shall include consideration of personnel safety, practicality of implementation, and impact on the effectiveness of the military readiness activity. The training activities described in the USMC's application are considered military readiness activities.

NMFS has carefully evaluated the applicant's proposed mitigation measures and considered a range of other measures in the context of ensuring that NMFS prescribes the means of effecting the least practicable adverse impact on the affected marine mammal species and stocks and their habitat. Our evaluation of potential measures included consideration of the following factors in relation to one another: (1) The manner in which, and the degree to which, the successful implementation of the measure is expected to minimize adverse impacts to marine mammals; (2) the proven or likely efficacy of the specific measure to minimize adverse impacts as planned; (3) the practicability of the measure for applicant implementation, including consideration of personnel safety, practicality of implementation, and impact on the effectiveness of the military readiness activity. NMFS has preliminarily determined that the proposed mitigation measures provide the means of

effecting the least practicable adverse impacts on marine mammals species or stocks and their habitat, paying particular attention to rookeries, mating grounds, and areas of similar significance while also considering personnel safety, practicality of implementation, and impact on the effectiveness of the military readiness activity.

The USMC, in collaboration with NMFS, has worked to identify potential practicable and effective mitigation measures, which include a careful balancing of the likely benefit of any particular measure to the marine mammals with the likely effect of that measure on personnel safety, practicality of implementation, and impact on the "military-readiness activity". These proposed mitigation measures are listed below.

(1) Range Sweeps: The VMR-1 squadron, stationed at MCAS Cherry Point, includes three specially equipped HH-46D helicopters. The primary mission of these aircraft, known as PEDRO, is to provide search and rescue for downed 2^{d} Marine Air Wing aircrews. On-board are a pilot, co-pilot, crew chief, search and rescue swimmer, and a medical corpsman. Each crew member has received extensive training in search and rescue techniques, and is therefore particularly capable at spotting objects floating in the water.

PEDRO crew would conduct a range sweep the morning of each exercise day prior to the commencement of range operations. The primary goal of the pre-exercise sweep is to ensure that the target area is clear of fisherman, other personnel, and protected species. The sweep is flown at 100-300 meters above the water surface, at airspeeds between 60-100 knots. The path of the sweep runs down the western side of BT-11, circles around BT-9 and then continues down the eastern side of BT-9 before leaving. The sweep typically takes 20-30 minutes to complete. The PEDRO crew is able to communicate directly with range personnel and can provide immediate notification to range operators. The PEDRO aircraft would remain in the area of a sighting until clear if possible or as mission requirements dictate.

If marine mammals are sighted during a range sweep, sighting data will be collected and entered into the US Marine Corps sighting database, web-interface, or report generator and this information would be relayed to the training Commander. Sighting data includes the following (collected to the best of the observer's ability): (1) Species identification; (2) group size; (3) the behavior of marine mammals (e.g., milling, travel, social, foraging); (4) location and relative distance from the BT; (5) date, time and visual conditions (e.g., Beaufort sea state, weather) associated with each observation; (6) direction of travel relative to the BT; and (7) duration of the observation.

(2) Cold Passes: All aircraft participating in an air-to-surface exercise would be required to perform a "cold pass" immediately prior to ordnance delivery at the BTs both day and night. That is, prior to granting a "First Pass Hot" (use of ordnance), pilots would be directed to perform a low, cold (no ordnance delivered) first pass which serves as a visual sweep of the targets prior to ordnance delivery to determine if unauthorized civilian vessels or personnel, or protected species, are present. The cold pass is conducted with the aircraft (helicopter or fixed-winged) flying straight and level at altitudes of 200-3000 feet over the target area. The viewing angle is approximately 15 degrees. A blind spot exists to the immediate rear of the aircraft. Based upon prevailing visibility, a pilot can see more than one mile forward upon approach. The aircrew and range personnel make every attempt to ensure clearance of the area via visual inspection and remotely operated camera operations (see Proposed Monitoring and Reporting section below). The Range Controller may deny or approve the First Pass Hot clearance as conditions warrant.

(3) Delay of Exercises: An active range would be considered "fouled" and not available for use if a marine mammal is present within 1000 yards (914 m) of the target area at BT-9 or anywhere within Rattan Bay (BT-11). Therefore, if a marine mammal is sighted within 1000 yards (914 m) of the target at BT-9 or anywhere within Rattan Bay at BT-11 during the cold pass or from range camera detection, training would be delayed until the marine mammal moves beyond and on a path away from 1000 yards (914 m) from the BT-9 target or out of Rattan Bay at BT-11. This mitigation applies to both air-to-surface and surface-to-surface exercises.

(4) Range Camera Use: To increase the safety of persons or property near the targets, Range Operation and

Control personnel monitor the target area through tower mounted safety and surveillance cameras. The remotely operated range cameras are high resolution and, according to range personnel, allow a clear visual of a duck floating near the target. The cameras allow viewers to see animals at the surface and breaking the surface, but not underwater.

A new, enhanced camera system has been purchased and will be installed on BT-11 towers 3 and 7, and on both towers at BT-9. The new camera system has night vision capabilities with resolution levels near those during daytime. Lenses on the camera system have focal lengths of 40 mm to 2200 mm (56x), with view angles of 18 [degrees] 10' and 13 [degrees] 41', respectively. The field of view when zoomed in on the Rattan Bay targets will be 23' wide by 17' high, and on the mouth of Rattan Bay itself 87' wide by 66' high.

Again, in the event that a marine mammal is sighted within 1000 yards (914 m) of the BT-9 target, or anywhere within Rattan Bay, the target would be declared fouled. Operations may commence in the fouled area after the animal(s) have moved 1000 yards (914 m) from the BT-9 target and/or out of Rattan Bay.

(5) Vessel Operation: All vessels used during training operations would abide by the NMFS' Southeast Regional Viewing Guidelines designed to prevent harassment to marine mammals (http://www.nmfs.noaa.gov/pr/education/southeast /).

(6) Stranding Network Coordination: The USMC would coordinate with the local NMFS Stranding Coordinator for any unusual marine mammal behavior and any stranding, beached live/dead, or floating marine mammals that may occur at any time during training activities or within 24 hours after completion of training.

Proposed Monitoring and Reporting

In order to issue an ITA for an activity, Section 101(a)(5)(A) of the MMPA states that NMFS must set forth "requirements pertaining to the monitoring and reporting of such taking". The MMPA implementing regulations at 50 CFR 216.104(a)(13) indicate that requests for incidental take authorizations must include the suggested means of accomplishing the necessary monitoring and reporting that will result in increased knowledge of the species and of the level of taking or impacts on populations of marine mammals that are expected to be present. Monitoring measures prescribed by NMFS should accomplish one or more of the following general goals: (a) An increase in our understanding of how many marine mammals are likely to be exposed to munition noise and explosions that we associate with specific adverse effects, such as behavioral harassment, TTS, or PTS; (b) an increase in our understanding of how individual marine mammals respond (behaviorally or physiologically) to gunnery and bombing exercises (at specific received levels) expected to result in take; (c) an increase in our understanding of how anticipated takes of individuals (in different ways and to varying degrees) may impact the population, species, or stock (specifically through effects on annual rates of recruitment or survival); (d) an increased knowledge of the affected species; (e) an increase in our understanding of the effectiveness of certain mitigation and monitoring measures; (f) a better understanding and record of the manner in which the authorized entity complies with the incidental take authorization; (g) an increase in the probability of detecting marine mammals, both within the safety zone (thus allowing for more effective implementation of the mitigation) and in general to better achieve the above goals.

Proposed Monitoring

The suggested means of accomplishing the necessary monitoring and reporting that will result in increased knowledge of the species and of the level of taking or impacts on populations of marine mammals expected to be present within the action area are as follows:

(1) Marine Mammal Observer Training: Pilots, operators of small boats, and other personnel monitoring for marine mammals would be required to take the Marine Species Awareness Training (Version 2), maintained and promoted by the Department of the Navy. This training would make personnel knowledgeable of marine mammals, protected species, and visual cues related to the presence of marine mammals and protected species.

(2) Weekly and Post-Exercise Monitoring: Post-exercise monitoring would be conducted concomitant to the next

regularly scheduled pre-exercise sweep. Weekly monitoring events would include a maximum of five pre-exercise and four post-exercise sweeps. The maximum number of days that would elapse between pre- and post-exercise monitoring events would be approximately 3 days, and would normally occur on weekends. If marine mammals are observed during this monitoring, sighting data identical to those collected by PEDRO crew would be recorded.

(3) Long-Term Monitoring: The USMC has awarded DUML duties to obtain abundance, group dynamics (e.g., group size, age census), behavior, habitat use, and acoustic data on the bottlenose dolphins which inhabit Pamlico Sound, specifically those around BT-9 and BT-11. DUML began conducting boat-based surveys and passive acoustic monitoring of bottlenose dolphins in Pamlico Sound in 2000 (Read et al., 2003) and specifically at BT-9 and BT-11 in 2003 (Mayer, 2003). To date, boat-based surveys indicate that bottlenose dolphins may be resident to Pamlico Sound and use BT restricted areas on a frequent basis. Passive acoustic monitoring (PAM) is providing more detailed insight into how dolphins use the two ranges, by monitoring for their vocalizations year-round, regardless of weather conditions or darkness. In addition to these surveys, DUML scientists are testing a real-time passive acoustic monitoring system at BT-9 that will allow automated detection of bottlenose dolphin whistles, providing yet another method of detecting dolphins prior to training operations. Although it is unlikely this PAM system would be active for purposes of implementing mitigation measures before an exercise prior to expiration of the proposed IHA, it would be operational for future MMPA incidental take authorizations.

(4) Reporting: The USMC would submit a report to NMFS within 90 days after expiration of the IHA or, if a subsequent incidental take authorization is requested, within 120 days prior to expiration of the IHA. The report would summarize the type and amount of training exercises conducted, all marine mammal observations made during monitoring, and if mitigation measures were implemented. The report would also address the effectiveness of the monitoring plan in detecting marine mammals.

Estimated Take by Incidental Harassment

The following provides the USMC's model for take of dolphins from explosives (without consideration of mitigation and the conservative assumption that all explosives would land in the water and not on the targets or land) and potential for direct hits and NMFS' analysis of potential harassment from small vessel and aircraft operations.

Acoustic Take Criteria

For the purposes of an MMPA incidental take authorization, three levels of take are identified: Level B harassment; Level A harassment; and mortality (or serious injury leading to mortality). The categories of marine mammal responses (physiological and behavioral) that fall into harassment categories were described previously in this notice. A method to estimate the number of individuals that will be taken, pursuant to the MMPA, based on the proposed action has been derived. To this end, NMFS uses acoustic criteria that estimate at what received level Level B harassment, Level A harassment, and mortality of marine mammals would occur. The acoustic criteria for underwater detonations are comprehensively explained in NMFS' proposed and final rulemakings for the U.S. Navy's Cherry Point Range Operations (74 FR 11057; 74 FR 28370) and are summarized here:

Criteria and thresholds for estimating the exposures from a single explosive activity on marine mammals were established for the Seawolf Submarine Shock Test Final Environmental Impact Statement (FEIS) ("Seawolf") and subsequently used in the USS Winston S. Churchill (DDG 81) Ship Shock FEIS ("Churchill") (DoN, 1998 and 2001). NMFS adopted these criteria and thresholds in its final rule on the unintentional taking of marine animals occurring incidental to the shock testing which involved large explosives (65 FR 77546; December 12, 2000). Because no large explosives (> 1000 lbs NEW) would be used at Cherry Point during the specified activities, a revised acoustic criterion for small underwater explosions (i.e., 23 pounds per square inch [psi] instead of previous acoustic criteria of 12 psi for peak pressure over all exposures) has been established to

predict onset of TTS.

I.1. Thresholds and Criteria for Injurious Physiological Impacts

I.1.a. Single Explosion

For injury, NMFS uses dual criteria, eardrum rupture (i.e., tympanic-membrane injury) and onset of slight lung injury, to indicate the onset of injury. The threshold for tympanic-membrane (TM) rupture corresponds to a 50 percent rate of rupture (i.e., 50 percent of animals exposed to the level are expected to suffer TM rupture). This value is stated in terms of an Energy Flux Density Level (EL) value of 1.17 inch pounds per square inch (in-lb/in2), approximately 205 dB re 1 microPa ^{2} - sec.

The threshold for onset of slight lung injury is calculated for a small animal (a dolphin calf weighing 26.9 lbs), and is given in terms of the "Goertner modified positive impulse," indexed to 13 psi-msec (DoN, 2001). This threshold is conservative since the positive impulse needed to cause injury is proportional to animal mass, and therefore, larger animals require a higher impulse to cause the onset of injury. This analysis assumed the marine species populations were 100 percent small animals. The criterion with the largest potential impact range (most conservative), either TM rupture (energy threshold) or onset of slight lung injury (peak pressure), will be used in the analysis to determine Level A exposures for single explosive events.

For mortality, NMFS uses the criterion corresponding to the onset of extensive lung injury. This is conservative in that it corresponds to a 1 percent chance of mortal injury, and yet any animal experiencing onset severe lung injury is counted as a lethal exposure. For small animals, the threshold is given in terms of the Goertner modified positive impulse, indexed to 30.5 psi-msec. Since the Goertner approach depends on propagation, source/animal depths, and animal mass in a complex way, the actual impulse value corresponding to the 30.5 psi-msec index is a complicated calculation. To be conservative, the analysis used the mass of a calf dolphin (at 26.9 lbs) for 100 percent of the populations.

I.1.b. Multiple Explosions

For multiple explosions, the Churchill approach had to be extended to cover multiple sound events at the same training site. For multiple exposures, accumulated energy over the entire training time is the natural extension for energy thresholds since energy accumulates with each subsequent shot (detonation); this is consistent with the treatment of multiple arrivals in Churchill. For positive impulse, it is consistent with the Churchill final rule to use the maximum value over all impulses received.

I.2. Thresholds and Criteria for Non-Injurious Physiological Effects

To determine the onset of TTS (non-injurious harassment)--a slight, recoverable loss of hearing sensitivity, there are dual criteria: An energy threshold and a peak pressure threshold. The criterion with the largest potential impact range (most conservative), either the energy or peak pressure threshold, will be used in the analysis to determine Level B TTS exposures. The thresholds for each criterion are described below.

I.2.a. Single Explosion--TTS-Energy Threshold

The TTS energy threshold for explosives is derived from the Space and Naval Warfare Systems Center (SSC) pure-tone tests for TTS (Schlundt et al., 2000; Finneran and Schlundt, 2004). The pure-tone threshold (192 dB as the lowest value) is modified for explosives by (a) interpreting it as an energy metric, (b) reducing it by 10 dB to account for the time constant of the mammal ear, and (c) measuring the energy in 1/3-octave bands, the natural filter band of the ear. The resulting threshold is 182 dB re 1 microPa ^{2} -sec in any 1/3-octave band.

I.2.b. Single Explosion--TTS-Peak Pressure Threshold

The second threshold applies to all species and is stated in terms of peak pressure at 23 psi (about 225 dB re 1 microPa). This criterion was adopted for Precision Strike Weapons (PSW) Testing and Training by Eglin Air Force Base in the Gulf of Mexico (NMFS, 2005). It is important to note that for small shots near the surface (such as in this analysis), the 23-psi peak pressure threshold generally will produce longer impact ranges than the 182-dB energy metric. Furthermore, it is not unusual for the TTS impact range for the 23-psi pressure metric to actually exceed the without-TTS (behavioral change without onset of TTS) impact range for the 177-dB

energy metric.

I.3. Thresholds and Criteria for Behavioral Effects

I.3.a. Single Explosion

For a single explosion, to be consistent with Churchill, TTS is the criterion for Level B harassment. In other words, because behavioral disturbance for a single explosion is likely to be limited to a short-lived startle reaction, use of the TTS criterion is considered sufficient protection and therefore behavioral effects (Level B behavioral harassment without onset of TTS) are not expected for single explosions.

I.3.b. Multiple Explosions--Without TTS

For multiple explosions, the Churchill approach had to be extended to cover multiple sound events at the same training site. For multiple exposures, accumulated energy over the entire uninterrupted firing time is the natural extension for energy thresholds since energy accumulates with each subsequent shot (detonation); this is consistent with the treatment of multiple arrivals in Churchill. Because multiple explosions could occur within a discrete time period, a new acoustic criterion-behavioral disturbance without TTS is used to account for behavioral effects significant enough to be judged as harassment, but occurring at lower noise levels than those that may cause TTS.

The threshold is based on test results published in Schlundt et al. (2000), with derivation following the approach of the Churchill FEIS for the energy-based TTS threshold. The original Schlundt et al. (2000) data and the report of Finneran and Schlundt (2004) are the basis for thresholds for behavioral disturbance without TTS. During this study, instances of altered behavior sometimes began at lower exposures than those causing TTS; however, there were many instances when subjects exhibited no altered behavior at levels above the onset-TTS levels. Regardless of reactions at higher or lower levels, all instances of altered behavior were included in the statistical summary. The behavioral disturbance without TTS threshold for tones is derived from the SSC tests, and is found to be 5 dB below the threshold for TTS, or 177 dB re 1 microPa ^{2} -sec maximum energy flux density level in any 1/3-octave band at frequencies above 100 Hz for cetaceans.

II. Summary of Thresholds and Criteria for Impulsive Sounds

The effects, criteria, and thresholds used in the assessment for impulsive sounds are summarized in Table 8. The criteria for behavioral effects without physiological effects used in this analysis are based on use of multiple explosives from live, explosive firing at BT-9 only; no live firing occurs at BT-11.

Take From Explosives

The USMC conservatively modeled that all explosives would detonate at a 1.2 m (3.9 ft) water depth despite the training goal of hitting the target, resulting in an above water or on land explosion. For sources that are detonated at shallow depths, it is frequently the case that the explosion may breech the surface with some of the acoustic energy escaping the water column. The source levels presented in the table above have not been adjusted for possible venting nor does the subsequent analysis take this into account. Properties of explosive sources used at BT-9, including NEW, peak one-third-octave (OTO) source level, the approximate frequency at which the peak occurs, and rounds per burst are described in Table 9. Distances to NMFS harassment threshold levels from these sources are outlined in Table 10.

To calculate take, the distances to which animals may be harassed were considered along with dolphin density. The density estimate from Read et al. (2003) was used to calculate take from munition firing. As described in the Description of Marine Mammals in the Area of the Specified Activity section above, this density, 0.183/km ^{2} , was derived from boat based surveys in 2000 which covered all inland North Carolina waters. Note that estimated density of dolphins at BT-9 and BT-11, specifically, were calculated to be 0.11 dolphins/km^2 , and 1.23 dolphins/km^2 respectively (Maher 2003), based on boat surveys conducted from July 2002 through June 2003 (excluding April, May, Sept. and Jan.). However, the USMC chose to estimate take of dolphins based on the higher density reported from the summer 2000 surveys (0.183/km ^{2}). Additionally, take calculations for munition firing are based on 100 percent water detonation, although the goal of training is to hit the targets, and no pre-exercise monitoring or mitigation. Therefore, take estimates can be considered conservative.
Based on dolphin density and amount of munitions expended, there is very low potential for Level A harassment and mortality and monitoring and mitigation measures are anticipated to further negate this potential. Accordingly, NMFS is not proposing to issue these levels of take. As portrayed in Table 9, the largest harassment zone (Level B) is within 209 m of a detonation in water; however, the USMC has implemented a 1000 m "foul" zone for BT-9 and anywhere within Rattan Bay for BT-11. In total, from firing of explosive ordnances, the USMC is requesting, and NMFS is proposing to issue, the incidental take of 25 bottlenose dolphins from Level B harassment (Table 11).

Take From Direct Hit
The potential risk of a direct hit to an animal in the target area is estimated to be so low it is discountable. A Range Air Installation Compatible Use Zone (RAICUZ) study generated the surface area or footprints of weapon impact areas associated with air-to-ground ordnance delivery (USMC 2001). Statistically, a weapon safety footprint describes the area needed to contain 99.99 percent of initial and ricochet impacts at the 95-percent confidence interval for each type of aircraft and ordnance utilized on the BTs. At both BT-9 and BT-11 the probability of deployed ordnance landing in the impact footprint is essentially 1.0, since the footprints were designed to contain 99.99 percent of impacts, including ricochets. However, only 36 percent of the weapon

footprint for BT-11 is over water in Rattan Bay, so the likelihood of a weapon striking an animal at the BT in Rattan Bay is 64 percent less. Water depths in Rattan Bay range from 3 m (10 ft) in the deepest part of the bay to 0.5 m (1.6 m) close to shore, so that nearly the entire habitat in Rattan Bay is suitable for marine mammal use (or 36 percent of the weapon footprint).

The estimated potential risk of a direct hit to an animal in the target area is extremely low. The probability of hitting a bottlenose dolphin at the BTs can be derived as follows: Probability = dolphin's dorsal surface area * density of dolphins. The estimated dorsal surface area of a bottlenose dolphin is 1.425 m^2 (or the average length of 2.85 m times the average body width of 0.5 m). Thus, using Read et al. (2003)'s density estimate of 0.183 dolphins/km^2 , without consideration of mitigation and monitoring implementation, the probability of a dolphin being hit in the waters of BT-9 is 2.61 x 10^{-7} and of BT-11 is 9.4 x 10^{-8} . Using the proposed levels of ordnance expenditures at each in-water BT (Tables 4 and 5) and taking into account that only 36 percent of the ordnance deployed at BT-11 is over water, as described in the application, the estimated potential number of ordnance strikes on a marine mammal per year is 0.263 at BT-9 and 0.034 at BT-11. It would take approximately three years of ordnance deployment at the BTs before it would be likely or probable that one bottlenose dolphin would be struck by deployed inert ordnance. Again, these estimates are without consideration to proposed monitoring and mitigation measures.

Take From Vessel and Aircraft Presence

Vessel movement is associated with surface-to-surface exercises, as described in the Specified Activities section above, which primarily occurs within BT-11. The USMC is not requesting takes specific to the act of maneuvering small boats within the BTs; however, NMFS has analyzed the potential for take from this activity. The potential impacts from exposure to vessels are described in the Vessel and Aircraft Presence section above. Interactions with vessels are not a new experience for bottlenose dolphins in Pamlico Sound. Pamlico Sound is heavily used by recreational, commercial (fishing, daily ferry service, tugs, etc.), and military (including the Navy, Air Force, and Coast Guard) vessels year-round. The NMFS' Southeast Regional Office has developed marine mammal viewing guidelines to educate the public on how to responsibly view marine mammals in the wild and avoid causing a take (http://www.nmfs.noaa.gov/pr/ education/southeast). The guidelines recommend that vessels should remain a minimum of 50 yards from a dolphin, operate vessels in a predictable manner, avoid excessive speed or sudden changes in speed or direction in the vicinity of animals, and not to pursue, chase, or separate a group of animals. The USMC would abide by these guidelines to the fullest extent practicable. The USMC would not engage in high speed exercises should a marine mammal be detected within the immediate area of the BTs prior to training commencement and would never closely approach, chase, or pursue dolphins. Detection of marine mammals would be facilitated by personnel monitoring on the vessels and those marking success rate of target hits and monitoring of remote camera on the BTs (see Proposed Monitoring and Reporting section).

Based on the description of the action, the other activities regularly occurring in the area, the species that may be exposed to the activity and their observed behaviors in the presence of vessel traffic, and the implementation of measures to avoid vessel strikes, NMFS believes it is unlikely that the operation of vessels during surface-to-surface maneuvers will result in the take of any marine mammals, in the form of either behavioral harassment or injury.

Aircraft would move swiftly through the area and would typically fly approximately 914 m from the water's surface before dropping unguided munitions and above 4,572 m for precision-guided munition bombing. While the aircraft may approach as low as 152 m (500 ft) to drop a bomb this is not the norm and would never been done around marine mammals. Regional whale watching guidelines advise aircraft to maintain a minimum altitude of 300 m (1,000 ft) above all marine mammals, including small odontocetes, and to not circle or hover over the animals to avoid harassment. NMFS' approach regulations limit aircraft from flying below 300 m (1,000 ft) over a humpback whale (Megaptera novaeangliae) in Hawaii, a known calving ground, and limit aircraft from

flying over North Atlantic right whales closer than 460 m (1509 ft). Given USMC aircraft would not fly below 300 m on the approach, would not engage in hovering or circling the animals, and would not drop to the minimal altitude of 152 m if a marine mammal is in the area, NMFS believes it is unlikely that the operation of aircraft, as described above, will result in take of bottlenose dolphins in Pamlico Sound.

Negligible Impact Analysis and Preliminary Determination

Pursuant to NMFS' regulations implementing the MMPA, an applicant is required to estimate the number of animals that will be "taken" by the specified activities (i.e., takes by harassment only, or takes by harassment, injury, and/or death). This estimate informs the analysis that NMFS must perform to determine whether the activity will have a "negligible impact" on the species or stock. NMFS has defined "negligible impact" in 50 CFR 216.103 as: "An impact resulting from the specified activity that cannot be reasonably expected to, and is not reasonably likely to, adversely affect the species or stock through effects on annual rates of recruitment or survival." A negligible impact finding is based on the lack of likely adverse effects on annual rates of recruitment or survival (i.e., population-level effects). An estimate of the number and manner of takes, alone, is not enough information on which to base a negligible impact determination. NMFS must also consider other factors, such as the likely nature of any responses (their intensity, duration, etc.), the context of any responses (critical reproductive time or location, migration, etc.), or any of the other variables mentioned in the first paragraph (if known), as well as the number and nature of estimated Level A takes, the number of estimated mortalities, and effects on habitat.

The USMC has been conducting gunnery and bombing training exercises at BT-9 and BT-11 for years and, to date, no dolphin injury or mortality has been attributed these military training exercises. The USMC has a history of notifying the NMFS stranding network when any injured or stranded animal comes ashore or is spotted by personnel on the water. Therefore, stranded animals have been examined by stranding responders, further confirming that it is unlikely training contributes to marine mammal injuries or deaths. Due to the implementation of the aforementioned mitigation measures, no take by Level A harassment or serious injury or mortality is anticipated nor would any be authorized in the IHA. NMFS is proposing; however, to authorize 25 Level B harassment takes associated with training exercises.

The USMC has proposed a 1000 yard (914 m) safety zone around BT-9 despite the fact that the distance to NMFS explosive Level B harassment threshold is 228 yards (209 m). They also would consider an area fouled if any dolphins are spotted within Raritan Bay (where BT-11 is located). The Level B harassment takes allowed for in the IHA would be of very low intensity and would likely result in dolphins being temporarily behaviorally affected by bombing or gunnery exercises. In addition, takes may be attributed to animals not using the area when exercises are occurring; however, this is difficult to calculate. Instead, NMFS looks to if the specified activities occur during and within habitat important to vital life functions to better inform its negligible impact determination.

Read et al. (2003) concluded that dolphins rarely occur in open waters in the middle of North Carolina sounds and large estuaries, but instead are concentrated in shallow water habitats along shorelines. However, no specific areas have been identified as vital reproduction or foraging habitat. Scientific boat based surveys conducted throughout Pamlico Sound conclude that dolphins use the areas around the BTs more frequently than other portions of Pamlico Sound (Maher, 2003) despite the USMC actively training in a manner identical to the specified activities described here for years.

As described in the Affected Species section of this notice, bottlenose dolphin stock segregation is complex with stocks overlapping throughout the coastal and estuarine waters of North Carolina. It is not possible for the USMC to determine to which stock any individual dolphin taken during training activities belong as this can only be accomplished through genetic testing. However, it is likely that many of the dolphins encountered would belong to the NNCE or SNCE stock. These stocks have a population estimate of 1,387 and 2,595, respectively. NMFS is proposing to authorize 25 takes of bottlenose dolphins in total; therefore, this number represents 1.8

and 1.0 percent, respectively, of those populations.

Based on the analysis contained herein of the likely effects of the specified activity on marine mammals and their habitat, and taking into consideration the implementation of the mitigation and monitoring measures, NMFS preliminarily finds that the specified USMC AS Cherry Point BT-9 and BT-11 training activities will result in the incidental take of marine mammals, by Level B harassment only, and that the total taking from will have a negligible impact on the affected species or stocks.

Subsistence Harvest of Marine Mammals

Marine mammals are not taken for subsistence use within Pamlico Sound; therefore, issuance of an IHA to the USMC for MCAS Cherry Point training exercises would not have an unmitigable adverse impact on the availability of the affected species or stocks for subsistence use.

Endangered Species Act (ESA)

No ESA-listed marine mammals are known to occur within the action area. Therefore, there is no requirement for NMFS to consult under Section 7 of the ESA on the issuance of an IHA under section 101(a)(5)(D) of the MMPA. However, ESA-listed sea turtles may be present within the action area.

On September 27, 2002, NMFS issued a Biological Opinion (BiOp) on Ongoing Ordnance Delivery at Bombing Target 9 (BT-9) and Bombing Target 11 (BT-11) at Marine Corps Air Station, Cherry Point, North Carolina. The BiOp, which is still in effect, concluded that the USMC's proposed action will not result in adverse impacts to any ESA-listed marine mammals and is not likely to jeopardize the continued existence of the endangered green turtle (Chelonia mydas), leatherback turtle (Dermochelys coriacea), Kemp's ridley turtle (Lepidochelys kempii), or threatened loggerhead turtle (Caretta caretta). No critical habitat has been designated for these species in the action area; therefore, none will be affected.

National Environmental Policy Act (NEPA)

On February 11, 2009, the USMC issued a Finding of No Significant Impact for its Environmental Assessment (EA) on MCAS Cherry Point Range Operations. Based on the analysis of the EA, the USMC determined that the proposed action will not have a significant impact on the human environment. NMFS adopted USMC's EA and signed a FONSI on August 31, 2010. NMFS has reviewed the proposed application and preliminarily determined that there are no substantial changes to the proposed action or new environmental impacts or concerns. Therefore, NMFS has determined that a new or supplemental EA or Environmental Impact Statement is likely unnecessary. Before making a final determination in this regard, NMFS will review public comments and information submitted by the public and others in response to this notice. The EA referenced above is available for review at http://www.nmfs.noaa.gov/pr/permits/incidental.htm.

Noise-induced tinnitus: A comparison between four clinical groups without apparent hearing loss

Author: Lindblad, Ann-Cathrine; Hagerman, Björn; Rosenhall, Ulf

Publication info: Noise & Health 13.55 (Nov 2011): 423-31.
ProQuest document link

Abstract: The number of people with normal hearing thresholds seeking medical help for tinnitus and other hearing problems is increasing. For diagnostic purposes, existence/nonexistence of lesions or combinations of lesions in the inner ear not reflected in the audiogram was evaluated with advanced hearing tests applied to tinnitus patients with certain backgrounds, including noise exposure. For forty-six patients with pronounced tinnitus, and other symptoms, tentative diagnoses were established, including judgments of the influence of four causative factors: (1) acoustic trauma, (2) music, (3) suspected hereditary, and (4) nonauditory, for example, stress or muscular tension. They were analyzed with a test battery sensitive to lesions involving the outer hair cells, damage from impulse noise, and dysfunction of the efferent system. There were significant differences in test results between groups with individuals with the same most likely causative factor. Most patients claiming acoustic trauma had a specific type of result, 'hyper-PMTF' (psychoacoustical modulation transfer function), and abnormal test results of the efferent system. Everyone in the hereditary group had dysfunction of the efferent system. All patients working with music, except one, had some abnormality, but without specific pattern. The nonauditory group mostly had normal test results. The investigation shows that it is possible to diagnose minor cochlear lesions as well as dysfunction of the efferent system, which might be causing the tinnitus. Those abnormalities could not be detected with routine audiological tests. Malfunctioning caused by impulse noise is an obvious example of this. These findings facilitate choice of treatment, rehabilitation programs, and medicolegal decisions.

Full text: Introduction

Tinnitus following occupational noise exposure has been correlated to noise-induced hearing loss, with negligible occurrence in noise-exposed workers with normal hearing. [1],[2] However, other occupational situations have been reported in which tinnitus is a promintent symptom even with no or minor hearing impairment. One important example is musical professions [3] and another is military officers and servicemen who have been exposed to acute acoustic trauma. [4],[5]

Tinnitus is most often correlated to hearing impairment, but many tinnitus patients have no or only minor hearing loss. Savastano [6] studied tinnitus patients and reported that 57% had hearing deficits and 43% had normal hearing (pure tone average 0.5-8 kHz, <20 dB). Wiberg et al. [7] reported that young tinnitus patients (<20 years of age) had, on an average, normal hearing thresholds in the frequency range from 500 to 8000 Hz. The hearing thresholds were slightly elevated in a group of tinnitus patients of working age and still more elevated (above all in the high frequencies) in retired persons with tinnitus.

Observations about tinnitus in patients with normal pure tone audiometry raise the question about the role of the peripheral auditory system for triggering tinnitus. A significant problem is that pure tone audiometry and also other audiological tests in current clinical use are poor indicators of minor cochlear dysfunction. The rapid development of auditory physiology during the last decades provides a possibility to study very early changes of the physiological function and of the micromechanics of the cochlea. Such changes occur before pure tone thresholds are noticeably affected. [8],[9],[10]

The aim of the present study was to investigate whether some auditory physiological and psychoacoustical tests are sufficiently sensitive to detect minute cochlear lesions that cannot be diagnosed by routine clinical audiological tests. Four different clinical study groups were selected, all of them comprising individuals with disabling, persistent tinnitus, but with no or only minor pure tone threshold elevations. Two of these groups were selected since they represent aspects of occupational noise-induced tinnitus; and for comparison, two other groups were included.

Study Groups

Subjects

All subjects in the study had consulted the services of the Department of Hearing and Balance, Karolinska University Hospital, Stockholm, for persistent tinnitus. One inclusion factor was normal hearing, or at most minor hearing loss, measured with pure tone audiometry; and the pure tone average across the frequencies 500, 1000, and 2000 Hz was <20 dB hearing level (HL). Narrow mid-frequency dips (<25 dB HL) were permitted. A mild, high-frequency sensorineural hearing loss was also accepted (<40 dB HL at 4000 Hz). The high-frequency threshold average (3000, 4000, 6000 Hz) had to be <35 dB HL. Conductive hearing loss, even very mild, was an exclusion criterion. Only patients with normal otomicroscopic findings were accepted. Patients with middle ear problems, or other otological diseases, were excluded. To reduce confounding effects of aging, an upper age limit of 60 years was chosen. [11]

Four clinical study groups, based on etiology, were selected for the study. Participants of two of the groups had been exposed to noise that could have caused the tinnitus: (1) subjects with acute, intense acoustic trauma as the most likely causative factor and (2) professional and semiprofessional musicians, with music as the most likely causative factor. For comparison, two other causative groups were tested: (3) persons with suspected hereditary tinnitus and (4) persons judged to have nonauditory, cross-modal tinnitus. [12]

The intention was to study a series of consecutive patients. However, that was not possible since about half of the proposed participants abstained, many of them because they were afraid to be exposed to sound even of moderate intensity. Forty-six patients fulfilled the inclusion criteria and accepted the invitation to participate in the study. Of these patients, 17 were women and 29 men (mean age: 35 years; SD: 13 years; range: 18-59 years).

Etiological classification

All patients were examined, on a regular visit to the clinic, by a doctor specialized in ENT diseases and audiological medicine (in most cases one of the authors, U.R.). An ENT examination including otomicroscopy was performed, and a thorough, structured medical history was taken. The impact of the four causative factors was judged for each patient on an arbitrary scale: 0 = no influence; 1 = mild influence; 2 = marked influence; 3 = very strong influence. [Table 1] gives detailed information of the use of the scale. Many patients had more than one causative factor with judged influence larger than 0. Each patient was assigned to one of the causative groups mentioned above, and each of the causative groups consisted of those individuals who had their highest judged value for the corresponding causative factor [Table 1].{Table 1}

Acoustic trauma group

The acoustic trauma group included 16 subjects (12 men and 4 women) who had been exposed to sudden, intense noise. All the cases reported that the symptoms started immediately after the exposure, and none had experienced any problems before the incident. In 11 cases, the exposure was an impulse noise. Seven were military conscripts: 3 cases exposed to fine-caliber firearms and 4 cases to heavy-caliber guns. They had met with shooting accidents either because of ill-fitting ear protectors or because of service of weapons without ear protectors. The other four impulse noise exposures were blows from a hammer in a factory, a bus tire exploding at a bus stop, explosions during a chemistry lesson, and from firecrackers. The remaining 5 cases had been exposed to intense, stationary noise at 115-130 dB sound pressure level (SPL), lasting for several minutes, for example, a burglar alarm, activated by mistake, in a military rock shelter. The military impulse noise cases were tested about 3 weeks after the exposure as well as after 2-3 months. The other cases were tested 1-9 years after the exposure. The mean and median ages were 24 and 30 years, respectively.

Music group

The music group included 10 cases (4 women and 6 men), all of them working professionally with music, some of them full time (6 cases) and some part time along with other occupations (4 cases). The group included various professions: drummer, contrabassist, violinist, singer, choir leader, music teacher, and sound engineer. Hyperacusis and tinnitus were about equally common as the main symptoms. Stress and muscular tension

were commonly reported in this group. This group was the most homogeneous regarding age, with the youngest member of the group being 28 years old. Both mean and median ages were 43 years.

Hereditary group

The hereditary group consisted of 9 cases (2 women and 7 men) with suspected hereditary origin of the symptoms. The diagnosis was based on a family history of tinnitus and hearing loss (parents, children, siblings, etc.). One case had a grandmother and an aunt who had tinnitus and hearing loss. Six cases had 2 or more relatives and 4 had 1 relative with auditory symptoms. Four of the cases belonged to the same family, a father and his three sons. Minor mid- or high-frequency dips were present in 7 cases. Seven patients had nonauditory symptoms, often mild, the most common being stress and muscular tension. The mean and median ages of the hereditary group were 35 and 37 years, respectively.

Nonauditory group

A nonauditory group of 11 patients (7 women and 4 men) without any family history of hearing problems and no apparent ototraumatic events was included. Hyperacusis and tinnitus were almost equally common as the main symptoms. The symptoms defining nonauditory factors were muscular tension, neck pain, tension headache, odontological problems, intense stress, anxiety, depression, dizziness, chronic pain, and chronic fatigue. Only nonauditory factors that preceded the auditory symptoms were accepted to avoid contamination of secondary stress and muscular tension caused by auditory problems. Some of the patients played music, but none of them was a professional musician. The mean and median ages of this group were 38 and 34 years, respectively. This group, presumably with little or no evidence of cochlear damage, can serve as a clinical reference group. All patients gave their informed consent to partipate in the study, which was approved by the local ethical committee.

Methods

The patients were examined with an auditory test battery. All patients were tested with pure tone audiometry and also fixed-frequency Békésy audiometry. For the purpose of detecting minute lesions affecting the cochlea and its regulatory system, two tests were selected: Psychoacoustical modulation transfer function (PMTF) and transient evoked otoacoustic emissions (TEOAEs) with and without contralateral noise. The test time for these tests was 2-3 h.

Psychoacoustical modulation transfer function

The active nonlinear process in the cochlea is mediated by the outer hair cells (OHCs) and facilitates the perception of the complex sound patterns in speech. These patterns are characterized by rapid sound variations combined with slow modulations caused by speech syllables, words, and intonation. A measurement termed the PMTF reflects the functioning of the inner ear when handling slow intensity variations such as those of speech. PMTF measures the thresholds of brief tones placed at the peaks and in the valleys of a fully, sinusoidally intensity-modulated, octave-band noise at various sound pressure levels. [13] The test has been shown to measure more subtle qualities of hearing, and there is evidence that it reflects hair cell function, above all that of the OHCs. [14]

PMTF measurements

The measurements were performed on the ear with the most pronounced symptoms with the brief tone, 4 ms, and the octave-band filtered noise at 4000 Hz, and with a modulation frequency of 10 Hz. The noise levels were 35-85 dB SPL in steps of 10 dB. Initially, the threshold for the brief tone was measured without noise to familiarize the subject with the brief tone.

Typical PMTF results

[Figure 1] shows a few stylized, but characteristic PMTF curves.{Figure 1}

The normal PMTF curves are nonlinear, with a maximum signal-to-noise-ratio (S/N) for the peak threshold, occurring at a noise level of about 55 dB SPL. (The term peak threshold is used for the threshold of the brief tone when the tone is placed at the peak of the noise. The term valley threshold is used when the tone is placed

in the valley of the noise.) For the valley threshold, there is a corresponding maximum at about 65 dB SPL [Figure 1]a.

For a sensorineural hearing loss of cochlear origin, the nonlinearity is weaker. Both maxima have lower S/N and they occur at higher noise levels [Figure 1]b. This type of pattern indicates reduced nonlinearity.

A second type of abnormal PMTF pattern is presented in [Figure 1]c. The S/N maxima of the peak and valley threshold curves have markedly increased amplitudes and occur at the same, low noise level (35-45 dB SPL). The peak and valley curves are almost identical, which implicates that the affected ear can hardly take advantage of the silent interval around the brief tone in the valley. The term "hyper-PMTF" was coined for this pattern.

There are also intermediate varieties between normal and hyper-PMTF. A mildly abnormal variety is shown in [Figure 1]d. Like in the hyper-PMTF, the S/N maxima of the peak and valley curves are positioned at the same noise level, but here they occur at a normal noise level (>45 dB SPL), and they are not as high as in the hyper-PMTF. The level dependence for peak and valley curves is the same. At every noise level used, the S/N for the peak threshold is a roughly constant number of decibels higher than the S/N for the valley threshold.

It is evident from the examples above that there are two main types of abnormal PMTF results: The positions of the maximum peak and valley thresholds can occur at higher or lower than normal noise levels (horisontal position in graph), and the corresponding S/N maxima are then either lower or higher than normal (vertical position in graph). Therefore, the only practical way of analysis is to use a qualitative method to define certain typical patterns, for example, the hyper-PMTF. This method will be described later.

Transient evoked otoacoustic emissions with and without contralateral noise

Otoacoustic emissions (OAEs) reflect the function of the OHCs. TEOAE recordings with and without contralateral noise can be used to study the efferent system - the medial olivocochlear (MOC) system. This system is constituted by neurons in the medial olivary complex and efferent neurons passing from the vestibular nerve to the cochlea. [15] The system modulates the cochlear function by acting on the OHCs. It has been suggested that the MOC system might influence the ear's resistance to noise trauma. [16],[17],[18] In the latter study, animals with the weakest MOC control suffered the most damage when exposed to traumatizing sounds. It is also interesting to note that Veuillet et al. [19] showed results indicating that military officers with good suppression measured after acoustic trauma had a better recovery than officers with less or no suppression. Janssen et al. [20] tested ears affected with sensorineural hearing loss with tinnitus. About half of them had decreased distortion product otoacoustic emission (DPOAE/DP) levels, which is considered normal for sensorineural hearing loss, and the other half had increased DP levels, hypothesized to be generated by cochlear hyperactivity that could cause both the abnormally high DP level and the tinnitus. Similarly, we found both increased and decreased TEOAE responses in a noise susceptibility project with young conscripts (unpublished): Groups exposed to continuous noise had low TEOAE amplitudes. In contrast, a group who had been exposed to strong, but not extremely intense, impulse sounds showed increased TEOAE responses (the correlated part) and intensified chaotic activity (uncorrelated responses to stimuli, mostly regarded as noise). Obviously, this phenomenon may complicate the interpretation of what is a normal TEOAE response.

Transient evoked otoacoustic emission measurements

For the measurements, clicks with the duration of 80 μs were repeated with a frequency of 50 Hz. The standard nonlinear mode was used to enhance those components in the response, which have a nonlinear dependence on the stimulus level, and to suppress the linear components in the response. [21] To accomplish this, the polarity of every fourth click is reversed and the sound pressure of the click is increased by a factor of 3. The acoustical responses from 1000 clicks are averaged, after removal of the primary click by time-windowing technique. Half of the click responses are averaged in one buffer, the other half of the responses are averaged in a second buffer. The stimulus level is specified as so-called peak equivalent sound pressure level, peSPL. Clicks at 75 and 85 dB peSPL were used with and without contralateral broadband noise at 70 dB SPL. The

RMS values in 1000-Hz-bands for the TEOAE response (the response that is common to the two buffers, i.e., correlated to the clicks), over the interval of measurement, were used in the analyses. Also, the uncorrelated response (the difference between the contents of the two buffers) was analyzed in 1000-Hz-bands. The bands were centered around 1000, 1500, 2000, 3000, 4000, 5000, 6000, 7000, and 8000 Hz. To obtain the suppression in those bands, the differences between the decibel values of responses without contralateral noise and the decibel values of the responses with contralateral noise were calculated. Thus, a suppression value is positive when the response decreases and it is negative when it increases with contralateral noise.

Equipment

Two test systems were used. Each of them consisted of a Tucker-Davis Technologies System III with RP2.1 processing unit with 24-bits A/D and D/A. The TDT systems were controlled by personal computers. Circumaural earphones, Sennheiser HDA 200, were used for the psychoacoustical measurements. The probe system used for measuring OAEs was of type ER-10C from Etymotic Research.

Classification of measured functions

The aim of the analysis was to find out how the four causative factors might induce abnormal function of the inner ear and/or the efferent system. With only 46 test subjects in this first analysis, we had to limit the number of variables in the outcome of the measurements. One reasonable way to do that was to use visual judgements to present the results. The first author, A.C.L., working in the research laboratory situated in another part of the city, and blind to the judgements of causative factors, made all interpretations using experience from earlier test subjects and patients of various ages.

Three dependent variables were studied. Like the causative factors, these variables were classified on four-graded scales, from no abnormality at all (0) to a strongly marked abnormality (3).

Outer hair cells function

The quality of the OHC function was judged from TEOAE levels and from the nonlinearity function of PMTF. ([Figure 1]a shows a normal nonlinearity and [Figure 1]b shows a reduced nonlinearity.) The OHC function was classified as follows: 0 = normal, no abnormality; 1 = slight abnormality (mild decrease of the PMTF nonlinearity and/or weakened TEOAE responses); 2 = marked abnormality (strongly reduced PMTF nonlinearity function [Figure 1]b and weakened TEOAE responses); 3 = strongly marked abnormality (very strongly reduced PMTF nonlinearity and affected TEOAE levels).

Psychoacoustical modulation transfer function positioning

Experience suggests that a variable describing the PMTF positioning (i.e., the positioning of the maxima of the peak and valley threshold curves in the PMTF results) could be useful. The hyper-PMTF would then be the most extreme abnormality. The PMTF positioning was classified as follows: 0 = normal [Figure 1]a 1 = slight abnormality (see [Figure 1]d; identical positioning of maxima for peak and valley threshold curves at noise levels higher than 45 dB SPL, or the maximum of the valley threshold curve falls at a lower noise level than that of the peak threshold curve); 2 = marked abnormality (irregularly shaped hyper-PMTF); 3 = strongly marked abnormality ([Figure 1]c; hyper-PMTF with high maxima at 45 dB SPL noise level or lower).

Efferent regulatory function - the medial olivocochlear function

The MOC function is presumed to be expressed by the suppression effect on TEOAEs when contralateral noise is presented. It sometimes happens that a person, of any age, has increasing reponses with contralateral noise in very specific and individual frequency bands. This lack of effectiveness of the efferent system has been measured on some tinnitus sufferers. [22] General statistical analyses over all frequency bands, separately or as a total, would hide such individual abnormalities. Regarding the suppression of TEOAEs with contralateral noise, the classifications were as follows: 0 = normal; 1 = slight abnormality (decreased suppression or no suppression); 2 = marked abnormality (some increase, instead of decrease, in TEOAE responses with contralateral noise, i.e., negative suppression); 3 = strongly marked abnormality (strong negative suppression). For some ears with extremely strong uncorrelated activity in the TEOAE measurements, this deficiency in

regulation was taken into account in the classification.

Statistical analyses

The statistical analysis was performed with Statistica, release 7. Analyses of variance (ANOVAs) were performed for the four etiological groups, which were based on the most likely causative factor, versus OHC function, MOC function, and PMTF positioning. A corresponding analysis was done for groups versus high-frequency threshold average (3000, 4000, 6000 Hz). Correlations between age or pure tone thresholds, especially the high-frequency threshold average (3000, 4000, 6000 Hz), and abnormal function of the inner ear or efferent system were also looked at. Multiple analyses of variance (MANOVAs) could be performed for auditory test results versus individual causatives factors only if the causative factors were two-graded, that is, "No" - no or only mild influence, or "Yes" - marked or very strong influence. Tukey's honestly significant difference (HSD) test was used when needed.

Results

Judged causative factors and auditory test results in etiological groups

The prevalence of judged causative factors as well as the outcome of the auditory tests in the four patient groups are presented in [Table 2] and [Figure 2]. Because there were significant correlations between some pure tone thresholds and the judged OHC and MOC functions, the means and standard deviations of the pure tone thresholds at 3000, 4000, and 6000 Hz are included in the table. It is apparent that the most abnormal results of the audiological tests were seen in two patient groups: the acute noise trauma group and the hereditary group. The prevalence of marked or strongly marked abnormalities in test results was lower in the music group, and almost absent in the nonauditory group.{Table 2}{Figure 2}

About half of the test subjects, especially those with the worst hearing thresholds, presented slight OHC abnormalities manifested in PMTF curves with decreased nonlinearity and/or low TEOAE levels, but no patient in this study, considering people with normal or nearly normal hearing thresholds, had the highest degree of OHC abnormality. In contrast, there were 17 subjects with a high degree of abnormality regarding the positioning of the PMTF-curve maxima, like the hyper-PMTF, the extreme example in [Figure 1]c. For most of them, acoustic trauma had been judged to be the most likely causative factor.

Almost all hereditary cases (~90%) had a high degree of MOC abnormality. The same was the case for ~70% of the subjects in the trauma group, 50% in the music group, and ~30% in the nonauditory group.

The PMTF positioning had no significant correlation to hearing thresholds or any of the other measured functions. OHC and MOC functions were significantly correlated to each other ($P<0.01$) and to the high-frequency threshold average ($P<0.01$). There was no significant influence of age.

Group differences in auditory test results

ANOVAs were performed for the four clinical groups versus OHC function, PMTF positioning, and MOC function, with threshold average (3000, 4000, 6000 Hz) as a covariate. A following Tukey's HSD test showed a few significant and characteristic differences between the etiological groups ($P<0.05$). [Table 3] shows an overview of the significant differences between groups.{Table 3}

Regarding the PMTF positioning, the acoustic trauma group presented the most abnormal test results, and this group was significantly different from the other three groups: hereditary ($P=0.0023$), nonauditory ($P=0.0023$), and music ($P=0.016$) groups.

Regarding the MOC function, the hereditary group had the most abnormal test results, which were significantly different from those of the nonauditory group ($P=0.0011$). Also, the results of the acoustic trauma group were significantly different from those of the nonauditory group ($P=0.0032$). The results of the music group fell in between.

There was a significant difference ($P=0.032$) in the OHC function between the acoustic trauma group and the nonauditory group. However, the OHC damage was not very pronounced in any of the groups.

The nonauditory group had a better high-frequency threshold average (3000, 4000, 6000 Hz), which differed

significantly from that of the hereditary group (P=0.018), and there was a trend for a difference from the acoustic trauma group too (P=0.092). (This was analyzed with a one-way ANOVA with the said threshold-average as independent variable and group as factor, and with a subsequent Tukey's HSD test.) The age of the participants had no influence on the analyses by group.

Individual causative factors and auditory test results

MANOVAs for auditory test results versus individual causative factors could not be performed for the four-graded scales. However, MANOVAs (plus Tukey's HSD tests) with causative factors only two-graded (i.e., "No" - no or only mild influence, or "Yes" - marked or very strong influence) showed some significant differences. Individuals judged to have been markedly or very strongly influenced by acoustic trauma showed worse test results in all three auditory tests - PMTF positioning (P=0.00019), MOC (P=0.028), and OHCs (P=0.0034) - than those judged not at all or only mildly influenced. There was also a significant difference regarding the causative factor nonauditory with better PMTF positioning (P=0.0044) for subjects judged to have at least marked influence of nonauditory problems than for those without or only mild such problems. (Very few judged to have nonauditory problems were judged to have been influenced by acoustic trauma, and very few judged to have been influenced by acoustic trauma were judged to have nonauditory problems.) Regarding the causative factor hereditary, the subjects supposed to have marked or worse hereditary influence had significantly better PMTF positioning (P=0.017) and worse OHCs (P=0.017) than those judged without or with only mild hereditary influence. The average MOC result was worse for the suspected heriditary cases than for others, but not significantly so. There were no significant differences in auditory test results for the causative factor music.

Discussion

Tinnitus is a symptom, not a diagnosis. In order to be able to manage tinnitus patients properly, it is important to diagnose separate tinnitus entities. This applies especially to normal-hearing patients with tinnitus, in whom only limited diagnostic information about the state of the cochlea can be extracted from the pure tone audiogram. Nevertheless, cochlear diagnostics are regularly based on demonstration of pure tone threshold elevations. Tests based on auditory physiological principles offer a possibility to sharpen the diagnostic capability, and the hypothesis of this study is that a carefully designed physiological test battery is a means to achieve this goal. The tinnitus patients of this study were selected to represent four different causative groups, two of them related to noise exposure. They were diagnosed according to a structured medical history, and on other clinical observations not related to any of the physiological principles applied in the test battery. This allows a validation of these physiological tests.

For the patients with tinnitus that appeared after short, intense sound exposure, the acoustic trauma group, it can be assumed that they should have some damage affecting the function of the inner ear. The test results support this assumption. All patients who were judged to have suffered acoustic trauma had at least two abnormalities within the test battery. The most common marked abnormalities affected PMTF positioning plus MOC function. However, two of them had strongly affected MOC function but fairly normal PMTF positioning. The measurements of OHC function were in most cases slightly abnormal. These findings suggest a combination of inner ear damage (in spite of normal or slightly abnormal pure tone audiograms) and disturbed efferent modulation of the cochlea. The results of the acoustic trauma group are in concordance with other reports. [9],[10],[19],[23] In the study by Attias et al. involving military personnel, [9] DPOAEs could be measured on ears with hearing thresholds as high as 75 dB HL, which suggests severe damage to inner hair cells (IHCs). It has been shown that normal or near-normal thresholds in animals do not exclude damage first to IHC cochlear nerve terminals and later to IHCs. [24],[25] A large percentage of IHC afferent synapses could be damaged despite normal thresholds. Moreover, Attias et al. mention that ipsilateral enhancement of OAEs could stem from decreased MOC efferent feedback to the OHCs because of IHC damage and reduced input from the afferent arm. This agrees well with our findings of extreme TEOAE responses (or, through contralateral regulation, increase instead of decrease of TEOAEs when contralateral noise was presented) for some subjects

and also with the findings of Attias et al. [8] in tinnitus patients with normal hearing thresholds.
The group of musicians presented ambiguous results regarding the mechanisms causing the symptom. All but one had cochlear dysfunction of some kind, for example the two of them who had fully developed abnormal PMTF positioning (hyper-PMTF). The statistical analysis of this small group does not give much information regarding the possible presence of minor but typical cochlear dysfunction. This is not surprising, since there is a large variety of individual mixes of types of music exposure and other circumstances for people working with music or in rooms where music is played. A larger study in progress takes this into account.
In the nine cases, for whom heredity was judged as the main causative factor, all but one had a high degree of abnormality in efferent function, and the statistical analyses showed that the main characteristic of the hereditary group was abnormal MOC function. The MOC function was mainly judged from the contralateral suppression of TEOAEs. Especially suspected hereditary cases had strongly abnormal suppression (strongly increased response) in individual combinations of frequency bands. Overall values of suppression or prechosen frequency band do not necessarily reveal such abnormalities. One may ponder if a defect MOC, at least in a young person, might signal a hereditary defect, and that such a dysfynction may sensitize the cochlea to noise damage. The latter assumption is strenghtened by the existence of a significant correlation between the results of the MOC and OHC measurements in the study. However, a larger patient material is necessary to confirm these assumptions. To the best of our knowledge, this is the first report on a type of hereditary tinnitus, related to abnormal MOC function, and possibly resulting in decreased resistance to noise damage.
The nonauditory group represents patients with tinnitus with, presumably, unaffected cochlear function. [12],[26],[27] With a couple of exceptions, with test results hinting at acoustic trauma, the outcome of the tests in this group showed little evidence of abnormal function. The statistical analysis shows that factors triggering tinnitus in the nonauditory group should preferably be searched for outside the peripheral auditory system. Two other possible factors - the age of the participants and the presence of audiometric dips - did not predict the presence of inner ear dysfunction or abnormality affecting the efferent system.
The outcome of the test battery shows that PMTF positioning and MOC function suggests abnormalities in the group where these are most likely to appear - the acoustic trauma group. Moreover, the MOC function appears to be impaired in this group. Especially the PMTF positioning test appears to provide important diagnostic information even after relatively limited noise exposure, causing tinnitus but not pure tone threshold elevations. The test of the OHC function (TEOAEs and PMTF nonlinearity) is less important for this patient category. Still the results deviate significantly between the the nonauditory group and the acoustic trauma group [Figure 2]. The same test pattern appears in an individual analysis of no or mild influence versus marked/very strong influence of causative factors (e.g., exposure to noise). This analysis shows significantly poorer OHC function for individuals with acoustic trauma, but also for individuals with suspected heredity as a risk factor, than for individuals without these risk factors.
In this study the subjects were categorized into groups according to most likely causative factor. However, most patients had more than one judged causative factor. For some patients the results of the hearing tests point toward causative factors that were judged possible, but not judged as the most likely one. This indicates the diagnostic value of the test battery. However, it is plausible that more than one causative factor has caused a patient's tinnitus. Thus, there might be an uncertainty in interpretation of test results and a difficulty to find a one-to-one relationship between causative factor and test outcomes. The music group, at least as a group, might be an example of that.
The present study indicates that it is possible to reach a diagnostic capability of, for example, noise-induced hearing loss far beyond what is possible with pure tone audiometry only. Such a refined capacity offers possibilities to support medicolegal assessments of, for example, noise-induced hearing loss, to select appropriate treatment programs and to improve counseling for the patients.
Conclusions

The results of the present study suggest that the diagnostic capability can be improved by using modern physiological methods. Tinnitus and related symptoms can be caused by a broad variety of unrelated triggering factors. We found distinct cochlear lesions especially in cases where acoustic trauma or heredity are possible causative factors. A new entity of hereditary tinnitus with abnormal MOC function, and possibly increased sensititvity to noise, is described.

Acknowledgments

The study was supported by grants from Swedish Skandia Life, The Foundation Tysta Skolan, the Federation of Hard of Hearing People (HRF), and the Swedish Council for Working Life and Social Research. We express our gratitude also to Ann Johansson and Helena Norell, who performed the measurements, and to our test subjects. Support from Åke Olofsson was invaluable to the project.

Abstract: This study provides a meta-analysis of the difference between children with primary or specific language impairment (LI) and their typically developing peers on tasks of sustained attention. The meta-analysis seeks to determine whether children with LI demonstrate subclinical deficits in sustained attention and, if so, under what conditions. Articles that reportedempirical data fromthe performance of children with LI, in comparison to typically developing peers, on a task assessing sustained attention were considered for inclusion. Twenty-eight effect sizes were included in the meta-analysis. Two moderator analyses addressed the effects of stimulus modality and attention-deficit/hypereactivity disorder exclusion. In addition, reaction time outcomes and

the effects of task variables were summarized qualitatively. The meta-analysis supports the existence of sustained attention deficits in children with LI in both auditory and visual modalities, as demonstrated by reduced accuracy compared with typically developing peers. Larger effect sizes are found in tasks that use auditory-linguistic stimuli than in studies that use visual stimuli. Future research should consider the role that sustained attention weaknesses play in LI as well as the implications for clinical and research assessment tasks. Methodological recommendations are summarized.

Purpose: This study provides a meta-analysis of the difference between children with primary or specific language impairment (LI) and their typically developing peers on tasks of sustained attention. The meta-analysis seeks to determine whether children with LI demonstrate subclinical deficits in sustained attention and, if so, under what conditions.
Method: Articles that reportedempirical data fromthe performance of children with LI, in comparison to typically developing peers, on a task assessing sustained attention were considered for inclusion. Twenty-eight effect sizes were included in the meta-analysis. Two moderator analyses addressed the effects of stimulus modality and attention-deficit/hypereactivity disorder exclusion. In addition, reaction time outcomes and the effects of task variables were summarized qualitatively.
Results: The meta-analysis supports the existence of sustained attention deficits in children with LI in both auditory and visual modalities, as demonstrated by reduced accuracy compared with typically developing peers. Larger effect sizes are found in tasks that use auditory-linguistic stimuli than in studies that use visual stimuli.
Conclusions: Future research should consider the role that sustained attention weaknesses play in LI as well as the implications for clinical and research assessment tasks. Methodological recommendations are summarized.
Key Words: attention, specific language impairment, meta-analysis, cognition

Children with primary language impairment (LI) appear on clinical caseloads and in the research literature under a variety of names, including specific language impairment (SLI), language disorders, and language-based learning disabilities. Consistent with a growing number of researchers, we prefer the term primary language impairmenthere, as it encompasses the subtle nonlinguistic processing weaknesses that exist alongside the defining deficits in language yet maintains the distinction between this diagnostic category and LI attributed to frank sensory, cognitive, or neurological disorders (e.g., Kohnert,Windsor, &Ebert, 2009; Tomblin, Zhang,Buckwalter,&O'Brien, 2003).For children withLI, several areas of language may be affected, including vocabulary, morphosyntax, discourse, written language, and social language (for reviews, see Leonard, 1998; Schwartz, 2009).

Although poor performance on language tasks, in the face of otherwise typical development, is considered the critical marker of LI, subtle processing inefficiencies extend beyond language to the general cognitive domain. Mounting empirical evidence points to at least three general areas of cognitive-processing inefficiency in children with LI: working memory, speed of information processing, and attention (for reviews, see Gillam, Montgomery, &Gillam, 2009; Windsor &Kohnert, 2009). The extent of these subclinical, cognitive-processing weaknesses and their relationship to the more obvious language deficits in children with LI is not yet clear. Our concern here is with attention. The high comorbidity rate between language disorders and clinical disorders of attention is robustly supported (e.g., Willinger et al., 2003). However, the connection between delayed or inefficient language and attention may extend beyond comorbidity to more subtle deficits.

We present a meta-analysis and narrative summary of the empirical literature assessing one subtype of attention, sustained attention, in children with LI. Our purpose was to synthesize the evidence that supports or refutes the existence of sustained attention deficits in children with LI. This information is needed to guide future investigations, which will, in turn, pave the way for advances in both language theory and clinical practice. To

provide the context for this systematic review, we first consider the major conceptual approaches to attention and the theoretical basis for connections between attention and language development.We then discuss the rationale for focusing specifically on sustained attention. Finally, we explain the motivation for using a metaanalysis to consider the evidence related to this potential component of the LI profile.

Models of Attention and Links to Language

Attention is a basic cognitive skill that underlies performance on most information-processing tasks. The breadth and importance of this skill has led to several distinct conceptualizations of attention, many of which directly link attention and language. We review three of the most common conceptualizations of attention. These three conceptualizations are not mutually exclusive; however, each has distinct predictions regarding the impact of attention skills on language development. Thus, we consider each model, with its implications, separately.

In the first major model, the key division of attention is between automatic (or unconscious) and controlled (or conscious) information processing. Controlled attention requires the effortful maintenance of a goal in mind and is thus closely related to executive functions (Miyake, Friedman, Rettinger, Shah, &Hegarty, 2001). It can be assessed through higher level cognitive tasks as well as working memory tasks. Controlled attention is implicated in language acquisition because a language learner must successfully focus on relevant auditory input in the face of distracting stimuli. Conscious attention to the relevant linguistic input may then activate unspecialized neurons, assisting with the learning process (seeWindsor&Kohnert, 2009, for review). In addition, children with LI may demonstrate impairments in controlled attention (Marton, 2008). The relationship between controlled attention and LI may be mediated by a common association with working memory and higher level cognitive tasks: Controlled attention can be assessed through higher level cognitive tasks and working memory tasks (Miyake et al., 2001), and evidence strongly indicates that weaknesses in workingmemory and higher level cognitive tasks are a component of the LI profile (Kohnert et al., 2009; Montgomery, 2002).

The second model conceptualizes attention as a limited-capacity system. In this model, an individual's attentional resources are allocated to tasks as needed, but problems arise when task demands exceed the individual's attentional capacity (Montgomery, Evans, &Gillam, 2009). Because the working memory system is often also conceptualized as a limited-capacity system (Just &Carpenter, 1992), attention is again closely related to working memory in this model. Language acquisition and attention are linked within this theory as well because language learners must allocate their attentional resources to incoming linguistic stimuli in order to process it. Evidence within both the working memory (Montgomery, 2002) and attention frameworks (Montgomery et al., 2009) indicate that children with LI demonstrate notable capacity limitations.

A third major approach to conceptualizing attention is to divide it into components (e.g., Gomes, Molholm, Christodoulou, Ritter,&Cowan, 2000; Mirsky, Anthony, Duncan, Ahearn, &Kellam, 1991). The purpose of such an approach is to characterize the functioning of distinct pieces of the complex attention system more precisely, allowing for more accurate identification of points of breakdown in attentional problems. In addition, neuroanatomical evidence indicates that distinct brain regions are associated with each component of attention (Mirsky et al., 1991). Component approaches differ somewhat in the way they conceptualize the critical pieces of attention. Mirsky et al. (1991) argued that there is both behavioral and neuroanatomical evidence for four distinct components of attention: focus, inwhich information is selected for processing; sustain, in which this focus is maintained over time; shift, in which attentive focus is moved to new information; and encode, in which information is mentally registered.

All components of attention have a role in language acquisition (Gomes et al., 2000). A language learnermust focus on relevant linguistic input and ignore irrelevant input. Heor shemust sustain this focus in order to take in complete input for processing. When the source of language input shifts, the language learner must also shifthis or her attention to avoid missing relevant input. Finally, he or she must attend to encoding the information in order to make it available for future use.

As with the first two attention models reviewed, empirical evidence also links weak attention skills to LI in the

component model. Initial evidence suggests that attentional shifting may be intact in children with LI (Schul, Stiles,Wulfeck,&Townsend, 2004). However, recent studies indicate that children with LI have deficits in sustained attention (Finneran, Francis, &Leonard, 2009; Spaulding, Plante, &Vance, 2008); in focus, or selective attention (Stevens, Fanning, Coch, Sanders, &Neville, 2008); and in encoding, which is similar to working memory.

Thus, from each distinct perspective, the contribution of attention to language acquisition can easily be hypothesized. In other words, it is likely that attention skills combine with other cognitive constructs (such as memory) to facilitate language learning (Windsor &Kohnert, 2009). In addition, converging evidence suggests that weak attention skills play a role in LI. These patterns support a closer analysis of subtle attention deficits as a component of the LI profile, joining more established cognitive-processing deficits such as speed of processing and working memory. However, this brief discussion of attention also underscores the difficulty of capturing the diverse conceptualizations of attention in a single, operational definition. Such an operational definition is necessary for conducting a sound systematic review and meta-analysis, as systematic reviews must focus on a concise question (Schlosser,Wendt,&Sigafoos, 2007). Thus, narrowing our view of attention to a single perspective-and, even further, to a particular subtype of attention-facilitates synthesis of a portion of the evidence for attentional deficits in LI.

In the present study, we adopt a component theory of attention and consider the specific dimension of sustained attention. The component theory of attention is designed to break attention down into discrete potential areas of deficit, which can be assessed separately (Mirsky et al., 1991). In contrast, both controlled attention and limited-capacity attention are inextricably intertwined with the concept of working memory, making assessment of attention and not working memory very difficult.

Sustained Attention

Within the component theory of attention, we focus on sustained attention as a starting point because there is reason to believe it is problematic in children with LI. Mirsky et al. (1991) define sustained attention as "the capacity to maintain focus and alertness over time, or vigilance" (p. 112). The authors of at least two separate studies claimed to have observed impaired vigilance in children with LI, with a resulting impact on task performance. Stark and Montgomery (1995) observed that children with LI who were completing a sentenceprocessing task "would sometimes gaze around the test room, play with the headphones, or slump, glassy-eyed, while the sentences were being presented" (p. 150). In addition, Helzer, Champlin, and Gillam (1996) found that children with LI and their typically developing (TD) peers had remarkably similar auditory temporal resolution skills. However, the children with LI required more trials to achieve a threshold. Because this reflects inconsistency in responses, the authors interpreted this difference as a reflection of poorer sustained attention skills among the LI group. However, sustained attention was not measured directly in either of these studies.

There has also been indirect evidence indicating that weak sustained attention skills play a role in treatment gains. Results from a large randomized trial suggest that language gains following intensive treatment programs may be related to gains in sustained attention. Gillam et al. (2008) assigned over 200 schoolage children with LI to one of four treatment conditions. All participants attended treatment for 3.5 hr per day, but participants in one condition received a control treatment not specific to language. Significant but equivalent language gains were found across the four groups, leading Gillam et al. (2008) to question whether the intensive treatment conditions caused participants to improve their information-processing skills, including sustained attention (p. 113). Implicit in this claim is the premise that children with LI have impaired sustained attention skills prior to the intervention. Two singlesubject experimental design treatment studies (Ebert &Kohnert, 2009; Gillam, Crofford, Gale,&Hoffman, 2001) made very similar inferences, hypothesizing that intensive intervention may boost language in part through sustained attention improvements. It is important to note that in these two studies, the authors used a design that limits the ability to generalize to the population and thus made weaker claims than

did Gillam et al. (2008). However, an even more important limitation of all three studies is that they lack a direct measure of attention either before or after intervention and, therefore, cannot provide direct evidence either of weak attention skills in LI or of attention skill improvements with treatment.

In addition, several recent studies have directly investigated the presence of subclinical sustained attention deficits in children with LI (e.g., Bishop&Norbury, 2005; Finneran et al., 2009; Spaulding et al., 2008). These publications highlight increasing interest in the potential relationship between sustained attention and LI. In summary, both indirect and direct evidence suggest that sustained attention skills are potentially subtly impaired in children with LI. However, single studies provide conflicting results and are not strong enough to definitively establish the presence or characteristics of such deficits. A systematic review of the topic is warranted.

A Systematic Review and Meta-Analysis of Sustained Attention in LI

The purpose of a systematic review is to identify and synthesize evidence relevant to a specific question in a transparent and an unbiased manner (Dollaghan, 2007). Systematic reviews are an essential tool for directing future research and for guiding clinical decision making (Schlosser et al., 2007). In this case, a synthesis of the evidence regarding potential sustained attention deficits in children with LI would inform the LI profile for both researchers and clinicians. Meta-analysis, a subtype of systematic review, is often valued over other types of systematic reviews because of the quantitative nature of the results (Dollaghan, 2007).

The primary purpose of this meta-analysis was to synthesize the evidence for and against sustained attention deficits in children with LI. If robust evidence of sustained attention deficits in LI is found, then a secondary purpose of the review will be to characterize these deficits. Thus, we address two specific questions:

1. Do children with LI demonstrate deficits on tasks of sustained attention?
2. What are the methodological circumstances under which these differences are most evident, in terms of task, participant, and outcome variables?

To answer these questions, we conducted a search for articles in which both children with LI and TD peers completed a task of sustained attention. We defined children with LI using conventional criteria for LI/SLI (e.g., Leonard, 1998). To define a task of sustained attention, we adopted the suggestion by Mirsky et al. (1991) that the standard task for assessing sustained attention is a continuous performance task, or CPT (cf.Williams, Stott, Goodyer, &Sahakian, 2000). The CPT assesses vigilance or sustained attention by requiring the participant to monitor a series of stimuli over time for specific target stimuli (Corkum&Siegel, 1993). Adopting a narrow definition of a sustained attention task allowed us to avoid confusing cognitive weaknesses already associated with LI, such as working memory and executive function, with sustained attention weaknesses.

Method

Inclusion Criteria

Prior to initiating the search, several inclusionary criteria for articles were established. To avoid publication and language bias (Schlosser et al., 2007), the search targeted published articles as well as unpublished theses and dissertations in the public domain, in any language. It was determined that articles would be included in the review only if they met the following criteria:

1. The inclusion of at least one group of participants with LI. A variety of terms for LI were accepted (e.g., SLI, developmental language delay, dysphasia, etc.) as long as the participants met conventional criteria for LI, including nonverbal IQ within the average range, as demonstrated by a standardized test or author report, normal hearing, no identified neurological or behavioral disorders, and delayed language development in comparison with peers that is not restricted exclusively to the phonological domain of language (i.e., speech concerns may be present but should not be the only area of language affected). Exact criteria for the definition of delayed language development differed across studies;means of meeting this criterion included using a clinical diagnosis, requiring scores on one or more standardized language tests to be well below age expectations (e.g., >1.25 SDs below the mean), and requiring a significant discrepancy between standardized language and nonverbal IQ scores. Studies were included as long as they made a case for notable delays in

language development, in order to accommodate studies that spanned a wide range of both time and geography. In addition, some studies that were reviewed did not explicitly state a method for excluding children with attentiondeficit/ hyperactivity disorder (ADHD) from their LI sample (see the Moderator analyses subsection for more details). However, studies in which all LI participants also were diagnosed with ADHD (e.g., Oram-Cardy, Tannock, Johnson, &Johnson, 2009) were excluded.

2. The reporting of new empirical data from the administration of a behavioral task. Articles in which data only from parent or teacher observations of behavior were reported were excluded on the grounds that such checklists subjectively assess overt characteristics of inattention, such as those seen inADHD. The purpose of this review was to look for objective evidence of subtle attention deficits in children with LI.

3. The assessment of sustained attention via the behavioral task using some form of a CPT, although these tasksmay be referred to by other names (e.g., go/no-go task, sustained attention task, auditory or visualmonitoring task, etc.). Specifically, the present review was restricted to tasks that required the participant to monitor a stream of stimuli. Studies in which attention was assessed using more complex cognitive tasks, such as the Wisconsin Card Sorting Test (Kongs, Thompson, Iverson,&Heaton, 2000) or Tower of London (Culbertson&Zillmer, 2001; Marton, 2008), were excluded on the grounds that performance may reflect more complex executive functions (Kohnert et al., 2009) rather than the subcomponent of sustained attention. Similarly, in order to avoid rereviewing evidence that children with LI have deficits in working memory capacity, attention tasks that were framed as assessments of processing capacity (e.g., the competing language processing task)were not reviewed.

4. The comparison of reported results of the performance of participants with LI with the performance of a group of TD peers without LI on at least one outcome measure from the task. Some authors (e.g., Finneran et al., 2009) argue that a true measure of sustained attention must capture the decrement in performance over time during an extended task, and thus simple measures of accuracy or response time from a CPT are indices of selective attention only. However, this strict definition of sustained attention appears to be adopted by a small minority of authors, and its application to populations with LI remains rare: Only two studies that reported a measure of performance decrement over time were located. Thus, a more lenient criterion for acceptable outcome measures was adopted. Physiological outcome measures such as event-related potential waveforms were not included in the review on the grounds that such measures of attention do not compare with behavioral measures of attention in a straightforward way.

5. The inclusion of the first or primary measure reported for review when more than one outcome measure was reported for a single task administration. For example, Hanson and Montgomery (2002) reported both hit and false-alarm rates for the same sustained attention task; they described the hit rate as the "primary" dependent variable (p. 84), and therefore only the hit rate data were included in the present review. This stepwas adopted to avoid overemphasizing data from a single task in the review's conclusions.

Literature Search

A systematic search for empirical articles addressing sustained attention in children with LI was conducted in January andFebruary 2010.Databases searched include ERIC, GoogleScholar, HighWire Press, Medline, PsycINFO, and Web of Science. The search term combinations language impair* and attention and language disorder and attention were applied to titles, keywords, and abstracts in each database.

A total of 1,030 articles were identified in these searches. In the first round of article evaluation, abstracts were reviewed to exclude articles that clearly did not meet the search criteria established above. In otherwords, articleswere discarded if they did not contain participants with LI (e.g., participants had acquired aphasia, autism, or another language disorder distinct from LI), did not contain empirical data, or did not report behavioral results from a task that potentially assessed sustained attention. Any article that may have contained a task meeting search criteria, including those tasks labeled using terms other than sustained attention, were retained for further review. Duplicate articles were also excluded during this stage. Following the first round of article

evaluation, 45 articles were identified for further review.

The full text of these 45 articles was obtained. In the second round of article review, the first author reviewed the text of each to verify that the article did meet all search criteria. Five articles were written in languages other than English (three in Spanish and two in German). The English and Spanish articles were reviewed by the authors, and the German articles were reviewed by a consultant fluent in German. Following the full article review, 17 articles were identified for inclusion in the analysis. These 17 articles reported performance data from children with LI and from their TD peers on 33 separate sustained attention tasks. All 33 tasks reported accuracy data; 10 tasks also reported reaction time (RT) data. Table 1 lists these 17 studies along with a summary of participants, task characteristics, and results.

Reliability. A portion of the search was reconducted by the second author in order to establish its replicability. The second author, who did not take part in the initial search, reviewed 18% of randomly selected results from the search. Agreement with the first author as to whether or not the article met search criteria was 98% for these articles, prior to conferring.

Analysis

In order to perform the meta-analysis, effect sizes for each contrast of interest (i.e., children with LI vs. TD children) were calculated for the task accuracy data from each of the 33 tasks that met search criteria. The standardized mean difference between groups (Cohen's d; Cohen, 1988) was calculated from reported or graphically displayed group means and standard deviations when possible. Three studies (Greyerbiehl, 1981; Lum, Conti-Ramsden, &Lindell, 2007; McArthur &Bishop, 2004) subdivided the LI group; for these studies, data from all LI children were pooled to create the effect of interest.When the relevantmeans and standard deviations were not reported (i.e.,Wiig &Austin, 1972), a reported F statistic was used to calculate effect size (Cooper, Hedges, &Valentine, 2009). One study (Noterdaeme, Amorosa, Mildenberger, Sitter, &Minow, 2001) containing four tasks of interest reported only group medians, statistics for a three-way group comparison, including a group with autism, and a descriptive statement that the LI group performed significantly below the TD and autism groups on the tasks of interest. This study was judged not to provide enough information to accurately calculate d; it is included in qualitative portions of the review but was excluded from the meta-analysis.

These procedures generated 29 effect sizes for analysis. Visual inspection of the distribution of effect sizes indicated an obvious outlier with a d value nearly 3 times as large as the second greatest effect size in the distribution (Wiig &Austin, 1972; d = 3.41). This study was also eliminated from the meta-analysis portion of the review.

Calculations were made assuming a fixed-effects model. Each of the 28 remaining effect sizes were converted into Hedge's g to prevent bias from small sample sizes (Cooper et al., 2009), and the inverse variance of each effect size was used to weight the relative contribution of each study to the overall effect size. The weighted average effect size across all studies was then calculated.

Moderator analyses. Two moderator analyses were also conducted. The first moderator analysis addressed the question of whether sustained attention deficits in children with LI are restricted to the auditory modality (Noterdaeme et al., 2001; Spaulding et al., 2008). Tasks were divided into three groups according to the type of stimuli used: visual, auditory-linguistic, or auditory- nonlinguistic. A distinction was made between linguistic and nonlinguistic stimuli in the auditory domain because, by definition, children with LI perform poorly on language-based tasks; a true weakness in sustained attention in the auditory modality should appear in studies in which nonlinguistic stimuli are used.

The second moderator analysis examined whether studies that state explicit criteria for ensuring that participants did not have ADHD differ from studies that do not. A number of studies found in the literature search described their participants as having no known neurological or behavioral disorders but did not describe a test for ensuring that participants did not have ADHD specifically. This group of studies was compared with those studies in which a procedure for excluding children with ADHD (e.g., a screening test, parent report, or

teacher rating scale) was described.

Finally, a qualitative synthesis of results was performed for two additional areas: RT results and task variables. In each of these areas, the number of studies that could be included in ameta-analysiswas quite small. However, both areas were of interest a priori: RT differences between LI and TD children have been robustly supported in recent literature (Kohnert et al., 2009; Miller et al., 2006), and a previous review of CPT tasks (Corkum&Siegel, 1993) indicates that key task variables may be central to interpreting results from these tasks. Therefore, the data were extracted and analyzed qualitatively in these areas.

Results

Table 2 displays the results of the overall metaanalysis and the two moderator analyses. The weighted average effect size across all studies was 0.69. This result differs significantly from zero ($Z = 13.17$, $p < .001$), indicating that children with LI perform significantly below TD peers on sustained attention tasks. The test of homogeneity of variance among effect sizes was also significant ($Q = 59.16$, $p < .001$).

The moderator analysis for modality indicated that the weighted average effect size in each of the three modalities that were analyzed (visual, auditory-linguistic, and auditory-nonlinguistic) differed significantly from zero (auditory-linguistic: $g = 0.82$, $Z = 11.34$, $p < .001$; auditory- nonlinguistic: $g = 0.61$, $Z = 5.86$, $p < .001$; visual: $g = 0.47$, $Z = 4.24$, $p < .001$). The moderating variable explained a significant amount of variance in the effect sizes ($Qb = 24.87$; $p = .02$). In other words, the modality of stimuli does affect LI deficits on sustained attention tasks. However, a significant amount of within-group variance remained in the auditory-linguistic ($Qw = 23.34$, $p < .05$) and visual ($Qw = 15.13$, $p < .05$) groups. Thus, effect sizes in these two groups differed even after accounting for the effects of stimulus modality.

We conducted post hoc contrasts between the three modalities using Bonferroni correction. These analyses indicated that only the difference between the visual and auditory-linguistic means reached statistical significance at the $p < .05$ level.

The second moderator analysis examined the difference betweenstudieswith explicitADHDexclusioncriteria and those without. The between-groups heterogeneity statistic did not reach statistical significance ($Qb = 0.59$), indicating no difference in effect size between these two groups of studies.

RT Outcomes

RT data were reported for 13 of the 33 tasks that met search criteria, providing insufficient data for quality meta-analysis (Cooper et al., 2009). Children with LI demonstrated significantly slower RTs than did their TD peers on only one of these 13 tasks: the sustained auditory attention task reported by Noterdaeme et al. (2001). Taken at face value, this seems to indicate that speed of response on CPTs is unaffected by LI, a finding inconsistent with a growing body of literature indicating small RT differences for children with LI even on relatively simple perceptual motor tasks (e.g., Kohnert et al., 2009; Miller et al., 2006). We return to this point in the Discussion section.

Task Variables

Task differences may be the source of conflicting results in studies of sustained attention (Corkum &Siegel, 1993). Although all tasks within the reviewed studies met a relatively narrow definition of a sustained attention task, they differed along several dimensions. The key variables we extracted for comparison were the percentage of stimuli that are targets and the duration of the targets. We selected these variables for review because Corkum and Siegel's (1993) review of CPTs shows that manipulation of the percentage of targets and duration of targets has a notable effect on results. Numerous other variables, such as the task duration or the interstimulus interval, have the potential to affect outcomes, but clear and consistent patterns between these variables and task outcomes have not been established (Corkum& Siegel, 1993).

Table 1 presents task features, as well as dependent variables, for each of the 33 tasks reviewed. The duration of stimuli was reported for 22 of the 33 tasks. Stimuli ranged from 75 ms to 2 s in duration. The percentage of stimuli that were targets ranged from 10% to 50% for the 23 tasks that reported the information.

Discussion

The results of the meta-analysis establish the presence of sustained attention deficits in children with LI in comparison with TD peers. The weighted average effect size across studies indicates that the task accuracy of children with LI fell more than half a standard deviation below that of their TD peers. The effect size does, however, indicate some overlap between the LI and TD populations on sustained attention tasks (Cohen, 1988).

Corrected effect sizes ranged widely across studies, from g = -0.08, indicating that LI children performed slightly better than TD children, to g = 1.41, indicating that children with LI performed nearly 1.5 standard deviations below TD peers. We explained some of the variability among effect sizes by analyzing the role of stimulus modality on effect size. One of the prominent claims in the literature reviewed here is that children with LI demonstrate sustained attention deficits specific to the auditory rather than the visual modality (Noterdaeme et al., 2001; Spaulding et al., 2008). We differentiated between linguistic and nonlinguistic stimuli in the auditory domain on the grounds that tasks using linguistic stimuli may be more indicative of language than attention deficits in the LI population.Results supported this distinction: Although stimulus modality did play a role in effect size, only the difference between auditory-linguistic tasks and visual tasks reached significance. The average effect size for auditory-nonlinguistic tasks (g = 0.61) lies closer to the average effect size for visual tasks (g = 0.47) than for auditory-linguistic tasks (g = 0.82).We note, however, that all four of the studies in which both visual and auditory tasks were administered to the samechildren revealed deficits only on the auditory tasks (Dodwell &Bavin, 2008; Noterdaeme et al., 2001; Spaulding et al., 2008; Townsend&Tallal, 1989). It is possible that the difference between auditory-nonlinguistic and visual sustained attention tasks could reach significance with more data; such a result would provide compelling evidence of modality specificity in sustained attention deficits in children with LI. In summary, there was clear evidence of poorer performance by participants with LI across all three subtypes of sustained attention tasks, although the magnitude of this difference varied.

One potential limitation of the meta-analysis is that most of the reviewed studies investigated the attentional capacities of children with LI without ensuring that those children did not also have ADHD.Without any screening for attention disorders, samples of children with LIwould be expected to contain more children with ADHD than samples of TD children, and children with ADHD would be expected to perform poorly on a task of sustained attention. The results of the second moderator analysis address this concern. The small value of the betweengroups heterogeneity index indicates that studies with and without explicit ADHD exclusion do not differ substantially from each other. This result implies that other studies did, in fact, take steps to exclude children with ADHD but did not describe them in the article, stating instead that children in the LI group did not have behavioral or neurological disorders. Thus, the conclusion that children with LI demonstrate sustained attention deficits does not appear to be driven by the presence of children with comorbid ADHD in study samples.

RT

In contrast to the accuracy data, the RT results reviewed here provide little support for the claim that children with LI performmore slowly than TD peers on tasks of sustained attention. A number of factors temper this conclusion, however. First, RT measures are conventionally determined for accurate responses only. In a CPT, although both target and distractor trials can be used to calculate accuracy measures, only target trials can be used for RTcalculations (because there is no response on a correct distractor trial). In some cases, the number of targets on which valid measures of RTcould be made was relatively small. For example, the percentage of targets in Spaulding et al. (2008) was 17%(16) per task. Finneran et al. (2009) included 40%targets, yet given the very large group difference between LI and TD peers in accuracy, the number of stimuli on which valid calculations of RT could be made would be significantly reduced.

A second factor that limits the interpretation of RT results is the lack of statistical control for developmental effects in some of the studies. For example, Buiza- Navarrete, Adrián-Torres, and González-Sánchez (2007) found no significant between-groups difference in RT on a visual sustained attention task for participants who

ranged fromage 5;0 (years;months) to 12;11 (see Table 1). The potential effect of age within each group was not investigated. It is quite possible that within-group variation related to age overwhelmed any potential betweengroups RT differences. In a study in which simple and choice visual detection tasks in 8- to 13-year-olds were investigated, Kohnert and Windsor (2004) found that age accounted for a significant 40% of the variance in RT for monolingual children with LI, and 39% for their TD peers. In addition, two of the four studies that report RT data have the youngest participants in the review. It is possible that high variability in this population contributes to the lack of significance in RT results (Spaulding et al., 2008). Finally, only four studies reported RT data for children with LI on a sustained attention task. Clearly, additional RT data are needed to confirm or refute the hypothesis that children with LI do not demonstrate RT deficits on tasks of sustained attention.

On the basis of the existing empirical literature, accuracy measures yield the most robust differences in sustained attention between children with LI and their TD peers. Furthermore, the finding of reduced accuracy on sustained attention tasks by children with LI indicates that limitations in sustained attention skills in this population are separable from more generalized slowing in information processing.

Task Variables

Additional methodological differences that may affect results are the duration of stimuli and the percentage of stimuli that are targets. These variables were not included in themeta-analysis becausemany studies did not report this information, and the information obtained could not always be easily compared (e.g., some stimuli durations were measured in syllables, and others in seconds). However, these variables may explain variability in outcomes and deserve consideration.

Corkum and Siegel (1993) suggest that tasks with shorter stimuli durations and higher percentages of targets place a greater demand on attentional resources and therefore better discriminate between children with impaired and intact attention. Corkumand Siegel reviewed only tasks with visual stimuli and concluded that 50-200 ms is an optimal stimulus duration for such tasks. In the present review, significant results were obtained using stimuli that ranged from 75 ms to 1 s in duration, suggesting that sustained attention deficits in LI are apparent under a range of task conditions. However, Corkum and Siegel's review may help explain patterns in the results that did not reach significance. At least three of the reviewed tasks using visual stimuli that did not find significant results used stimuli durations of 1-2 s (an additional three tasks did not report stimuli durations). These durations fell well outside the range of 50-200 ms and could have affected the power of those tasks to find sustained attention deficits.

The percentage of stimuli that are targets is another task variable with the potential to influence results. Corkum and Siegel (1993) argued that a higher percentage of targets increases task monotony and therefore increases the task's potency to detect sustained attention deficits. Percentage of targets does not appear to have a clear effect on the present results. Significant differences between LI and TDchildrenwere found across the range of percentage targets, from 10% to 50%. Studies with nonsignificant results also appear to be distributed across that range.

Finally, as noted in the Results section, another task variable-such as task duration-could affect outcomes. Significantwithin-group variability remained in two of the three groups of studies after accounting for the effect of stimulus modality. Either of the two task variables reviewed here could explain some of this variability, as could another variable that was not highlighted by Corkum and Siegel (1993). It will be important for future work in this area to describe all task parameters to illuminate the relationship between task variables and outcomes.

Potential Biases

Thepotential for source bias is a general concernwith any systematic review (Schlosser et al., 2007). Publication bias is a particular concern; it is possible that the weighted average effect size found here is artificially inflated because studies in which smaller, nonsignificant effect sizes were found were not published. However, several considerations reduce the likelihood of significant publication bias in this study. Three of the 15 studies included

in the final meta-analysiswere, in fact, unpublished work (Greyerbiehl, 1981; Redey-Nagy, 2009; Townsend &Tallal, 1989). In addition, the sustained attention task was not the primary focus of many of the studies found in the literature search. Instead, the task was a component of a larger battery of tests (e.g., Arboleda-Ramírez et al., 2007; Buiza-Navarrete et al., 2007), a subcomponent of a single task (Lum et al., 2007), or an assessment used to predict performance on a separate task of interest (e.g., Dodwell &Bavin, 2008; McArthur &Bishop, 2004). Consequently, the publication status of these articles was unlikely to be driven by the significance of the sustained attention task, or lack thereof.

We also attempted to minimize language bias, as we sought studies published in any language, and source bias, as we searched a variety of databases. However, the possibility of relevant data that was not uncovered by the search must be acknowledged as a limitation.

Conclusions and Implications

We adopted the component theory of attention and selected evidence on a single subtype of attention within this theory to review. On the basis of this review, it appears that deficits in sustained attention are part of the LI profile. The evidence for sustained attention deficits in children with LI affects both clinical practice and research. Clinicians should be aware of the potential for decreased attention to task over time when administering and interpreting assessments of children with LI. Test results obtained from lengthy sessions may be negatively affected by attention skills.

Researchers should also be aware of the potential impact of sustained attention deficits on task performance. Children with LI have been found to demonstrate deficits relative to TD peers on a wide variety of cognitive tasks. The vast majority of these tasks contain a component of sustained attention, in that performance will suffer if task vigilance is not maintained. Thus, the presence of sustained attention deficits among participants with LI raises the possibility that poor task performance in LI groups is driven at least in part by attention. Given the theoretical basis for attention's impact on language learning, the possibility that attention weaknesses make a causal contribution to LI cannot be discounted. The claims that language gains following treatment may be driven in part by improvements in attention also support this possibility.

Results of this review provide a number of additional guidelines for future investigations of sustained attention in children in LI. Specific criteria for excluding children with ADHD should be articulated. Both visual and auditory attention should be investigated in tasks, using nonlinguistic stimuli to decouple basic cognitive functions from language demands. Additional RT data are needed to verify the apparent equivalence of LI and TD children in sustained attention RT; studies in which RT is calculated should include enough target trials to obtain reliable RT means. In addition, statistical calculations in these studies should control for the contribution of participant age, particularly when they include children across a wide and very dynamic period of cognitive development. Finally, it will be essential for future work to consider the skills of children with LI in other areas of attention. This review focused on a small subset of attention in order to facilitate feasibility, but the hypothesis that attention deficits in the LI population extend to other attentional components (such as focus, shift, or encode) remains untested.

Abstract: The objective of the study was to investigate the influence of bimodal stimulation upon hearing ability for speech recognition in the presence of a single competing talker. Speech recognition was measured in 3 listening conditions: hearing aid (HA) alone, cochlear implant (CI) alone, and both devices together (CI + HA). To examine the use of low-frequency cues, the competing masker voice was manipulated with respect to fundamental frequency (F0) and formant frequencies. Twelve implanted adults were included in the study.

Group results revealed only a relatively small benefit of CI + HA compared with the CI alone. A detailed analysis of errors, which was assumed to be an indicator for the release from masking, revealed that this benefit was not attributed to improved target-masker segregation. The variable determined to be responsible for segregating target and masker talkers was a large difference in F0 of the voices. This held true for all CI alone, HA alone, and CI + HA listening conditions. Bimodal hearing improved overall speech recognition of both the target and the masker. No evidence for better target- masker separation with bimodal fitting could be found.

Purpose: The objective of the study was to investigate the influence of bimodal stimulation upon hearing ability for speech recognition in the presence of a single competing talker.
Method: Speech recognition was measured in 3 listening conditions: hearing aid (HA) alone, cochlear implant (CI) alone, and both devices together (CI + HA). To examine the use of low-frequency cues, the competing masker voice was manipulated with respect to fundamental frequency (F0) and formant frequencies. Twelve implanted adults were included in the study.
Results: Group results revealed only a relatively small benefit of CI + HA compared with the CI alone. A detailed analysis of errors, which was assumed to be an indicator for the release from masking, revealed that this benefit was not attributed to improved target-masker segregation. The variable determined to be responsible for segregating target and masker talkers was a large difference in F0 of the voices. This held true for all CI alone, HA alone, and CI + HA listening conditions.
Conclusions: Bimodal hearing improved overall speech recognition of both the target and the masker. No evidence for better target- masker separation with bimodal fitting could be found.
Key Words: bimodal hearing, hearing aid, cochlear implant, informational masking, fundamental frequency, formant frequencies

In many communication settings, people are exposed to speech from multiple concurrent talkers (e.g., in a cocktail party situation). Typically the listener does not need to attend to all talkers but only to one target talker selectively. In this case, the competing talkers are a distraction and prevent the listener from receiving the relevant information from the target talker. Two types of masking are involved in these listening situations and determine the recognition of the target speech signal. Energetic masking (EM) occurs when the spectral energy of a masking signal overlaps with the energy of a target signal so that proportions of the speech signals are inaudible at the periphery of the auditory system (i.e., at the basilar membrane). Informational masking (IM) describes the disturbances that contextual information has on the detection and discrimination of target components in a complex sound. The additional information is irrelevant for the listener and therefore interfering (Leek, Brown, &Dorman, 1991). IM is based on two important effects. The first effect is called stimulus uncertainty and corresponds to the listener's inability to ascertain which elements belong to the target signal and which belong to the masker signal. The second effect is referred to as target-masker similarity, which is related to spectral, temporal, and intensity similarity between target and masker signals. Both effects are interrelated (Durlach et al., 2003).

Normal hearing (NH) people are usually able to segregate concurrent talkers. This ability is based on auditory grouping mechanisms (Bregman, 1990). Brungart (2001) examined the effects of signal-to-noise ratio (SNR) and different masker voices on the perception of a target sentence masked by a single competing talker in NH subjects. The results indicated that performance was enhanced with increasing differences between target and masker, producing a release from IM. Darwin, Brungart, and Simpson (2003) confirmed the results of Brungart and provided more detailed information. They examined the influence of the fundamental frequency (F0) and of the vocal-tract length, influencing formant frequencies (Fn) on the NH subjects' ability to attend to one of two competing speech signals. Differences in F0 produced greater improvements in segregating the competing

talkers than did differences in Fn. The benefit of a joint change of F0 and Fn components exceeded the additive benefit of both speech cues alone. This is referred to as a super-additive effect. However, manipulating F0 or Fn artificially did not improve performance as much as using talkers of different gender with inherently different F0 and Fn components, as found by Brungart.

In contrast to NH subjects, listeners with a cochlear implant (CI) have great difficulties in situations with competing talkers. Stickney, Zeng, Litovsky, and Assmann (2004) measured speech recognition in CI listeners with maskers consisting of a competing sentence. The performance of CI users deteriorated significantly in this condition compared with their performance in quiet. This deterioration in complex listening situations is attributable to the limited spectral, temporal, and intensity resolution available in CIs. Because of these technical restrictions, CI users do not show advantages from temporal or spectral gaps in competing signals to obtain release from masking (Nelson, Jin, Carney, &Nelson, 2003). Because of the reduced spectral information, CI listeners mainly rely on the information of the amplitude envelope of the signals. However, these envelopes are disrupted when introducing competing signals. The information from the amplitude envelope of the speech signal is therefore not reliable; hence, speech recognition is strongly affected by fluctuating maskers (Nelson &Jin, 2004).

Because of the limited resolution of acoustic cues, CI users have only restricted access to the relevant information of low-frequency voice cues, such as F0 and Fn, needed to identify talkers (Vongphoe &Zeng, 2005). Better spectral resolution, especially in the low frequencies, might facilitate the identification and therewith the segregation of competing talkers (Qin &Oxenham, 2006; Turner, Gantz, Vidal, Behrens, &Henry, 2004). As many unilateral CI recipients have residual hearing ability for the low frequencies in the non-implanted ear, the use of acoustic amplification transmitted via a hearing aid (HA) in this ear in combination with the electrical stimulation from the CI ear may be of further benefit. This is referred to as a bimodal fitting. The improvement of hearing performance through bimodal stimulation may be attributed to complementarity of the information provided from both devices. TheHAamplifies and transmits the low frequencies and complements the highfrequency information delivered via the CI contralaterally (Ching, van Wanrooy, &Dillon, 2007).

Listening with both ears is also potentially advantageous, as it may make additional information available through binaural processing, such as binaural redundancy. ForNHpeople, this can lead to an improvement in their speech reception threshold of 1-2 dB. However, for CI users, this effect is inconsistent, with subjects varying in their ability to use binaural redundancy cues (Ching, van Wanrooy, Hill, &Dillon, 2005). Compared with hearing with the CI alone, researchers have demonstrated that the addition of acoustic amplification contralaterally improved speech understanding in quiet (Dooley et al., 1993; Hamzavi, Pok, Gstoettner, &Baumgartner, 2004) and in noisy (Ching, Incerti, &Hill, 2004; Morera et al., 2005) environments as well as sound localization ability (Dunn, Tyler, &Witt, 2005; Tyler et al., 2002).

Zhang, Dorman, and Spahr (2010) determined the minimum amount of low-frequency acoustic information needed to achieve better speech recognition in bimodally fitted CI listeners. The recognition of words in quiet and sentences in noise was evaluated, with the acoustic stimuli presented to the non-implanted ear being either low-pass filtered or unfiltered. Both word recognition in quiet and sentence recognition in noise improved because of the added low-frequency information, even when the acoustic information was limited to a 125-Hz low-passed signal. Therefore, Zhang et al. concluded that the F0 and therewith the improved representation of voicing can account for themajority of the speech recognition benefit.

Similarly, Kong, Stickney, and Zeng (2005) examined how residual low-frequency acoustic hearing in the contralateral non-implanted ear can provide essential information for pitch perception and, in turn, can improve speech perception in CI listeners over the CI-alone condition. They investigated speech recognition in a competing-talker situation for listening with the CI alone, the HA alone, and CI + HA. Although speech was completely unintelligible with the HA alone, the combination of CI and HA showed significantly better results compared with the CI-alone condition, especially in high SNRs above 10 dB. They showed that this

improvement was considerable if the masker was a female talker whose voice pitch and spectral characteristics differed greatly from the male target talker. In general, the beneficial effect of bimodal hearing over CI alone was pronounced when the competing voices differed not only in frequency cues but also in intensity level.

In contrast, a subsequent study of Kong and Carlyon (2007) demonstrated different effects. The authors examined the contribution of F0 and low-frequency phonetic cues to speech recognition in simulated combined acoustic and electric hearing. According to their definition, low-frequency phonetic cues comprise the first formant, formant transitions, and manner and place of articulation of consonants. The combined hearing advantages found in this study persisted at low SNRs below 5 dB when the F0 cue was removed from the acoustic simulation. These advantages disappeared at higher SNRs at 10 dB when F0 cues were preserved but low-frequency phonetic cues were removed. The authors concluded that F0 information was not sufficient to improve speech recognition in the presence of speech maskers but that the low-frequency acoustic stimulus contained information other than F0 that enhanced speech recognition when combined with information in the electrical stimulus. Likewise, Brown and Bacon (2009) examined the contribution of low-frequency speech cues in simulated electric-acoustic hearing. The low-frequency acoustic signal was replaced by a sine wave that was modulated in frequency, in amplitude, or in both. Their results revealed that F0 and the amplitude envelope contributed to better understanding in simulated electric-acoustic stimulation conditions. Nevertheless, the observed benefits were not due to a better segregation.

The above-mentioned studies focus on the effects of real or simulated bimodal hearing when speech maskers are used but do not explicitly address the problem of IM. Using the same sentence in all masker conditions (i.e., Kong et al., 2005) reduces the effect of stimulus uncertainty, whereas using reversed speech as a masker (i.e., Kong &Carlyon, 2007) omits information and reduces the effect of target-masker similarity. Therefore, the contribution of irrelevant information might be small in those cases.

The underlying mechanisms for segregating competing talkers with combined acoustic and electric hearing and the impact of the F0 representation are still a controversial issue. Hence, the present study supplements this discourse by examining the contribution of a contralaterally fitted HA in adult CI users to speech understanding in a situation with one competing talker. Although a single-talker masker is not the masker type producing the most effective IM (Cullington &Zeng 2008), it was used to put particular focus on the adverse effect provided by the masker. Therefore, a detailed analysis of the proportion of response errors caused either by confusion of target and masker signals or substitutions was conducted. Following Brungart (2001), the analysis of different error types is regarded as an important parameter for the assessment of IM.

To evaluate the influence of different voice parameters, the voice of the masker talker was manipulated with respect to F0 and Fn. As such, parameters regarding target-masker similarity and stimulus uncertainty were controlled. To focus on voice pitch and Fn, intensitylevel differences between target andmaskerwere not varied. The rationale behind thismethodwas to assesswhich voice parameters are used to obtain release from IM.

It is hypothesized that bimodal stimulation through bimodal fitting can improve speech understanding for speech against a background with one competing talker compared with the CI-alone condition. This is in part due to the effect of complementarity between the information provided through the two devices as described above (Ching et al., 2007). Furthermore, it is suggested that the additional low-frequency information provided through the HA worn in the contralateral ear enables CI users to better segregate competing talkers, making available cues considered essential for the recognition of individual voice cues (Ching et al., 2007). As a consequence, it is anticipated that target-masker similarity is reduced, yielding release from IM that should be apparent in a lower proportion of confusion errors observed.

Method

Subjects

Subjects were recruited from the Cochlear Implant Centre of the University of Cologne. Twelve postlingually deafened adultCI users-sixwomen and six men, with ages ranging from 18 to 72 years (M= 56 years)-

participated in the study. Table 1 displays demographic information of all CI recipients.
All subjects had residual hearing in the contralateral non-implanted ear and continued wearing their HA on a daily basis afterCI activation. Figure 1 shows their (a) unaided hearing thresholds in the non-implanted ear and (b) their aided hearing thresholds in the non-implanted ear as measured in the free-field for warble tones. Their unaided thresholds in the non-implanted ear showed moderate to profound flat or ski-slope hearing losses for frequencies of 250-4000 Hz. The mean unaided thresholds for all subjects, calculated across frequencies from 250 Hz to 4000 Hz, ranged between 70 and 94 dB HL. In contrast, aided thresholds showed mild to severe hearing loss levels with relative flat configurations across the frequency range up to 1000 Hz. The mean aided thresholds for all subjects, calculated across frequencies from 250 Hz to 4000 Hz, ranged between 41 dB HL and 57 dB HL for the HA ear. Thresholds in the aided CI condition were relatively flat between 30 and 40 dB HL, with two outliers: one at 70 dB HL and one at 15 dB HL for the frequencies 250 Hz and 6000 Hz, respectively. Mean aided thresholds for the CI ear calculated across frequencies from 250 Hz to 6000 Hz ranged between 30 dB HL and 39 dB HL.
For the study, the subjects used their daily settings in their CI and HA without any additional fine-tuning performed prior to testing outside of loudness balancing between the two devices. HAs were previously adjusted by an acoustician according to the recommended procedure described in Ching, Hill, Dillon, and van Wanrooy (2004). To ensure that the CI and HA produced similar loudness percepts, an adaptive categorical loudness scaling procedure was performed (Brand &Hohmann, 2002). Speech-shaped noise with a bandwidth of 85- 5500 Hz with varying intensity across stimuli was presented via loudspeaker. Subjects were asked to estimate the loudness of each stimulus on an 11-point response scale, with categories ranging from inaudible to too loud.
On the basis of their estimations, hearing thresholds and loudness growth could be determined per individual. Differences in hearing thresholds between HA and CI did not exceed 10 dB for any subject. Mean difference across individuals was 4.8 dB. Loudness growth functions of the two devices were comparable. Moreover, loudness scaling revealed that the stimuli used in this study were audible for each subject, as thresholds were observed at least 20 dB lower than the stimulus level.
All subjects achieved a speech understanding of at least 90% in quiet with the CI alone when measured with the Oldenburg Sentence Test (OlSa; Wagener, Brand, &Kollmeier, 1999) at an overall level of 70 dB SPL. This was used as subject inclusion criteria for the study. The study tasks are clinically known to be demanding tests of audition for the CI listeners. To avoid floor effects that would be observed at an SNR of 0 dB for poor to average performers, we only included "good" CI performers with speech recognition scores of 90% or higher in quiet only. Speech understanding in quiet with the HA alone was above 50% at 70 dB SPL in all subjects. Therefore, the patient population was rather different compared with patients participating in other studies.
All subjects gave written consent prior to their participation. The study protocol was in accordance with the Declaration of Helsinki and was approved by the ethics committee of the University of Cologne. Subjects were reimbursed for travel expenses.

Stimuli

The stimuli were derived from the OlSa. This speech material consists of five-word nonsense sentences (name-verb-number-adjective-noun), such as "Stefan [name] sieht [verb] acht [number] nasse [adjective] Sessel [noun]" ("Stefan sees eight wet armchairs"). For each lexical position, 10 possible words exist that are combined at random, yielding a high number of different sentences. Utterances of theOlSawere recordedwith a male speaker. In the competing-talker condition, stimuli consisted of two simultaneous sentences from the OlSa. This sentence test is appropriate to measure tasks with a single competing talker or multiple competing talkers for several reasons: An important advantage in view of IM is that a key word can be defined to indicate the target sentences. On the basis of a preceding study, the key word chosen was "Stefan," which revealed the lowest risk of confusion with the other names (Pyschny, Landwehr, Walger, von Wedel, &Meister, 2009). A further

advantage is that the sentences do not contain additional attributes that allow perceptual streaming, which might be used as an a priori cue to separate the target from the masker. Moreover, predictability of single words in a sentence is very low (Wagener et al., 1999).

The superimposed masker sentences were similar in length to the target sentences but contained randomly selected words other than those used in the respective target sentence. No sentence was used more than once within the test lists. Four different lists with 15 stimuli each were generated for the actual test. Because of the low predictability of the OlSa, it is possible to present test lists repeatedly to the subjects (Wagener et al., 1999). Masker sentences were modified with respect to F0 and Fn using a script (Darwin et al., 2003) based on the signal processing softwarePraat (Boersma&Weenink, 1996). The F0 of the masker was raised by 40 Hz or 80 Hz, whereas the target talker remained at 100 Hz. By shortening the vocal tract length of the masker, Fn were increased by 8% or 16% so that all higher Fn were changed to the same degree. This is based on the average formant-frequency ratio between female and male voices (Peterson &Barney, 1952). Moreover, modifications in F0 and Fn were combined. The smaller difference in F0 (40 Hz) was combined with the smaller difference in Fn (8%), and the greater difference in F0 (80 Hz) was combined with the greater difference in Fn (16%). Because they produced an unnatural ratio of F0 and Fn, the conditions DF0 + DFn = 40 Hz + 16% and DF0 + DFn = 80 Hz + 8% were not used for the masker voice. Masker sentences were not changed with respect to the level, yielding an SNR of 0 dB in all conditions to consider effects only related to F0 or Fn. An implementation of alternative SNRconditions would have introduced another additional acoustic factor that CI recipients may have been able to use to further separate the target from the masker stimuli (Pyschny et al., 2009).

Procedure

Subjects were evaluated under three listening conditions: CI alone, HA alone, and CI + HA together. Pre-testing began with three lists of 10 sentences each presented in quiet at an overall level of 70 dB SPL for the CI-alone and HA-alone conditions. The testing in quiet allowed the subjects to become accustomed to the voice of the target talker. Furthermore, subjects became familiar with the limited word material of the OlSa, whereby learning effects were minimized prior to recording performance scores. Only speech understanding scores for the third list were recorded to represent performance in quiet for each subject. Afterward, a training session with 20 superimposed sentences was conducted to familiarize subjects with the competing-talker condition prior to recording test scores. Subjects used the CI + HA combination in the training session. Feedback about the correctness of their responses was given during training. Sentence pairs used during the training session were not reused for the test session.

In each test run, sentence pairs were preceded with a 1-kHz pure-tone stimulus of 500 ms in duration to draw the subjects' attention to the upcoming stimulus. The presentation order of the stimuli was randomized within every test list. The subjects' task was to reproduce thewords fromthe target sentence indicated by the name "Stefan." The investigator kept track of the subjects' answers and entered them into the computer. All words except the key word subject name "Stefan" were included in the percent-correct score calculation, with a total score possible of 60words for each of the four test lists. The tests included seven different target-masker conditions (DF0 = 40 Hz, 80 Hz; DFn = 8%, 16%; DF0 + DFn = 0 Hz + 0% [unprocessed], 40 Hz + 8%, 80 Hz + 16%). For each condition, two test lists were applied. Thus, 42 measurements (7 target-masker conditions ×2 test lists ×3 listening conditions) were conducted. The measurement conditions were performed in randomized order to minimize bias from sequence of testing or learning effects. The sequence of hearing devices was randomized too. Two test lists were measured with one hearing device condition before switching the hearing device to avoid permanent alternating.

All tests were performed in a soundproofed booth (2.9 m ×4 m) via a single loudspeaker (Event Electronics, 20/20bas V2) placed in front of the subject at a distance of 1.2 m. The combined signals were presented at an overall level of 70 dB SPL measured at the subject's head. Testing was split into two sessions that took place within 1 week. Each session lasted approximately 3 hr, including individual breaks.

Analysis

Having different masker sentences for each target sentence allows analyzing different effects. Basically, there are two main types of errors that can appear in a listening situation with two simultaneous talkers. On the one hand, errors result from a confusion of target and masker words-for example, "Stefan sieht acht nasse Sessel," and "Britta kauftneun grobe Autos," resulting in "Stefan sieht acht nasse Autos" ("Autos" instead of "Sessel")-which are referred to as A-type errors. On the other hand, there are non-confusions that are either close acoustic approximations to the target words ("Messer" instead of "Sessel") or errors of omission (e.g., the subject said nothing or "I don't know"), which are referred to as B-type errors. The amount of A-type errors is an indication of the ability to separate target from masker and addresses IM in terms of both target-masker similarity and stimulus uncertainty (Brungart, 2001). In contrast, B-type errors also occur when noise is used as a masker and may therefore relate more to EM effects or signal degradations (Brungart, 2001). Statistical analysis was conducted with the SPSS statistical analysis program PASW 18. Target speech recognition and the two types of errors were expressed as percentage of correct and incorrect responses, respectively. Data were arcsine transformed, and one-way analyses of variance (ANOVAs) with repeated measures were conducted for the hearing devices (CI,HA, and CI +HA) and for the different target-masker conditions (ΔF0, ΔFn, and ΔF0 + ΔFn). Wilks' lambda was used as global test statistic. Further multiplepaired comparisons were performed. The p values were Bonferroni adjusted (significance level = .05/3 = .017). The experimental design was not multifactorial, as two target-masker conditions were discarded (ΔF0 + ΔFn = 40 Hz 16%, and ΔF0 + ΔFn = 80 Hz 8%). Thus, a multifactor ANOVA was not feasible.

Results

Target Speech

Figures 2A-2C show mean scores (%) of the 12 CI recipients for speech recognition as a function of HA alone, CI alone, and CI + HA at an SNR of 0 dB. Panel A shows scores for differences in F0 of target and masker. Panel B shows scores for target and masker differing in Fn. Panel C shows scores for DF0 + DFn. Error bars represent ±1 SD from the mean. For better comparison, the unprocessed condition is displayed in all panels. For hearing devices, Figures 2A-2C display that with the HA alone, subjects achieved speech recognition scores across the different target-masker conditions withmean values ranging from22%to 33%and relatively large standard deviations ranging between 14%and 26%. This large standard deviation is due to the fact that three subjects were not able to understand target speech with their HA alone in the competing-talker condition. In contrast, using CI +HA, as well as using the CI alone, yielded higher recognition of the target sentences. The largest bimodal benefit (12% for the mean) over the CI alone was measured in the DF0 = 80 Hz condition (see Figure 2A). Collapsed across subjects and all target- masker conditions, the mean difference between performance with the CI alone and CI + HA was only 6%. Nevertheless, the data suggest that the observed bimodal benefit increases with increasing differences in F0 (40Hz, 80 Hz in Figure 2A) and in F0 + Fn = 80 Hz + 16% (see Figure 2C). Interestingly, applying differences in Fn in the masker had the tendency to reduce recognition of the target speech, especially in the CI-alone condition.

Looking at the individual results (see Appendix A) revealed that speech recognition varied across subjects in all listening conditions. Although in the HA-alone condition three subjects demonstrated 0% intelligibility (S 02, S 05, and S 07), a bimodal benefit over the CI alone was measured for two of these subjects (S 05 and S 07). Two subjects (S 03 and S 09) revealed very good speech recognition ability in the HA-alone condition that partly exceeded speech recognition with the CI alone. Their results with CI + HA were not better than with the HA alone. The remaining subjects showed similar results for both devices alone or showed better results with CI alone compared with HA alone. Those subjects revealed better results for CI + HA predominantly in the situations with large differences in F0 between target and masker. Although a uniform pattern could not be observed, all subjects showed similar trends in performance, resulting in a significant effect for the group mean performance differences that were discussed above. It is important to note that our subjects were not typical CI

users.

Statistical data are shown in AppendicesBand C. In Appendix C, only statically significant values are shown. As the main focus of the hearing device conditions is on the comparison of CI alone versus CI + HA, those results are described in detail. Results for the different target- masker conditions are also described in detail only for CI alone and CI +HA. Comparisons of the target-masker conditions were only done within each voice parameter-for example, ΔF0 = 40 Hz versus 80 Hz-and not across voice parameters-for example, ΔF0 = 40 Hz versus ΔFn = 8%.

Statistical data showed that performance was significantly superior with CI + HA compared with CI alone in the following test conditions: DF0 (40 Hz, 80 Hz) and ΔF0 + ΔFn = 80 Hz + 16% (see Appendix B). Modifications of the masker voice presented a significant effect of F0 on speech recognition for both the CI alone and CI + HA. Scores increased when F0 of the masker was changed by 40 Hz or 80 Hz. Applying differences in Fn in the masker (see Figure 2B) had the tendency to reduce recognition of the target speech in the CI-alone condition. The combination of differences in both F0 + Fn, displayed in Figure 2C, revealed a significant effect only for listening in the bimodal condition for F0 + Fn = 40 Hz + 8% compared with the unprocessed condition (see Appendix C).

Error Patterns

Figures 3A-3C show the mean distribution of the listeners' confusion errors (A-type errors) in percentages as a function of HA alone, CI alone, and CI + HA for the different target-masker conditions: DF0 (Panel A), DFn (Panel B), and DF0 + DFn (Panel C). Figures 4A-4C display the mean distribution of the listeners' non-confusion errors (B-type errors) in percentages as a function of HA alone, CI alone, and CI + HA for the different target- masker conditions: DF0 (Panel A), DFn (Panel B), and DF0 + DFn (Panel C). Error bars represent ±1 SD from the mean. For better comparison, the unprocessed condition is displayed in all panels.

Across all target-masker conditions, listening with the HA alone produced very high B-type errors approximating 60% (see Figures 4A-4C). In contrast, the proportion of A-type errors (see Figures 3A-3C) remained small across the various target-masker conditions. A-type errors were considerably larger when using the CI alone or CI + HA. In these two hearing device listening conditions, the amount of A-type errors differed considerably across the various target-masker conditions. Unlike A-type errors, the proportion of B-type errors was rather stable across the various target-masker conditions but was consistently lower for the CI + HAlistening condition than for the CI-alone condition.

A-type errors. Significant effects for A-type errors between the CI alone and CI + HA were found only in the unprocessed condition (see Appendix B). Changing the masker voice in F0 significantly affected A-type errors in all three hearing device conditions. The DFn induced an increase of A-type errors for the CI alone, especially in the ΔFn = 16% condition. The combination of ΔF0 + ΔFn had a significant impact on the amount of A-type errors only in the CI + HA listening condition, as can be seen in Appendix C.

B-type errors. Between the hearing devices CI alone and CI + HA, a significant effect appeared only in the ΔF0 = 80 Hz test condition (see Appendix B). There were no significant differences between target-masker conditions for B-type errors (see Appendix C).

In summary, significant differences in target speech recognition scores between CI-alone and CI + HA listening conditionswere observed for the testmaterial condition with differences in F0 and great differences in F0 + Fn. No significant differences in A-type errors were observed. In contrast, B-type errors were significantly different between the CI-alone and CI + HA listening conditions when changing F0 to a great amount.

In view of the effect of manipulations in the masker voice, the insertion of differences in the F0 between talkers yielded higher speech recognition scores as well as significant reductions of A-type errors in the CI-alone and CI + HA listening conditions. Large modifications in Fn of the masker speech reduced scores, especially in the CI-alone listening conditions.

Discussion

The aim of the present study was to investigate the influence of bimodal hearing on speech perception with a single competing talker applying various modifications to select acoustic cues. Special focus was on the contribution of IM and on the benefit that can be drawn from the acoustic information provided through the HA to assist the listener to separate competing talkers. It was hypothesized that the addition of theHA leads to improved speech understanding and to an improved ability to segregate two competing talkers auditorily. Therefore, in examination of the results, an analysis of the type of errors was performed. To further explore which of the low-frequency cues in voices help to separate target and masker signals predominantly, sentences with isolated manipulations of F0 and Fn components were superimposed.

The results revealed that understanding of the target talker tends to improve in the CI + HA listening condition compared with the CI-alone condition. However, the effect of the additional information provided through the HAwas relatively small, reaching statistical significance in the test conditions with manipulations in ΔF0 and with large modifications in ΔF0 + ΔFn only.

Kong et al. (2005) reported a significant superadditive effect of CI + HA in bimodally fitted subjects. The HA-alone condition led to 0% speech recognition, whereas the combination of CI + HA significantly improved performance over the CI alone. Nonetheless, this suggested an additive benefit of the HA when used in combination with the CI. Such a super-additive effect could only be observed in two of our subjects. Those two subjects did not understand anything in the competingtalker situation with the HA alone. The remaining patient population differed from those described in the former articles by understanding at least parts of the sentences in the competing-talker situation with the HA alone. Therefore, a comparison with the literature should be treated with caution. Nevertheless, the ability to understand speech with the HA could be an explanation for the missing super-additive effect.

Turner et al. (2004) reported similar results as Kong et al. (2005). They investigated people receiving electric-acoustic stimulation in the same ear, who are likely to benefit from the same mechanisms as people with bimodal fitting in which two ears are involved. However, improved performance was observed only when target and masker signals differed in frequency characteristics and in intensity level. In Kong et al.'s study, the largest benefits observed when using CI + HA were found for high SNRs, but differences markedly decreased for SNR = 0 dB, which is in line with our results.

Kong et al. (2005) proposed that the observed improvement in target recognition in the CI + HA listening condition compared with the CI-alone condition was attributed to an enhanced ability to separate target and masker signals. However, in their study, target-masker similarity was low, as the same masker sentence-which was well-known to the subjects-was used throughout testing. Therefore, confusion between target and masker was unlikely. Thus, it is not clear whether the improvement was exclusively due to a better ability to separate the two competing signals.

In the present study, no evidence for better target- masker separation with bimodal fitting was found. This was evaluated with an analysis of response errors. A-type errors are an indication for difficulties in separating target and masker voices, whereas B-type errors are an indication for the overall speech recognition, including target and masker (Brungart, 2001). If the combination CI + HA had yielded more release from IM than the CI alone, a lesser amount of A-type errors would have demonstrated that the HA helped subjects to separate the competing talkers. A better segregation should yield better target word understanding because of lower stimulus uncertainty. However, this was not observed; accordingly, a release from IM was not the effect by which scores of CI + HAwere improved over CI-alone scores.

In contrast, a lesser amount of B-type errors without a decrease in A-type errors would have indicated that the HA helped to improve overall recognition but not the ability to separate. This might be an explanation for the finding that the A-type errors even increased slightly with CI + HA in some conditions: If speech recognition increases in general, and it is not possible to separate target from masker signals (as with 0 Hz + 0%), the amount of confusions will increase as a consequence. This might be more related to EM than to IM. It was

observed that the amount of B-type errors for the CI + HA listening condition compared with the CI-alone condition was lower in all test material conditions and reached significance in the DF0 condition of 80 Hz. This could be explained by the fact that an HA provides more low-frequency information than a CI (Cullington& Zeng, 2011). Providing voice-pitch information transmitted via the HA complements the higher frequencies delivered via the CI. Because of voice pitch, the access to voiced and voiceless information in the speech signal is improved. This can be used by the listener to improve speech recognition of the target talker. This explanation is based on the findings of other studies, which showed that even unintelligible low-frequency sound improved performance when frequencies were limitedly transmitted below 150 Hz (Cullington &Zeng, 2010).

Another explanation for the decrease in B-type errors and therewith the increase in speech recognition could account for complementary speech information. Mok, Grayden, Dowell, and Lawrence (2006) tried to determine speech information obtained from an HA that is additive to the speech information of the CI. Adding the HA to the CI improved the perception of lower frequency phoneme groups, such as diphthongs, semivowels, and nasals. The auditory system seemed to be able to combine the speech information coming from the two different hearing devices. With this explanation in mind, the decrease in B-type errors in our study would be rather due to a phonemic summation (eventually because the resolution of the first formant might be improved by the additional HA) than a release from EM.

Generally, the finding that the amount of B-type errors decreased in the CI + HA condition compared with the CI-alone condition suggests an advantage associated with binaural redundancy and summation. The only factor that reduced the amount of A-type errors observed in our study was the difference in F0. A difference of 80 Hz between the target and masker signals led to a significant decrease in the A-type errors observed. This held true for all three listening conditions (CI alone, HA alone, and CI + HA), supporting the assumption that subjects have the ability to separate competing talkers when presenting large differences in F0 even with the CI alone. It could be expected that A-type errors would have emerged more clearly if overall there were less potential for B-type errors, for example, with more favorable SNRs. However, results of a former study (Pyschny et al., 2009), which investigated the effect of SNR in speech recognition situations with a competing talker, did not support this assumption.

Nevertheless, it has to be kept in mind that for both CI and HA users, overall EM has a greater detrimental effect on speech recognition even for much better SNRs (Qin &Oxenham, 2003). This might be due to the restricted access to relevant speech information in CIs.

Although the beneficial effect of F0 differences in the separation of target and masker could be anticipated, the findings regarding modifications of Fn were unexpected. Kong et al. (2005) showed a beneficial effect for the CI + HA listening condition, especially when the male target talkerwas superimposed by a femalemasker. In this condition, the difference regarding F0 and Fn was considerably large. Applying these findings to our manipulations of these voice cues, we would have expected that the combination of DF0 and DFn should have led to an even bigger improvement compared with changes in either F0 or Fn alone. However, the present study does not support this claim.

In contrast, changing Fn of the masker signal alone even had a negative influence on target word recognition in the CI-alone listening condition. The effect was found only when the difference in Fn was expanded by 16%. No such effect appeared when the difference in Fn was expanded by 8%. Darwin et al. (2003) found that small changes in Fn (8% or less) did not improve speech recognition in NH listeners. The authors assumed that the difference in Fn of 8% might be too small to perceive as a change in the talkers' identity. Because of the restricted representation of spectral speech cues in CIs, this holds true for our experiment.

Changing Fn did not reduce speech recognition in the CI + HA condition. Again, this could be explained because of the effect of phonemic summation. Additive complementary speech cues, transmitted via the HA, were missing, and the target was not recognized correctly with the CI alone.

Furthermore, the degraded speech recognition with large difference in Fn might be related to findings of

Cullington and Zeng (2008), who used child voices as a masker signal. They investigated speech recognition of CI users with varying numbers and types of competing talkers. CI users benefited from voice pitch differences between target and masker signals, with female talkers providing significantly less masking than male talkers. However, child talkers produced more IM than the other talkers, although their voice pitch was much higher than that of the female talker. Cullington and Zeng tried to determine the cues that could cause this high masking effect-such as talking rate, variation in F0 within a sentence, and temporal envelope modulation characteristics-but no correlation could be found. Child voices exhibit not only higher F0s but also higher Fn. Changing Fn only while keeping F0 constant makes a voice more "childlike." The results of the present study suggest that compared with the unprocessed condition, IM even increased when only the Fn were changed, whereas changing only the F0 yielded a release from masking. Hence, an explanation for the higher IM produced by the child talker in Cullington and Zeng's study could be due to their higher Fn.

Changing only Fn makes the voice also sound somewhat unnatural and draws the listener's attention to the masker's voice,which is referred to as odd-sex distraction (Brungart, Simpson, Ericson, &Scott, 2001). Odd-sex distraction is a special form of IM in which a prominent masker causes the listener's attention to be drawn away from the target. This occurs only when the overall levels of the talkers are nearly equal so that the listener must rely entirely on vocal characteristics. However, odd-sex distraction cannot entirely explain why speech understanding for CI as well as for CI + HA listening conditions for signals presented with differences in both F0 + Fn components remains poorer than speech understanding in the presence of a competing signal with a 80-Hz difference in the F0 alone (see Figure 1). The combinedmanipulation ofF0 andFn corresponds most closely to a change from a male voice to a female voice. Stimuli do not sound unnatural when the configuration of the changes in F0 and in Fn matches (Darwin et al., 2003), as is the case in our study.

The F0 contributed significantly to a release from masking in all three listening conditions, as shown in the analysis of the A-type errors. However, no significant advantage could be shown for the CI +HAcondition over the CI-alone condition, as separation of the talkers is obviously possible to a certain degree with the CI alone. Adding the HA does not significantly reduce the A-type errors observed.

Kong and Carlyon (2007) tried to answer the question of which low-frequency cues are responsible for the combined hearing advantages with simulations of CI processing and low-frequency hearing. They found that information of the low-frequency region like voicing and information of the amplitude envelope provided benefit in combined hearing. They suggested that the amplitude envelope might help listeners by indicating when to listen or "glimpse" the target. Hence, glimpsing might at least partly explain the effects of F0 if it is assumed that the F0 might provide an indication of when to listen, much like that provided by the amplitude envelope.

Li and Loizou (2008) examined glimpsing in the context of combined acoustic and electric hearing. They pointed out an effect that is related to a low-frequency SNR advantage when speech is corrupted by interferers with low-pass spectral characteristics as competing talkers. During voiced speech segments of the target, the masker reveals on average a lower level in low-frequency bands than in the high-frequency range. According to the authors, this holds especially true if target and masker differ greatly. This resembles the results found for the F0 difference of 80 Hz between target and masker in our study. They explained that F0 cues might be helpful in combined acoustic and electric hearing to indicate when to listen into the dips and thus detect male and female talkers in a competing-talker situation. The mechanisms of glimpsing might be an important aspect of improving speech recognition with a bimodal fitting. However, it is not entirely clear how far glimpsing and segregation are related. Brown and Bacon (2009) stated that both F0 and envelope cues might provide an indication when to listen into dips. This would assume that the listeners first have to segregate target and masker on the basis of F0, which is not supported by our results. Thus, further examinations designed to address this issue might be necessary.

In conclusion, the effects of low-frequency acoustic hearing with HA complementing the high-frequency information provided via CI were small in our study, as well as the effects of changing the F0 or the Fn of the

masker. This might be in part due to the fact that most of our subjects were good HA-alone performers.
The assumption that bimodal hearing yields better separation of target and masker and thus reduces effects relevant with IM could not be proven. A large difference in F0 (i.e., 80 Hz) between target and masker was the only parameter for decreasing the A-type errors, but this applied similarly for both the CI and CI + HA listening conditions. Adding changes in Fn even increased the probability of mixing up words from target and masker signals. A consistent, albeit nonsignificant, effect of the HAwas that the amount of B-type errors was reduced for the CI + HA condition compared with the CI-alone condition. This might be an effect of complementary speech information or, according to Brungart (2001), rather a release from EM. In the present study, however, adding the HA is not the mechanism responsible for a release from IM.

Acknowledgments
This research was supported by Cochlear Deutschland GmbH &Co. KG. (See Pyschny, Landwehr,Walger, vonWedel, and Meister [2008] for the presentation of this project at the German Society of Audiology conference [June 2008]). We thank the cochlear implant subjects for their time and dedication. We also thank H. Cullington for providing valuable comments. Finally, we thank Guy Lightfoot and Josephine Wyss for proofreading the article.

Visual Cues and Listening Effort: Individual Variability

Author: Picou, Erin M; Ricketts, Todd A; Hornsby, Benjamin W Y

Publication info: Journal of Speech, Language and Hearing Research (Online) 54.5 (Oct 2011): 1416-1430.

Abstract: To investigate the effect of visual cues on listening effort as well as whether predictive variables such as working memory capacity (WMC) and lipreading ability affect the magnitude of listening effort. Twenty participantswith normal hearingwere tested using a paired-associates recall task in 2 conditions (quiet and noise) and 2 presentation modalities (audio only [AO] and auditory-visual [AV]). Signal-to-noise ratios were adjusted to provide matched speech recognition across audio-only and AV noise conditions. Also measured were subjective perceptions of listening effort and 2 predictive variables: (a) lipreading ability and (b) WMC. Objective and subjective results indicated that listening effort increased in the presence of noise, but on average the addition of visual cues did not significantly affect the magnitude of listening effort. Although there was substantial individual variability, on average participants who were better lipreaders or had larger WMCs demonstrated reduced listening effort in noise in AV conditions. Overall, the results support the hypothesis that integrating auditory and visual cues requires cognitive resources in some participants. The data indicate that low lipreading ability or low WMC is associated with relatively effortful integration of auditory and visual information in noise.

Purpose: To investigate the effect of visual cues on listening effort as well as whether predictive variables such as working memory capacity (WMC) and lipreading ability affect the magnitude of listening effort.
Method: Twenty participantswith normal hearingwere tested using a paired-associates recall task in 2 conditions (quiet and noise) and 2 presentation modalities (audio only [AO] and auditory-visual [AV]). Signal-to-noise ratios were adjusted to provide matched speech recognition across audio-only and AV noise conditions. Also measured were subjective perceptions of listening effort and 2 predictive variables: (a) lipreading ability and (b) WMC.
Results: Objective and subjective results indicated that listening effort increased in the presence of noise, but on average the addition of visual cues did not significantly affect the magnitude of listening effort. Although there was substantial individual variability, on average participants who were better lipreaders or had larger WMCs demonstrated reduced listening effort in noise in AV conditions.
Conclusions: Overall, the results support the hypothesis that integrating auditory and visual cues requires cognitive resources in some participants. The data indicate that low lipreading ability or low WMC is associated with relatively effortful integration of auditory and visual information in noise.
Key Words: listening effort, vision, background noise

Speech recognition is important for verbal communication in everyday life. Recognizing spoken words is a complicated task that relies on bottom-up, datadriven processing of the acoustic features of speech (e.g., Foss &Blank, 1980) and top-down, conceptually driven processing of the meaning and context of the stimuli (e.g., McClelland&Elman, 1986; Samuel, 1996). Indeed, both processes are thought to coexist, likely functioning in parallel (Dell &Newman, 1980; Newman &Dell, 1978; Tyler, Voice, &Moss, 2000). As a result of this set of intertwined and sometimes redundant processes, adequate speech recognition is commonly maintained even when the acoustic signal is degraded, as in the case when a listener is in background noise; however, perceptual success in challenging environments may come at the expense of increased demand on cognitive resources. This is important because increased demand may leave fewer cognitive resources available for interpreting, integrating, or responding to information during a conversation. Listeners may have substantial difficulty remembering information presented earlier in a conversation or learning new information. In addition, over time, depleted cognitive resources may lead to increased mental fatigue.

Listening Effort

The cognitive resources allocated for speech recognition are often conceptualized as listening effort (Fraser, Gagne, Alepins, &Dubois, 2010; Hicks &Tharpe, 2002). As cognitive demands increase, so too does listening

effort. Because cognitive capacity is limited (Kahneman, 1973), an increased demand level means that fewer resources are available for tasks such as rehearsal, recall, environmental monitoring, or following conversations (Kahneman, 1973; Kantowitz, 1974; Moray, 1967).

The ease of language understanding (ELU) model (Rönnberg, 2003; Rönnberg, Rudner, Foo, &Lunner, 2008) provides a conceptual framework for understanding listening effort. The model suggests that language serves as the input to a listener's memory buffer, which rapidly and automatically binds phonological, semantic, syntactic, and prosodic information. This bound information forms a mental representation of language and is then compared with long-term memory stores. If the language representation matches information in long-term memory, the listener can successfully and easily perceive the language input. Conversely, if there is a mismatch between the mental language representation and long-term memory, a listener must exert explicit processing to achieve understanding. In other words, working memory resources must be allocated to successfully perceive a message if the input is degraded in some way and thus does not match information stored in long-term memory. Thus,within the context of the ELUmodel, listening effort is the increase in cognitive resources necessary to resolve ambiguity between the language mental representation and the long-term memory store of a listener.

Listening effort can be measured objectively and subjectively. The underlying rationales for the objective measures are that, as listening effort increases, more cognitive resources are necessary for a listener to recognize speech. Because these resources must be devoted to speech recognition, there are fewer available for rehearsal or recall of items in a list or for responding to a secondary task. Listening effort has been measured objectively by fewer words recalled (McCoy et al., 2005; Murphy, Craik, Li, &Schneider, 2000; Rabbitt, 1968; Tun, McCoy, &Wingfield, 2009), fewer details remembered about a passage (Schneider, Daneman, Murphy, &See, 2000), and by decreased performance (Fraser et al., 2010;Rakerd, Seitz,&Whearty, 1996;Tun et al., 2009) or slowed reaction times on a secondary task (Hicks &Tharpe, 2002; Tun et al., 2009). Furthermore, because the pupils become more dilated under conditions of increased cognitive demand, listening effort also has been measured by assessing pupil dilation (Engelhardt, Ferreira, &Patsenko, 2009; Kramer, Kapteyn, Festen, &Kuik, 1997; Piquado, Isaacowitz, &Wingfield, 2010; Zekveld, Kramer, &Festen, 2010). Listening effort can be quantified subjectively by asking people their subjective impressions about the degree to which they exerted effort or work to understand speech (Gatehouse&Noble, 2004; Kramer, Kapteyn,&Houtgast, 2006). Although all of these methods purport to measure the same underlying construct, the relationship between the indices has not been fully investigated; that is, listening effort may be reflected by varying degrees according to the test methodology used because differences between methodologies remain unclear.

Despite these differences in methodologies, there is some consistency across studies of listening effort; specifically, with changes in background noise level, speech recognition performance and listening effort have both been shown to change. For example, when speech recognition performance gets worse, listening effort increases, as evidenced by fewer words recalled (Murphy et al., 2000), increased pupil dilation (Zekveld et al., 2010), and increased reaction times on a secondary task (Downs, 1982). However, listening effort is not always tied to speech recognition. In cases where speech recognition performance was relatively unaffected by changes in background noise (e.g., speech recognition performance is around 80%-100%), some investigators have reported that listening effort also increased (Fraser et al., 2010; Pichora-Fuller, Schneider, &Daneman, 1995; Rabbitt, 1968; Surprenant, 1999). For example, Surprenant (1999) reported that listeners recalled fewer words as the signal-to-noise ratio (SNR) worsened from quiet to +10 dB and then again to +5 dB, but speech recognition performance was not affected by the changes in background noise. Therefore, measuring listening effort, in addition to speech recognition performance, is important when investigating the effects of background noise on a listener.

Role of Vision

Until recently, listening effort had been measured only for auditory-only (AO) stimuli; in other words, situations in

which listeners are unable to see the talker's face. Although the underlying mechanisms for AO presentations are becoming better understood, it is important to examine listening effort for signals that provide auditory and visual cues. Most listeners use visual information when communicating in daily life, and speech recognition in auditory-visual (AV) conditions has been shown to be significantly better than performance in AO conditions. This visual benefit is particularly important in difficult listening situations and for listeners with impaired hearing. The addition of visual cues improves speech recognition performance over a wide range of SNRs (Erber, 1975; Grant, Walden, &Seitz, 1998; O'Neill, 1954; Sumby &Pollack, 1954), showing maximum AV benefits of 30% to 40% at intermediate SNRs (Ma, Zhou, Ross, Foxe, &Parra, 2009; Ross, Saint-Amour, Leavitt, Javitt,&Foxe, 2007). Furthermore, visual cues can improve one's speech recognition threshold (the level required for 50% correct speech recognition) by approximately 4 to 6 dB (MacLeod&Summerfield, 1990; Middelweerd &Plomp, 1987); however, only limited data are available regarding the effect of visual cues on listening effort.

There are several possible factors that lead to speech recognition benefit from the addition of visual cues. These include redundancy, complementary cues, enhanced detection, and focused attention. In listening situations when the auditory signal is audible (e.g., in quiet for listeners with normal hearing), the auditory and visual cues available provide redundant speech language information. Although this redundancy leads to only small improvements in speech recognition (Grant et al., 1998), there may a cognitive advantage resulting from the addition of redundant visual information. For example, Reisberg, McLean, and Goldfield (1987) tested the ability of listeners with normal hearing to shadow (repeat aloud) English sentences and found that, for grammatically complex sentences, visual cues improved the ability to shadow the sentences. Furthermore, foreign language students' abilities to shadow a native speaker of the language were improved when visual cues were provided (Reisberg et al., 1987). These results suggest that the addition of redundant visual cues from the talker's face may reduce listening effort and allow listeners to perform better on a cognitively demanding task. Although there is no direct evidence to support this hypothesis, electrophysiological data suggest that, in quiet, response latencies are shorter for AV signals than for AO signals (vanWassenhove, Grant,&Poeppel, 2005), implying that visual cues may speed processing. If cognitive processing is quicker, cognitive demands might be less and listening effort may be reduced in quiet with visual cues present.

Once noise is introduced, however, the additional visual cues may become less redundant with the auditory signal and become more complementary. A listener can take advantage of both the auditory and visual signals, which work in tandem to provide information for speech recognition. For example, place-of-articulation cues can be conveyed accurately by means of lipreading (Sumby& Pollack, 1954) but are easily disrupted auditorily by noise (Miller &Nicely, 1955). Furthermore, voicing and nasality cues are acoustically robust (Binnie, Montgomery, &Jackson, 1974; Miller &Nicely, 1955) but are nearly impossible to distinguish visually (Walden, Prosek, &Worthington, 1974). Therefore, we hypothesized that additional listening effort may be required for AV conditions if listeners are forced to integrate complementary information from two sensory modalities.

Another factor contributing to enhanced speech recognition in noise with the presence of visual cues is enhanced speech detection. In noise, when the acoustic information and visual information are coincident, speech detection thresholds are 1 to 2.5 dB better than when only the acoustic information is present or when the acoustic and visual information are incongruent (Grant, 2001; Spence, Ranson, &Driver, 2000). This effect in the speech domain is similar to the cuing effect in the psychoacoustic literature reported for simple stimuli (e.g.,Watson& Nichols, 1976). The primary utility of enhanced speech detection is for perception of voicing cues. Although voicing cues are acoustically robust (Binnie et al., 1974), as the SNR worsens, voicing cues become difficult to distinguish by means of audition alone. The presence of visual cues allows for enhanced speech detection by providing spectro-temporal information to the listener, who is then cued to attend to the voicing information (Schwartz, Berthommier, &Savariaux, 2004). As the SNR worsens, if listeners must utilize this information while at the same time integrating information from two sensory modalities, it is possible that the addition of visual cues will require an increase in listening effort in noisy situations.

The final factor contributing to AV benefit, focused attention, may have a positive effect on listening effort in noise by reducing the required extra effort as compared with the previously discussed factors. Focused attention may help in two ways: (a) by improving detection and (b) by improving the ability to ignore distracters. In terms of detection, visual cuing can improve target detection by reducing uncertainty in a signal (Egan, Greenberg, &Schulman, 1961; Egan, Schulman,&Greenberg, 1961; Green &McKeown, 2001; Hubner &Hafter, 1995). Adding visual cues to an auditory signal can also focus one's attention to help ignore distracters (Spence et al., 2000) by providing the illusion of spatial separation (Driver, 1996). It is well known that spatial separation enhances speech recognition (Broadbent, 1958; Cherry, 1953; Spieth, Curtis, &Webster, 1954). Spence et al. (2000) presented target words behind listeners and distracting words in front of listeners at 38° from midline. When the talker's face was presented in the same location as the distracting words, listeners had more difficulty shadowing the target speech. This result suggests that visual cues draw attention to the distracting words and away from the target words. In an extension of this finding, one might expect that providing visual cues that are coincident with a relevant message could focus attention on the relevant message and help listeners ignore distracting signals. Therefore, one might also expect that providing visual cues in the presence of background noise would reduce listening effort by reducing the cognitive demand of segregating target speech from background noise.

In summary, two plausible yet contrasting hypotheses may be proposed in relation to the addition of visual cues and cognitive resources in noise. AV presentation in noise may reduce one's listening effort by focusing attention on the target and helping to segregate the target speech and background noise; conversely, integrating complementary audio and visual cues may require additional listening effort at poor SNRs. There currently are converging lines of evidence to support the second hypothesis, at least in the presence of background noise. First, the authors Larsby, Hallgren, Lyxell, and Arlinger (2005) found that, while listening in noise, participants performed better on several cognitive tasks when visual cues were available. However, reaction times for these tasks were slower inAV conditions than inAOconditions, suggesting that although visual cues helped improve performance, processing the additional visual information required additional cognitive resources. These findings suggest that simultaneously processing auditory and visual cues requires additional cognitive resources. Second, research on audiovisual integration using the McGurk illusion (McGurk &MacDonald, 1976) suggests that attentional resources are necessary to bind multisensory features (Alsius, Navarra, Campbell, &Soto- Faraco, 2005). Finally, and more directly, Fraser et al. (2010) tested listening effort using a dual-task paradigm in noise usingAVandAOstimuli. Their results indicated that, for a fixed speech recognition performance level,AV stimuli resulted in greater listening effort. Furthermore, for a fixed SNR, AV stimuli resulted in better speech recognition than AO stimuli, but listening effort was the same across stimuli. In total, these results suggest that simultaneously processing auditory and visual stimuli in noise requires cognitive resources.

Studies to date have examined main effects for groups of participants; however, the impact of visual cues on listening effort may be different for different individuals. Specifically, an individual's working memory capacity (WMC) or lipreading abilities may affect the listening effort required when processing AV speech information. Several researchers have reported that individual differences in WMC can account for variability in reading comprehension (Turner &Engle, 1989) and the ability to ignore distracters (Conway, Cowan,&Bunting, 2001; Thompson, Garcia, &Malloy, 2007). Likewise, WMC may be related to a listener's susceptibility to the presence of noise in a recall task or to the ability to utilize visual cues to reduce listening effort.

Furthermore, there is substantial intersubject variability in lipreading benefit in untrained listeners, especially in adverse listening conditions (Erber, 1969, 1975; Rigo, 1986). For some listeners, lipreading may be easier or more automatic, and automatic processes are thought to require fewer cognitive resources (Hasher &Zacks, 1979). Listeners who have better lipreading ability may require fewer cognitive resources to integrate audio and visual stimuli, perhaps resulting in reduced listening effort; conversely, listeners for whom lipreading is more

difficult will likely require more cognitive resources to integrate audio and visual stimuli in order to perceive a coherent message. Indeed, previous research suggests that individuals who derive more benefit from vision on a speech recognition task are less susceptible to speech recognition decrements experienced with the addition of a secondary task (Rigo, 1986).

The purpose of this study was to investigate whether factors such asWMCand lipreading ability could be used to predict the effect that the addition of visual cues has on listening effort in individual listeners with normal hearing in quiet and in noise.

Method

To test listening effort, we used objective and subjective measures. The objective measure was a pairedassociates recall task, based on a paradigm developed by Madigan and McCabe (1971) and applied by Murphy et al. (2000) and Heinrich, Schneider, and Craik (2008). In this paradigm, a participant is presented with a list of five pairs of words sequentially, with a few seconds between each word pair. Immediately after presentation of a list, a participant is presented with the first word (probe) of one of the five pairs. The participant's task is to recall the word that was paired with the probe word. When performance across many trials is plotted as function of serial position, the results follow a pattern similar to a typical serial position curve, with the most recent words easier to recall and the first words more difficult (Heinrich et al., 2008; Madigan &McCabe, 1971; Murphy et al., 2000). The task is an objective measure of listening effort because, as listening effort increases, fewer resources are available for rehearsal and recall of words. The first three serial positions are the most sensitive to changes in cognitive demands because they were presented earlier and are thus more difficult to recall, whereas the last two serial positions are easier to recall and less reflective of listening effort (Heinrich et al., 2008; Murphy et al., 2000). As a subjective measure, we asked participants in this study to rate their perceived listening effort after each trial.

Participants

Twenty participants with normal hearing (<25 dB HL at audiometric frequencies 250-8000 Hz) ages 19 to 44 years (M = 27.9) took part in this study. Participants reported no history of otologic or neurological disease and demonstrated near-normal corrected binocular vision (better than 20/25 via Snellen chart; Hetherington, 1954). No participant had a history of formal lipreading training as determined by self-report. Participants were all highly educated, with an average of 19.65 years of school completed. They were volunteers and were not compensated for their time. Testing occurred over two test sessions, each lasting approximately 1.5 to 2 hr. Test sessions were separated by at least one full day. All testing was completed in accordance with Vanderbilt University's institutional review board's policies regarding human participants in research.

Stimuli

Recall task. Speech tokens were monosyllabic words spoken by a female talker. The words used were those in published or commercially available word lists, including words from the Central Institute for the Deaf W22 (Hirsh et al., 1952), Northwestern University Auditory Test No. 6 (Tillman &Carhart, 1966), Kindergarten Phonetically Balanced Word Lists (Haskins, 1949), and the Pediatric Speech Intelligibility Test (Jerger, Lewis, Hawkins, &Jerger, 1980). The speech tokens were recorded in a professional television studio with a professional quality video camera and a shotgun microphone (Sennheiser K6). The recordings were digitized (sampling rate: 41000 Hz, 29.97 frames per second) and edited to be single tokens each approximately 1,700 ms in length and all with the same average root-mean-square level. Pilot testing with listeners with normal hearing allowed the 480 words to be rank ordered on the basis of their intelligibility in noise. All of the words were ranked twice, once in an AO condition (-3 dB SNR) and once in an AV condition (-7 dB SNR). For each modality, we used 400 of the easiest words to create 40 trial lists consisting of five pairs of words each. All words in a given trial list were chosen to be approximately equal in difficulty. Probe words were chosen to be balanced for difficulty across serial position.We created two condition lists (List A and List B) with 20 trial lists in each, balanced for word difficulty. For half of the participants, List Awas used for the noise conditions. During

testing, speech stimuli were presented at 65 dBA.

A four-talker babble was created to serve as a competing noise. Four female talkers were recorded individually using anomnidirectional microphone (EarthWorks) placed approximately 20 cm from the speaker's mouth in an anechoic chamber. The four female talkers were different from the female talker used for the speech tokens. Each talker read passages from the Connected Speech Test (Cox, Alexander, &Gilmore, 1987), a speech recognition test that contains topic-specific passages derived from a children's encyclopedia. The average root-meansquare level of each sentence was matched across all speakers and all sentences. Sentences within each passage were kept together, and the passage order across the four talkers was randomized so that talkers were never reading the same passage at the same time in the final mix. The recordings for all four talkers were mixed and stored as a single-channel .wav file.

Subjective ratings. In addition to the objective measure of listening effort (recall performance), a subjective measure of perceived effort was recorded. Immediately after each trial, participants were asked the degree to which they had had to "put in effort to hear what was said." Participants were instructed to respond on an 11-point scale with endpoint anchors of 0 (no effort) to 10 (lots of effort). This is similar to a question from theSpeech, Spatial and Qualities of Hearing Scale (Gatehouse &Noble, 2004). Before testing started, participants were instructed to answer this question after each trial. Their verbal responses after each trial were recorded by the experimenter. If a participant failed to provide a subjective rating, the experimenter prompted the participant, who responded before the next trial was initiated. Because of a protocol change, only the final 15 study participants reported their subjective ratings.

Predictive variables. We measured performance on two predictive variables: (a) lipreading skills and (b)WMC. We evaluated each individual participant's lipreading skill using the Revised Shortened Utley Sentence Lipreading Test (ReSULT; Updike, 1989). The ReSULT is a shorter version of the Utley Sentence Lipreading Test (Utley, 1946) and was designed to test lipreading ability quickly and reliably. The ReSULT contains two sets of 10 sentences spoken by a female. Participants watch the speaker on a computer monitor but do not hear the speech. After each sentence, the participant's task is to repeat aloud what the speaker said. Participants earn 1 point for each word repeated correctly and do not receive credit for words repeated in the wrong order. The maximum possible scores are 43 and 46 on the first and second lists, respectively. Participants practiced using the first list of sentences (Form A) and were then tested using the second list (Form B). Because Form A was tested first, it was considered practice; we used the results of Form B for all analyses.

We used an automated operation spantask (AOSPAN) to measure WMC (Unsworth, Heitz, Schrock, &Engle, 2005). The AOSPAN is a dual-task paradigm designed to measure WMC and has been shown to be correlated with higher level tasks such as reading comprehension (Turner &Engle, 1989; Unsworth et al., 2005). During the AOSPAN, participants are presented with an equation on a computer screen (e.g., [6 + 5]/2) and instructed to read and solve the equation. The participant is then presented with a possible solution on a new screen and asked to make a judgment about the correctness of this solution by using a mouse to click either "True" or "False" on the computer screen. After a choice is made, the participant is shown a letter that is to be committed to memory. After the presentation of a set of equation- letter pairs, the participant is asked to recall as many of the letters as possible. At the time of recall, a 4 ×3 matrix of letters is presented to each participant, whose task is to select the letters presented in order, using the mouse. After a practice session, set sizes vary from three to seven (three trials with each set size presented randomly). All equations include addition or subtraction inside a set of parentheses, followed by multiplication or division. Each participant receives two scores: (a) an absolute score (total number of letters recalled from perfectly recalled sets) and (b) a total score (number of letters recalled from all sets). For both scores, the total possible is 75. Because the absolute score and total scores likely measure the same underlying construct (WMC), and because the absolute score is amore traditional scoringmethod (Unsworth et al., 2005), we used the absolute score for all analyses.

Test Environment

During testing, the participants were seated in the center of a sound-attenuated booth. A 24-in. LCD video monitor placed on top of a loudspeaker (Tannoy System6) was positioned 1.5 m from the participant. All stimuli were presented via the same loudspeaker/monitor system. For recall testing and SNR setting, Presentation software (Neurobehavioral Systems v. 14.2) on a personal computer outside the test booth delivered themonosyllabic tokens via custom programming. The audio output was routed to an audiometer (GSI 61) for level control and then to the loudspeaker. The background noise, if present, was delivered to the test loudspeaker from a CD player (Sony CDP-CD315) via the other channel of the audiometer. For lipreading testing, the ReSULT was played from a Panasonic DVD player and delivered to the monitor inside the test booth. For WMC testing, the AOPSAN task was administered via E-Prime (Psychology Software Tools v. 2.0) using custom programming (Unsworth, Heitz, Schrock, &Engle, 2005).

Procedure

During the initial evaluation, we collected individuallevel variables, including hearing status (pure-tone audiometric thresholds), corrected binocular visual acuity (Snellen chart), WMC (AOSPAN), and lipreading ability (ReSULT). These data were collected in quiet with no background noise present. Also during the initial visit, the SNR used for testing was set individually for each participant. Although the SNRs were set to equate performance in theAOand AV conditions, it is reasonable to expect changes in listening effort because listening effort is not always tied to speech recognition performance (e.g., Fraser et al., 2010; Rabbitt, 1968; Surprenant, 1999). To set the SNR for testing, we created four AO lists and four AV lists, each composed of 60 words. Because the information had been collected and rank ordered by difficulty, it was possible to ensure that all eight lists were approximately equally intelligible. At a givenSNR, the speech recognition of 60 wordswas tested. The initial SNRs were +4 dB and 0 dB for the AO and AV conditions, respectively. We then adjusted the SNR to more closely approximate speech recognition of 75%, and 60 more words were tested. We made SNR adjustments by adjusting the level of the noise in 1- to 4-dB steps, depending on a participant's performance. A 1-dB change in SNR typically resulted in a 10% change in speech recognition performance for both AO and AV stimuli. If performance was at 75% (±5%), we used 120 more words to confirm the performance level; otherwise, the SNR was adjusted again and the speech recognition of 60 more words was tested. If necessary, the final 60 words were used to confirm the appropriate SNR setting. We used the same procedure with AO and AV stimuli. Because the SNRs used for testing were chosen individually to match speech recognition performance in the AO and AV conditions, the paired-associate recall task was completed at the same speech recognition performance level for AO and AV stimuli (see Table 1). The average SNR used in the AO conditions was 2.5 dB (minimum = 0 dB, maximum = 5 dB). The average SNR used in the AV conditions was -2.15 dB (minimum = -4 dB, maximum = 0 dB). Because the level of the speech stimuli was fixed at 65 dBA, the background noise varied from 60 to 65 dBA for the AO conditions and 65 to 69 dBA SPL for the AV conditions. During a second visit on a subsequent day, participants completed paired-associates word recall testing in quiet and in the presence of noise for AO and AV presentations. Test orderwas counterbalanced across participants both by presentation mode (AO, AV) and by noise level (quiet, noise). All participants completed a practice condition, first in quiet and then in noise (six trials each). The practice wordswere not presented again during testing. Thepresentation mode of the practice was determined by the first test condition; for example, if the first test condition was AV quiet, the mode of presentation for practice was AV.

During a trial of the recall task, five pairs of words were presented consecutively, with a 4-s interpair interval and 100-ms interword intervals. During list presentations, participants were also asked to repeat the words as they were presented. In this manner, a word that was misheard could still be correctly recalled and the intelligibility of lists could be assessed. For example, if a participant said "hog" when the correct word was dog, but recalled hog, this was scored as a correct recall. Because the SNRs were chosen to maintain relatively good speech recognition performance, even in noise, no participant failed to respond immediately after a word presentation. Immediately after the participant's repetition of the fifth word pair, a 500-ms, 1000-Hz warning tone was

presented, the noise (if present) was removed, and the first word from one of the five pairs was presented. The participant was then asked to recall the second word of the pair. There was no time limit for recall. After the participant recalled (or reported that he or she could not recall) the second word in a pair, he or she verbally reported the subjective rating for listening effort for the trial. Then the next trial was initiated by the experimenter.

There were four experimental conditions (two presentationmodes and two noise levels). In each experimental condition, 20 trials of five word pairs were presented. Therefore, for each serial position in each experimental condition, four trials were presented. The order of the probe word's serial position was randomized within a given condition.

Results

Recall

Before conducting the analyses, we converted recall performance scores from percentage correct to rationalized arcsine units (RAUs) according to the equations found in Studebaker (1985). The average recall performance (in RAUs) for all four conditions and all participants as a function of serial position is presented in Figure 1. To evaluate the effect of noise and visual cues, we performed an analysis of variance (ANOVA) with three within-subject factors: (a) serial position (1-5), (b) noise (present or absent), and (c) visual cues (present or absent). It revealed a main effect of serial position, $F(4, 76) = 35.77$, $p < .001$, partial $\eta 2 = .462$, and a main effect of noise, $F(1, 19) = 49.67$, $p < .001$, partial $h2 = .121$. There was no main effect of visual cues, and there were no significant interactions. To follow up the significant main effect of serial position, we performed multiple pairwise comparisons using linear contrasts with Bonferroni adjustments to control for familywise error rate (Dunn, 1961). The results of these analyses revealed that recall performance in the fifth serial position was better than in all other serial positions ($p < .001$) and that recall performance was significantly better in the fourth serial position than in Positions 2 and 3 ($p < .001$). Furthermore, there were no significant differences between recall performance among the first three serial positions. Taken together, these results indicate that recall performance was better in quiet than in noise and was better in the fourth and fifth serial positions. They also suggest that the presence of visual cues did not affect recall.

Recognition. An ANOVA with three within-subject factors-(a) serial position (1-5), (b) vision (present, absent), and (c) noise (present, absent)-revealed a significant main effect of noise, $F(1, 19) = 252.91$, $p < .001$, partial $h2 = .499$, but no main effect of visual cues or serial position. There were no significant interactions. These results indicate that the trials were of approximately equal intelligibility across serial position. Indeed, average performance at any serial position varied by no more than 2.2% and 4.5% within the quiet and noise positions, respectively (see Table 1); therefore, differences in serial position recall were not due to lists being differentially difficult to understand. In addition, word recognition performance was similar in theAOand AV conditions.

Subjective ratings. In addition to using recall performance as an indication of listening effort, participants were asked to give a subjective rating of listening effort after every trial. Although they were asked to rate an entire trial (i.e., effort for all 10 words), their ratings were recorded and scored while maintaining the serial position information for the probe words. Maintaining and evaluating the potential effects of serial position was important to ensure that the trials were equally difficult in terms of perceived listening effort. If there were differences in perceived listening effort or speech recognition across trials that probed different serial positions, then the effect of serial position on the recall task would be more difficult to interpret.

We used nonparametric analyses (FriedmanANOVA) for the subjective data. Due in part to the fact that an omnibus nonparametric statistic does not exist that allows for evaluation of main effects and interactions, we made an a priori decision to complete separate Friedman ANOVAs to evaluate serial position, vision, and noise. For these analyses, we corrected the p value for familywise error rate of multiple comparisons by dividing the initial value of p (.05) by the number of comparisons (eight; Dunn, 1961); therefore, $p < .00625$ was defined as significant. These eight planned comparisons reflected all main effects and interactions among serial position,

modality, and noise conditions; specifically, we evaluated the effect of serial position in each of the four modality and noise combinations (AO quiet, AO noise, AV quiet, AV noise).We also evaluated the effect of background noise for each of the modalities (AO and AV) and the effect of vision for each of the background noise conditions (quiet and noise) to test for any significant interactions.

The average subjective ratings of listening effort as a function of serial position is displayed in Figure 2. The analysis results revealed no significant effect of serial position in any of the four conditions (AO quiet, AO noise, AV quiet, AV noise) and no effect of visual cues in either quiet or noise; however, there was a significantmain effect of noise without visual cues, $F(1, 14) = 109.19$, $p < .0001$, and with visual cues, $F(1, 14) = 112.62$, $p < .0001$. The results support the objective data in that presence of visual cues did not influence listening effort, but the addition of background noise increased listening effort. The results also suggest that the effects of serial position evident in the recall task were not the result of differentially difficult trials and thus the lists were balanced. Therefore, the effects of serial position on the recall task are due to the increased cognitive demand on the earlier serial positions, and the recall task and speech recognition task were testing two separate constructs (listening effort and speech recognition ability, respectively).

Individual Variability

Despite the lack of a significant main effect of vision on recall performance, there were large individual differences in benefit from visual cues (see Figures 3 and 4). Consistent with the purpose of this investigation, we measured two predictive variables-WMC and lipreading ability-to examine whether these factors might account for some the individual differences in recall performance. We used the absolute AOSPAN score (total number of letters recalled from perfectly recalled sets) and the results from FormB on the ReSULT for the analyses. In the case of both lipreading ability and WMC, we calculated a correlation between predictive variables and average benefit from visual cues in the first three serial positions. Benefit from visual cues was defined as the difference in recall performance (RAUs) between the AV and AO conditions for the first three serial positions only. We chose the first three serial positions because they are thought to be indicative of listening effort (Heinrich et al., 2008; Murphy et al., 2000). A higher benefit from vision score indicates that a participant correctly recalled more words in the AV modality than in the AO modality.We performed correlation analyses between each predictive variable and the benefit from vision in quiet as well as in noise. For each of the four correlation analyses (lipreading and recall in quiet, lipreading and recall in noise, WMC and recall in quiet, WMC and recall in noise), a linear regression line was fitted and tested for significance at the .05 level. The results of the correlation analyses between lipreading ability and benefit from vision revealed no significant relationship in quiet ($r2 = .02$), but there was a significant relationship between lipreading ability and benefit from visual cues in noise ($r2 = .284$), $F(1, 18) = 7.154$, $p < .05$. Although there remains considerable individual variability, these results suggest that listening effort in a noisy background was reduced more for participants who were better lipreaders with the introduction of visual cues (see Figure 3).

In addition to lipreading, we investigated the correlation between WMC and recall benefit from vision (in quiet and in noise; see Figure 4). Correlation analyses revealed no significant correlations between WMC and recall benefit from visual cues in quiet or in noise ($r2s = .01$ and $.15$, respectively). Although the correlation was not significant, inspection of Figure 4 reveals a trend for people with high WMC to benefit more from visual cues in noise.

One of the reasons for the lack of significant correlationmaybe the large intersubject variability, as evidenced in Figure 4. For example, for three participants, the average benefit from vision on the recall task was 51.45, but their AOSPANscores were 16, 62, and 57. Therefore, the participants ranged widely in their WMC but were able to derive the same benefit from vision in the recall task. An additional reason that the correlation was not significant may be that the relationship between WMC and benefit from vision is not linear. Other authors have suggested that there may be a certain threshold level of WMC necessary for successful speech recognition, and if that level is not met, then listeners must rely on other communication or coping strategies for successful

speech recognition (Lyxell, Andersson, Borg, &Ohlsson, 2003). A similar relationship may hold for benefit from vision in a recall task.

To investigate this potential effect further, wedivided the scores into two groups: (a) Participants with scores 38 and below (n = 7) were categorized as having low WMC, and (b) the remaining 13 were placed in the high-WMC group. This division was based on average data reported by the test developers, who reported an average score of 37.5 in a group of 296 participants ages 18 to 35 (Unsworth et al., 2005). The average benefit from vision in quiet and noise as a function of WMC group is shown in Figure 5.We conducted an ANOVA on these data with one within-subject variable (recall benefit from vision in quiet and in noise) and one between-subjects variable (low or high WMC). The results revealed no main effect of WMC or noise, but there was a significant interaction betweenWMCand noise, $F(1, 18) = 4.851$, $p < .05$, partial $h2 = .434$. Follow-up analysis (Tukey's honestly significant difference test) revealed a significant difference between benefit from vision in quiet and in noise only for participants with high WMC ($p < .05$). These results indicate that, as a group, individuals with highWMCwere able to derive more recall benefit from visual cues while listening in noise than in quiet. In contrast, the recall benefit from visual cues was the same in quiet and in noise for participants with low WMC.

On the basis of the lipreading and WMC results, we thought it would be interesting to determine whether the relationship between each of these factors and recall benefit was due to a relationship between them; however, a correlation analysis revealed no significant relationship between lipreading ability andWMC($r2 = .022$, $p > .05$). This lack of relationship is consistent with previous literature indicating that lipreading ability in quiet is not related to cognitive capacity or other verbal reasoning abilities (Lyxell &Rönnberg, 1989, 1993; Summerfield, 1991) and suggests that the benefits to recall from good lipreading ability and high cognitive capacity were independent. We also thought it would be interesting to determine whether differences between individuals could account for differences in speech recognition. Correlation analyses revealed that there was no relationship between speech recognition performance (RAUs) in the AV condition and lipreading ability ($r2 = .024$, $p > .05$). Finally, we also wanted to determine whether differences in recall performance were related to differences in speech recognition. A correlation analysis revealed no significant relationship between benefit from vision on the recognition and recall tasks in quiet ($r2 = .027$, $p > .05$) or in noise ($r2 = .013$, $p > .05$). In total, these nonsignificant relationships suggest that speech recognition performance (in RAUs) or benefit from vision for speech recognition (in dB) did not influence performance or benefit from vision in the recall task. Furthermore, individual differences in speech recognition ability, WMC, and lipreading ability were independent fromeach other. Although these results are somewhat inconsistent with previous studies that have shown a relationship between speech recognition in noise and WMC (e.g., Lunner, 2003) or lipreading ability (e.g., Erber, 1969, 1975), these previous studies tested participants over a wide range of SNRs and speech recognition abilities. Conversely, participants in the current study demonstrated a relatively narrow range of speech recognition performance, due in part to the study's design.

Discussion

Effect of Noise

The results of this study indicated that the presence of a four-talker babble increased listening effort, as indicated by poorer recall in the presence of noise (see Figure 1). It is not likely that the poorer recall is an artifact of poorer speech recognition performance, because participants were given credit for recalling a word that they misheard. In this way, speech recognition performance might be affected by background noise, but recall performance could theoretically be perfect. Thus, the poorer recall demonstrated when background noise was introduced likely reflects increased listening effort. Furthermore, the subjective ratings of listening effort were consistent with the objective measures of listening effort. Raters consistently rated the conditions with noise as requiring more listening effort (see Figure 2). These findings are consistent with previous work suggesting that the presence of noise increases listening effort (Heinrich et al., 2008; Murphy et al., 2000;

Rabbitt, 1968). Despite some differences in methodology, the current findings are similar to those reported by Murphy et al. (2000). In general, the recall performance by serial position functions was similar, and the effect of noise was more visible at earlier serial positions than later serial positions (e.g., approximately 17 average points at Positions 1 and 2 and approximately 5 points for Position 5 in both studies).

Some differences between results exist, however. Recall performance was approximately 30 points better in all serial positions in the current study in both quiet and in noise, perhaps as a result of different stimuli. The monosyllablic words in the current study were shorter than the multisyllabic words used by Murphy et al. (2000), and perhaps the shorter length facilitated recall. Furthermore, participants in the current study were familiarized with the words because we had conducted initial speech recognition testing to find each individual's SNR. Finally, in the current study participants were asked to repeat the words during testing so speech recognition as well as recall could be measured. This process may have facilitated recall through forced rehearsal, whereas recall was the only task participants performed in the experiments reported by Murphy et al. (2000).

Effect of Vision

On average, results from the recall task indicated no significant effect of visual cues on listening effort (see Figure 1). Furthermore, subjective ratings indicated that, when absolute performance levels were matched, perceived listening effort was independent of visual cues (see Figure 2). These results are inconsistent with previous reports of increased listening effort in AV conditions when speech recognition performance is fixed between AO and AV stimuli (Fraser et al., 2010). Although the reasons for the differences between results are unclear, they may be due to differences in methodology. First, we used open-set monosyllable speech stimuli, whereas Fraser et al. (2010) used closed-set sentence stimuli. Furthermore, we did not measure the speed of participants' responses, whereas Fraser et al. measured reaction time for speech recognition and the secondary task, both of which were slower in the AV than the AO modality. Perhaps the recall task we used was less sensitive to measures of listening effort because participants' responses were not timed. However, visual cues did affect listening effort for some individuals, so the paired-associates recall task is not likely insensitive to listening effort. Given these differences, further work aimed at directly examining the specific methodologies most sensitive to visual cues and listening effort may be worth pursuing.

Individual Variability

Individual data indicated there were significant relationships between each of the two predictive variables (lipreading ability and WMC) and listening effort with the introduction of visual cues. Although there was significant variability in the data (see Figures 3 and 4), there were some interesting significant effects, and these effects were dependent on the presence or absence of noise. In quiet, there were no effects of lipreading ability or WMC. Coupled with no average main effect of visual cues in quiet, these results suggest that visual cues did not affect listening effort in the quiet conditions we evaluated. These results are somewhat inconsistent with previous studies that show improved cognition in quiet with visual cues present (Reisberg et al., 1987). It is possible, however, that the present task was not difficult enough in quiet to require participants to utilize visual cues. For example, Reisberg et al. (1987) found that participants were better able to shadow speech in their nonnative language if visual cues were present. In this case, visual cues may enhance performance by providing additional information about the foreign language. Conversely, in the current study speech recognition in quiet with no visual cues was nearly perfect for all participants. Therefore, the addition of the visual cues did not facilitate speech recognition because the words were already easily identifiable and thus vision provided no further cues. Indeed, many participants reported looking at the video monitor during AV conditions in quiet but not actually paying attention to the monitor, despite specific instructions to attend to the monitor. If the video monitor were not being used by the participants, no effect of visual cues would be expected.

Conversely, in noise, participants needed to utilize the video monitor to achieve similar speech recognition performance at the more difficult SNR. This experiment was designed to lead to similar speech recognition performance in the AV and AO conditions. In the presence of matched performance, the poorer SNR in the AV

condition suggests that participants clearly demonstrated speech recognition benefit from the visual cues. Despite this benefit to speech recognition, there was no significant main effect of visual cues on recall performance. Although there was no significant main effect of visual cues, there were large individual differences, suggesting the possibility of increased or decreased listening effort as a result of visual cues in individual listeners. On the basis of the interactions between the two predictive variables and the benefit from vision, we hypothesize that these individual differences can be explained in terms of processing efficiency; specifically, individuals with high WMC were able to derive more benefit from visual cues in noise than in quiet, whereas listeners with low WMC were not. Therefore, individuals who had more available cognitive resources were able to use visual information to reduce listening effort for audiovisually presented speech, in contrast to individuals with less overall capacity and/or poorer processing efficiency for visual cues. We propose that listeners need sufficient cognitive resources to utilize visual cues, but if a listener has enough resources, visual cues may provide better signal representation. Consistent with the ELU model (Rönnberg, 2003; Rönnberg et al., 2008), improved signal representation is expected to facilitate recall and lead to decreased listening effort. As noted earlier, listeners with better lipreading ability experienced less listening effort with visual cues than without (see Figure 3). For people who are better lipreaders, utilizing visual cues is more automatic and the AV signal is better represented. Because automatic processes require fewer cognitive resources (Hasher &Zacks, 1979), we propose that people who are better lipreaders are likely to have more remaining cognitive resources available for processing and integrating the auditory and visual signals. Therefore, people who are good lipreaders can make use of the additional information that visual cues provide. Conversely, people who struggle with lipreading need to use more of their pool of limited cognitive resources to extract visual information and then also integrate the complementary cues to achieve a strong signal representation. Consistent with this hypothesis, the poorest lipreaders demonstrated substantially more listening effort when visual cues were present in noise than the best lip readers (see Figure 3).

Although the relationship between lipreading ability and listening effort has not been reported on previously, earlier work suggests that individuals who are better lipreaders derive more AV benefit on speech recognition tasks (MacLeod &Summerfield, 1990). On the basis of this previous work, one might be concerned that recall benefit was driven by differences in speech recognition performance; however, a correlation analysis revealed no significant correlation between lipreading ability and AV speech recognition benefit (dB) in noise ($r^2 = .0015$). Furthermore, a correlation analysis revealed no significant correlation between lipreading ability and AV speech recognition performance (RAUs) in noise ($r^2 = .0239$). Therefore, differences in AV speech recognition benefit did not contribute to differences in AVrecall benefit as a function of lipreading ability in the presence of background noise.

Another indication that a better signal representation yields reduced listening effort if cognitive resources are sufficient comes from an examination of the relationship betweenWMC and AV recall benefit in noise; specifically, when the participants were divided into two groups on the basis ofWMCsize asmeasured by theAOSPAN, on average participants who had higher WMCs exhibited more AV benefit in noise than in quiet. No such difference was found for the group of listeners with low WMCs. We propose that participants with higher WMCs had more cognitive resources available for integrating auditory and visual information. Because they were able to better integrate the auditory and visual stimuli, the signal representation was better, and thus listening effort was decreased. Conversely, listeners with more limited cognitive capacity did not have sufficient resources to utilize the better signal representation provided by the AV stimuli. For these listeners, there was no difference in AV recall benefit between quiet and noise. Providing visual cues did not improve listening effort, potentially because listeners did not have sufficient resources to integrate the audio and visual signals to enhance representation and reduce listening effort. Similar to lipreading ability results, this effect of WMC was not driven by differences in AV speech recognition benefit. On average, AV speech recognition benefit in noise was small and similar between groups (1.80 and 1.83 RAUs for those in the low- and high-WMCgroups,

respectively); thus, it is unlikely that differences in speech recognition benefit drove differences in recall benefit between the two groups.

Individual results suggest that listening effort was decreased in noisy environments by the presence of visual cues for some listeners.However, this benefit required greater cognitive resources, and despite significant variability those individuals who exhibited large WMCs or were good lipreaders were more likely to make use of the better signal representation of the AV stimuli in noise; that is, despite the fact that no significant effect of visual cues on listening effort was measured, on average, these data indirectly suggest that cognitive resources are necessary to use visual cues because listeners with limited resources were unable to benefit from visual cues. This conclusion is consistent with the findings of Fraser et al. (2010), who demonstrated an increase in listening effort with the addition of visual cues in a dual-paradigm task (a speech recognition primary task and a vibro-tactile secondary task). Although the findings of both studies support the notion that cognitive resources are required to use visual cues, we propose that the impact that this increased demand on cognitive resources has on listening effort depends on the methodology implemented; specifically, the effect of visual cues may be manifested as an increase in measured listening effort as demonstrated by Fraser et al., or a benefit from vision that is apparent only in listeners with sufficient resources, as demonstrated in the current study.

Conclusions

Consistent with the results of Murphy et al. (2000), noise increased listening effort across both AO and AV conditions, as indicated by better recall performance and lower ratings of effort in quiet than in noise (see Figures 1 and 2).

Visual cues did not affect listening effort (objectively or subjectively) in quiet (see Figures 1 and 2). Furthermore, there was no correlation between the predictive variables and benefit from visual cues in quiet.

On average, there was no main effect of visual cues on objective or subjective measures of listening effort (see Figures 1 and 2). However, there was some support for the hypothesis that processing visual cues during a speech recognition task requires cognitive resources; specifically, individuals with less overall cognitive capacity or poorer lipreading ability were not able to take advantage of available visual cues to reduce listening effort (improve word recall) for audiovisually presented speech in noise. Although there was substantial intersubject variability, the results indicate that listeners who were more efficient or effective lipreaders were more likely to benefit fromvisual cues than their counterparts who were poor lipreaders. Furthermore, listeners with highWMC were more likely to derive AVrecall benefit in noise, whereas those with lowWMC did not, on average, demonstrate this benefit. In total, these results suggest that listeners with sufficient cognitive resources can make use of visual cues to reduce listening effort.

Age-Related Benefits of Digital Noise Reduction for Short-Term Word Learning in Children With Hearing Loss

Author: Pittman, Andrea

Publication info: Journal of Speech, Language and Hearing Research (Online) 54.5 (Oct 2011): 1448-1463.
ProQuest document link

Abstract: To determine the rate of word learning for children with hearing loss (HL) in quiet and in noise compared to normalhearing (NH) peers. The effects of digital noise reduction (DNR) were examined for children with HL. Forty-one children with NH and 26 children with HL were grouped by age (8-9 years and 11-12 years). The children learned novel words associated with novel objects through a process of trial and error. Functions relating performance across trials were calculated for each child in each listening condition and were compared. Significant effects were observed for age (older >younger) in the children with NH and listening condition (quiet >noise) in the children with HL. Significant effects of hearing status were also observed across groups (NH >HL), indicating that the children with HL required more trials to learn the new words. However, word learning improved significantly in noise with the use of DNR for the older but not for the younger children with HL.

Hearing aid history and signal-to-noise ratio did not contribute to performance. Word learning was significantly reduced in younger children, in noise, and in the presence of hearing loss. Age-related benefits of DNR were apparent for children over 10 years of age.

Purpose: To determine the rate of word learning for children with hearing loss (HL) in quiet and in noise compared to normalhearing (NH) peers. The effects of digital noise reduction (DNR) were examined for children with HL.

Method: Forty-one children with NH and 26 children with HL were grouped by age (8-9 years and 11-12 years). The children learned novel words associated with novel objects through a process of trial and error. Functions relating performance across trials were calculated for each child in each listening condition and were compared.

Results: Significant effects were observed for age (older >younger) in the children with NH and listening condition (quiet >noise) in the children with HL. Significant effects of hearing status were also observed across groups (NH >HL), indicating that the children with HL required more trials to learn the new words. However, word learning improved significantly in noise with the use of DNR for the older but not for the younger children with HL. Hearing aid history and signal-to-noise ratio did not contribute to performance.

Conclusion: Word learning was significantly reduced in younger children, in noise, and in the presence of hearing loss. Age-related benefits of DNR were apparent for children over 10 years of age.

Key Words: children, hearing loss, noise reduction, word learning

(ProQuest: ... denotes formula omitted.)

Learning new words is a critical accomplishment of childhood that lays the foundation for language and literacy development. A broad and deep vocabulary allows children to speak effectively, read comprehensively, and write meaningfully. Although a number of factors are known to promote the learning of new words (e.g., age of the child, size of the child's vocabulary, similarity of the new word to other known words), hearing loss (HL) has been shownto pose a significant barrier. This notion is supported by evidence relating the severity of a child's HL to the size of his or her vocabulary (Briscoe, Bishop, &Norbury, 2001; Fellinger, Holzinger, Beitel, Laucht, &Goldberg, 2009; Kiese-Himmel, 2008; Sarant, Holt, Dowell, Rickards, &Blamey, 2008; Wake, Hughes, Poulakis, Collins, &Rickards, 2004). It has been shown that, on average, the vocabulary of school-aged children with mild-to-moderateHLis 2-3 years behind that of children with normal hearing (NH; Pittman, Lewis, Hoover, &Stelmachowicz, 2005). The effect of severeto- profound HL is an even slower rate of vocabulary development that further widens the gap between children with HL and children with NH over time (Blamey et al., 2001). Taken together, it appears that mild-to-moderate degrees of HL delay vocabulary development, whereas more severe HL impairs it. Although the differences between chronological and vocabulary age may be negligible at younger ages, concerns for social, academic, and mental health problems (Fellinger et al., 2009) can occur for children with HL who are chronologically 12 years of age but have the vocabulary of a 9-year-old.

Unlike the disordered word learning of children with specific language impairment (SLI), the basis of poor word learning in children with HL appears to be the result of their impaired peripheral auditory systems. Specifically, word learning in children with SLI has been attributed, in large part, to impaired working memory (Alt, 2010). On the other hand, research has shown that the working memory of children and adults with HL is independent of hearing loss (Hansson, Forsberg, Lofqvist,Maki-Torkko, &Sahlen, 2004; Lyxell, Andersson, Borg, &Ohlsson, 2003; Zekveld, Deijen, Goverts, &Kramer, 2007).One could argue, however, that a degraded representation of a new word also affectsworking memory. Degraded perception of speech has been shown to cause poor phonological processing in children (Briscoe et al., 2001) and may prevent the cognitive processes that are triggered when a new word is perceived (see, e.g., Storkel &Lee, 2011). For example, the words hat, sat, and

fat may be well-known to a child with HL, but each word contains low-level, high-frequency voiceless fricatives that may be difficult for a child to differentiate, even with amplification. Perception of a new word such as shat may be confused with these known words, thus resulting in misperception rather than a trigger for word learning. Therefore, the threshold for identifying a word as new is higher in children with HL. Even when a word is recognized to be new, multiple repetitions may be necessary to form a sufficient representation in order to differentiate it from other known words. This was demonstrated in children with HL and in children with NH who were asked to learn nonsense words that were subtly degraded by narrowing the bandwidth of the signal to that of typical hearing aids (Pittman, 2008). Word learning for both groups was significantly reduced, suggesting that a degraded signal can interfere with the word-learning process, even for children with NH.

Whereas standardized tests are used to quantify children's receptive and expressive vocabularies, paradigms focusing on the speed and accuracy ofword learning have been developed to determine those conditions that promote or impede the word-learning process (Akhtar, 2005; Akhtar, Jipson, &Callanan, 2001; Dollaghan, 1985; Lederberg, Prezbindowski, &Spencer, 2000; Rice &Woodsmall, 1988). One such paradigm was used in a recent study to examine the effects of certain hearing aid characteristics on receptive word learning in children with HL compared to children with NH (Pittman, 2008). In this paradigm, nonsense words are assigned to novel objects that have no common name. Children play a computer game that requires them to learn the names of the objects through a process of trial and error. On each trial, the children listen to a novel word and then select an object. Reinforcement is awarded for correct selections only, providing the children with the information needed to learn. At the end of the test (about 15 min), a function representing the children's increasing performance over 100 or more trials is generated to determine the number of exposures needed to achieve a criterion level of performance. With this paradigm, the effects of hearing loss and listening conditions on the rate of word learning may be examined. For example, noise is considered to be one of the most adverse listening conditions for hearing aid users (Kochkin, 2002). One form of hearing aid technology that has the potential to benefit children with HL when they are in noise is digital noise reduction (DNR). The goal of this technology is to improve listening comfort and preserve or improve the perception of speech. The advantages of examining the effects of DNR on auditory skills such as word learning over traditional speech perception measures are many. First, perception of the novel words does not require previous knowledge of or experience with the language. Second, a period of acclimatization with a particular form of signal processing is not necessary. Third, considerable data may be collected in a short period of time. And finally, word learning-similar to speech perception-has high face-validity in pediatric populations.

DNR

Chung (2004) provides a thorough description of the signal detection, analysis, decision rules, and execution of DNR in commercially available hearing aids. In general, alterations to the output of the hearing aid occur in selected frequency bands or over the entire frequency spectrum when steady-state noise is detected at the input to the hearing aid. Themanner in which noise reduction is achieved varies across hearing aid makes and models (Hoetink, Korossy, &Dreschler, 2009), but the most common approach is an overall decrease in output. The effects ofDNRare also more pronounced for steady-state noise than for speech signals because steady-state noise is more easily detected and managed byDNRalgorithms (Bentler &Chiou, 2006; Ricketts &Hornsby, 2005).

Despite the reduction in overall amplification, research has shown that speech perception in noise and speech reception threshold withDNR are well preserved in adults (Auriemmo et al., 2009; Bentler,Wu, Kettel, &Hurtig, 2008; Nordrum, Erler, Garstecki, &Dhar, 2006; Peeters, Kuk, Lau,&Keenan, 2009; Ricketts&Hornsby, 2005; Stelmachowicz et al., 2010). Similar results were found in two studies conducted inchildren. Stelmachowicz and colleagues (2010) examined speech perception in 16 children between the ages of 5 and 10 years with mild to moderately severe HL. The authors used behindthe- ear hearing aids having DNR technology that uses a modified spectral subtraction algorithm performed independently in 16 frequency bands. The aids were fit to

each child according to DSL targets (Scollie et al., 2005; Seewald, Moodie, Scollie,&Bagatto, 2005) and were verified using real-ear measures. The children's perception of nonsense syllables, monosyllabic words, and sentences in noise was examined as a function of age and DNR (activated vs. deactivated). Main effects of age and stimulus condition were observed; however, no effect of noise reduction was found. As with adults, the results suggest that children's performance with DNR is preserved despite the reduction in overall amplification. Auriemmo et al. (2009) reported similar results for speech recognition in 19 children with mild to moderately severe sensorineural HL between the ages of 6 and 12 years. The authors used behind-the-ear hearing aids employing a multichannel adaptive DNR algorithm that reduced the gain independently in 15 frequency bands. The overall signal-to-noise ratio (SNR) benefit provided by directional microphones, as well as the benefit of DNR in quiet and at three SNRs (+5 dB, 0 dB, and -10 dB), was determined. Although a significant SNR improvement was observed for the directional microphone condition over the omnidirectional condition, no differences in performance were observed with the use of DNR. Also, standardized tests of language development revealed that the children were not adversely affected by adaptive directional microphones and DNR after using the technology for a 1-year period.

Although it appears thatDNRpreserves speech perception in children and adults, a significant weakness of previous studies is that the parameters of the acoustic signal provided by DNR were not reported-that is, the amount by which the amplified signal was attenuated by DNR and the signal level relative to the noise were not reported. It is possible that little effect was observed because little noise reduction occurred. It is also possible that DNR imposed significant reductions on the amplified signal but performance was preserved due to the redundancy of speech. It has been well established that speech perception is robust and can withstand substantial degradation of the speech signal with little effect on perception (Remez, Pardo, Piorkowski, &Rubin, 2001; Walden, Prosek,&Worthington, 1975).Whenperception is further supported by the context of the message, the listener's familiarity with the speaker, and his or her knowledge of the topic, the listener with HL is better able to fill in the missing auditory information to perceive the message with confidence. However, the benefits of DNR may not be as apparent for auditory tasks that are not supported as well as speech perception. For children, learning new words is one such task-one of the most important auditory tasks that they must perform in order to communicate effectively.

The purpose of the present study was twofold. First, the impact of noise on children's ability to learn new words was determined for children with NH and children with HL. It was hypothesized that learning would decrease in noise for both groups-and more so for the children with HL. Second, the impact of DNR on word learning in children with HL was examined. It was hypothesized that the reduction in overall amplification imposed by DNR would slow the learning rate in noise. To capture the known effects of age on word learning, two age groups of children were recruited (ages 8-9 years, ages 11-12 years). These groups represent the period of greatest vocabulary growth (Anglin, Miller,&Wakefield, 1993; Johnson &Anglin, 1995), a period in which Bloom (2001) estimated that approximately 12 new words are learned per day (p. 44). It was hypothesized that word learning would be directly related to receptive vocabulary over and above hearing status.

Method

Participants

Forty-one children with NH (22 boys, 19 girls) participated in this study. Children were recruited on the basis of chronological age to form two age groups: a younger group consisting of 20 children between the ages of 8 and 9 years (M = 9;0 [years;months], SD = 0.7, range = 8;1- 9;11) and an older group of 21 children between the ages of 11 and 12 years (M = 11;11, SD = 0.65, range = 11;0- 12;11). On the day of testing, all children had hearing thresholds ≤20 dB HL bilaterally at octave frequencies between 0.25 kHz and 8 kHz. Normal middle-ear status was confirmed with acoustic immittance measures. These children served as the control group.

Children with HL were enrolled in the study if they were eligible for monaural or binaural amplification. The experimental group comprised 26 children (11 boys, 15 girls) with mild to moderately severe HL. Thirteen

children were between the ages of 8 and 10 years (M = 9;1, SD = 0.55 range = 8;1-9;11), and 13 were between the ages of 11 and 12 years (M = 11;11, SD = 0.66, range = 11;0-12;11). It was confirmed, through t tests, that there were no differences in age between the NH and HL groups for the younger, $t(31) = -0.662$, $p = .50$, and older, $t(32) = 0.304$, $p = .763$, children. Average age of HL identification was 3;1, with a range of 0 (birth) to 6 years of age. All but one of the children wore personal hearing aids. For those children having personal hearing aids, average age at amplification was 4;4, ranging from 6 months to 8 years of age. Length of amplification for these children ranged from 1;6 to 11;0, with an average of 5;11. Only one child wore hearing aids havingDNR enabled in a dedicated program.

On the day of testing, the participants received a full hearing evaluation, which included otoscopy, tympanometry, and pure-tone air- and bone-conduction audiometry. Children whose hearing thresholds were unchanged since their last hearing evaluation did not receive boneconduction testing. Table 1 contains the hearing thresholds of each child in the younger and older groups at octave frequencies between 0.25 kHz and 8 kHz. The children's gender, chronological age, type of hearing loss in each ear, and ears amplified during testing are also provided. Figure 1 shows the hearing thresholds of each child as a function of frequency for the right and leftears in the upper and lower panels, respectively. Average hearing levels (± 1 SD) for the younger group (filled symbols) and older group (open symbols) are shown in each panel. On average, the hearing thresholds were similar through 1 kHz, with somewhat poorer thresholds occurring at higher frequencies for the older children. The variability in HL configuration across children is typical of this population and is consistent with that reported in previous studies in this age group (Auriemmo et al., 2009; Delage &Tuller, 2007; Gravel, Fausel, Liskow, &Chobot, 1999; Jerger, Martin, Pearson, &Dinh, 1995; Jutras &Gagne, 1999; Scollie, Seewald, Moodie, &Dekok, 2000; Stelmachowicz et al., 2010; Stelmachowicz, Pittman, Hoover, &Lewis, 2002; Stelmachowicz, Lewis, Choi, &Hoover, 2007). Acoustic immittance was consistent with the middle-ear status of each child. All of the children (NH and HL) were enrolled in the grade that was appropriate for their age in public elementary schools or through home schooling.

Prior to testing, the receptive vocabulary of each child was determined using the Peabody Picture Vocabulary Test-III (Form IIIB; Dunn& Dunn, 2006). Recall that standardized measures of receptive vocabulary can reveal the long-term effects of childhood HL when compared to those ofNH peers (Blamey et al., 2001; Pittman et al., 2005). Figure 2 shows the results of the PPVT-III as a function of chronological age for the children with NH (filled symbols) and the children with HL (open symbols). PPVTage, standard score, and raw score are shown in the upper, middle, and lower panels, respectively. Asterisks indicate the children with HL who did not have a bilateral sensorineural hearing loss and who may be identified from Table 1 using the chronological age. For example, two children aged 8;11 scored similarly on the PPVT-III, even though one child had a moderateto-profoundmixed loss and the other had amild conductive loss. These results show that the receptive vocabulary of the children withNH is greater than that of the children with HL, with some overlap between the two. A two-way analysis of variance (ANOVA) confirmed significant main effects of age, $F(1, 63) = 38.203$, $p < .001$, and hearing status,$F(1, 63) = 16.917$, $p < .001$. The lack of an Age ×Hearing Status interaction, $F(1, 63) = 0.941$, $p = .336$, indicates a similar difference in vocabulary level for each age group. The difference is on the order of 3 years, which is consistent with previous studies (Pittman et al., 2005; Stelmachowicz, Pittman, Hoover, &Lewis, 2004).

Amplification

Each child was fitted with behind-the-ear hearing aids for use during the experimental tests (see Table 1). The DNR feature in this hearing aid consists of two independent DNR algorithms that operate simultaneously in each of 16 channels (see Mueller, Weber, &Hornsby, 2006, for a full description). The first is a modulation detection algorithm that causes the gain within each channel to be reduced when steady-state noise is detected. Gain is reduced independent of the signal level in the channel and can be adjusted with the manufacturer's programming software. The second DNR algorithm employs technology similar to aWiener filter,

which calculates the SNR and filter coefficient for each channel by tracking the envelope of the signal within the channel. This feature operates continuously regardless of the input signal (speech or noise) to the channel. Direct measures of the DNR feature in the hearing aids used in the present study showed an attack time of 3.2 s after the onset of steady-state, broadband noise and activated at input levels as low as 40 dB SPL. Effective gain reduction for the 50 dB SPL noise level employed during the word-learning tasks was 7 dB when set to maximum noise reduction.

The hearing aids were fitted using the child's personal earmolds. Four children did not have their personal earmolds with them at the time of testing, so temporary molds (Comply, Snap Tips) were used. The hearing aid manufacturer's software was used to program and finetune the devices based on the simulated real-earmeasures (SREM) performed with the Verifit (Audioscan, VF-1) hearing aid test system. Following the manufacturer's instructions, individual real-ear-to-coupler differences- as well as the child's hearing thresholds- were obtained and were entered into the Verifit. The output of the hearing aids was adjusted to within 5 dB of the targets prescribed for average (65 dB SPL) and soft(50 dB SPL) conversational speech by the Desired Sensation Level (DSL [i /o] 5.0) fitting algorithm (Scollie et al., 2005; Seewald et al., 2005). Real-ear measures were obtained for the first five children to confirm that the SREM procedure provided an accurate estimate (± 2 dB) of realear amplification. Thereafter, all hearing aids were programmed using the SREM function only.

For this investigation, two active programs were created in each hearing aid. In Program 1, all advanced signal-processing features offered in the hearing aid were disabled, including Speech and Noise Management (DNR), Sound Smoothing (reduction of impulse noises), eWind Screen (reduction of wind noise), and Feedback Blocker (feedback management). In Program 2, all advanced signal-processing features remained disabled with the exception of the Speech and Noise Management feature, which was set to maximum. The Speech-in- Noise-Only option, which activates the noise reduction feature only when both speech and noise are present, was disabled. This caused the hearing aid to activate the DNR feature whenever noise was detected, regardless of whether speech was present. The output of each program was equated to provide the same audibility in quiet with or without DNR activated.

The user controls for this hearing aid included a program button and a volume control. The hearing aids were set to indicate when it was in Program 1 or 2 by generating one or two beeps, respectively. The beeps were set to occur at a frequency and output level that was audible to the child. The range of the volume control was set to 0 (i.e., deactivated), which meant that it served as an on/offswitch only.

Prior to testing, each child was familiarized with the hearing aids and was trained to select the required program when directed to do so. Because all but one of the children were experienced hearing aid users, they required minimal orientation to the device. This experience allowed them to focus their attention on the "program" button, which was new to many of them. The children were required to indicate the number of beeps that they heard when the hearing aids were changed from one programto the next. Because the hearing aidswere equipped with a feature that linked the two hearing aids (E2E), changing the program in one hearing aid also changed the program in the other aid, causing the child to hear one or two beeps in each ear at nearly the same time. Most of the children were able to perceive the correct number of beeps generated by the hearing aid in each ear, whereas some did not. For those children, the examiner adjusted the hearing aids during testing. All other children adjusted the hearing aids by pressing the program on both aids.

Stimuli

Three sets of five nonsense words were created for this study. The words are listed in Table 2 with their orthographic and phonetic transcriptions from which the positional and biphone probabilities were calculated (Vitevitch &Luce, 2004).1 All of the words were two syllables in length and were pronounced with the stress on the first syllable, as is typical of two-syllable English words. The words within each list contained the same two vowels in the first and second syllables so that learning would depend on the perception of the lowerlevel consonants rather than the louder vowels. Consonant phonemes that occur frequently in English (Denes, 1963)

were represented multiple times within each list. In this way, the words contained both unique and similar acoustic phonetic information, requiring the children to use more than one phoneme to identify any given word (Pittman, 2008; Stelmachowicz et al., 2004).

Stimuli were spoken by a female talker with a standard American English dialect. Recordings were made at a sampling rate of 22.050 kHz using a microphone with a flat frequency response to 10 kHz. The words were concatenated (removing all silent gaps), equated for root-mean-square level, and saved in separate audio files. Periods of silence were added to the beginning and end of each file so that each file was 2000 ms in duration. For the experiment, the words were mixed with a continuous, steady-state, broadband noise having a flat frequency spectrum ranging from 0.2 kHz to 10 kHz. Stimuli were presented in the sound field at an overall level of 50 dB SPL at the calibrated position and at an SNR of 0 dB. This speech and noise level was sufficient to activate the DNR feature but was low enough to minimize the incidence of compression limiting. In a sound-treated room, 50 dB SPL is equivalent to quiet conversational speech. The children's task was to learn the set of words presented in quiet and another set of words presented in noise. The children with NH learned two sets of words (one in quiet and one in noise), whereas the children with HL learned three sets of words (one in quiet, one in noise, and one in noise with theDNR activated). The word lists were counterbalanced across listening conditions, and the order of testing was counterbalanced across children.

DNR

Figure 3 shows the amplified waveforms for one child (15 stimuli). The stimuli and noise are shown with DNR off(upper panel) and with DNR on (lower panel). Although the nominal SNR was 0 dB for this experiment, the effective SNR for each child with HL can differ because of noise introduced by the hearing aid during amplification. Therefore, the effective SNR received by each child with HL was calculated with and without the DNR feature engaged. An inversion technique described by Souza, Jenstad, and Boike (2006) was used to separate the speech signal from the noise. This procedure requires three audio files containing (a) the speech and noise stimuli as they were used in the study (original speech + original noise), (b) the noise inverted and mixed with the original speech (original speech + inverted noise), and (c) the speech inverted and mixed with the original noise (inverted speech + original noise). The audio files were routed to a hearing aid test chamber (Verifit [Audioscan, VF-1]) where the output of the hearing aid was captured in a 2-cm3 coupler (Frye, HA-2) with an appropriate adaptor for a probe microphone (Etymotic, ER-7C). The output of the probe microphone was routed to a SoundDelux soundcard in a desktop computer. Custom software was used to play the stimuli and record the output simultaneously. The recorded audio files were imported to an audio editor program (Adobe Audition, Version 1.5). Effective SNR was determined by mixing the first recorded audio file (original speech + original noise) with each of the other two files. Mixing caused the original and inverted components to cancel, whereas the amplitude of the in-phase component was doubled (6 dB). The overall level of the long-term average spectrum of the isolated speech and noise components was then calculated after applying a 6-dB correction. These measures revealed a decrease of 5.1 dB for the younger children and 5.3 dB for the older children when the DNR feature was engaged.

Figure 4 shows the effective SNR of the stimuli that each child with HL received from the hearing aid with and without DNR for the 8- to 9-year-olds (upper panel) and for the 11- to 12-year olds (lower panel). Overall SNR for the right and lefthearing aids were averaged, with the exception of the three children who were aided monaurally. The children are listed in order of overall SNR achieved with DNR from least to greatest. This order was also used in Table 1 so that overall SNR could be compared to the children's hearing thresholds. The effective SNR ranged from -8.4 dB to 4.2 dB across conditions for the nominal 0 dB SNR presentation. Overall SNR improved when DNR was activated for all but a few children. The average effective SNRwithoutDNRwas -1.7 dB and -2.6 dB for the younger and older children, respectively. When DNR was activated, the average effective SNR was 0.6 and -0.3 dB for the younger and older children, respectively, for an average improvement of 2.3 dB for both groups. No correlation was found between overall SNR and pure-tone average hearing

thresholds (averaged across ears) with DNR activated, r = .291, p = .150, or when DNR was deactivated, r = .215, p = .291.

Dynamic Word Learning Task

The children's task was to learn the object or character to which a nonsense word belonged using an interactive computer game that promoted learning through a process of trial and error. During the game, a nonsense word is randomly selected and presented to the participant. He or she must then select one of five buttons displayed on the leftside of a computer screen. Each button displays a picture of a nonsense object or character having no common name. Reinforcement for accurate selections is provided via a video game displayed on the right side of the computer screen (e.g., a piece of a puzzle was added to a picture). Reinforcement is not provided for incorrect responses. This trial-and-error process required the children to remember both their correct and incorrect selections in order to advance through the games.

Three sets of five pictures each were used and are displayed in Figure 5. Each set of pictures was internally consistent and represented toys, flowers, and aliens. In the event that a picture-word association was more salient than another or that one picture was simply more appealing to the children than the others, the nonsense word associated with each picture was systematically alternated across children, and the pictures were counterbalanced across word lists. This reduced the impact of possible picture or word preference by distributing the effect across listening conditions.

Procedure

All testing was conducted in a sound-treated booth in the presence of two examiners. The first managed the experimental equipment and monitored the child's performance. The second examiner familiarized the child with the game and remained with the child during testing. The child was seated at a small table approximately 1 m from a loudspeaker at 0° azimuth. The stimuli were presented through the loudspeaker using custom software on a standard desktop computer. Although the temporal parameters of the experiment were controlled by the laboratory software, the children's responses were self paced-that is, a stimulus file was presented (2,000-ms duration), the children responded at their own pace (15-s response window), reinforcement was provided when appropriate, and the next stimulus was presented after a short delay (1,000 ms).

A brief practice session involving simple shapes associated with three nonsense words was used to familiarize the children with the task. The following instructions were given to the child:

You are going to hear some silly names. Your job is to choose the picture on the screen that has that name by touching it with your finger or clicking on it with a mouse. If you choose the right picture, the game on the screen will play. If not, nothing will happen, and you will hear the next silly name. Don't be surprised if it takes a little while to figure out the name that goes with each picture.

Five repetitions of each word were randomly presented to the children for a total of 15 trials (< 2 min). When the children were comfortable with the game format, testing for the experimental conditions proceeded. Each word was presented 20 times for a total of 100 randomized trials (5Words ×20 Repetitions). Testing lasted approximately 10 min per listening condition. Children were provided breaks as necessary and were paid for their participation according to the procedures outlined by the Institutional Review Board at Arizona State University.

Analysis

To characterize each child's word learning in the quiet and noise listening conditions, the trial-by-trial data were reduced to 10 bins of 10 trials each. Each trial was considered to be either correct or incorrect, and the proportion of correct responses within each block of 10 trialswas calculated.For example, if a child responded correctly to two of the 10 trials, the score for that bin was 0.20. Figure 6 shows the data for an 11-year-old child with NH learning in the quiet listening condition. The trial blocks are labeled according to the midpoint of the block (e.g., 15 is the midpoint between Trials 10 and 20). The data were then fit with the following exponential growth function:

... (1)

where Pc is the probability of a correct answer, 1 - 0.8 reflects chance performance for this task (20%), e is 2.718. . ., n is the midpoint of the trial block (5, 15, 25, etc.), and c is the time constant of the process. When n = 0 (beginning of the test), Pc = 0.2, with the curve growing from that raised floor in a smooth fashion to 1.0. When the number of trials equals the time constant (n = c), performance is approximately 70% (70.57%) correct. This was accomplished by adjusting estimates of c to minimize the sum of the squared deviations between the observed data and the points predicted. The dashed line in Figure 6 represents the point at which n = c (or, 70% correct). In this example, 67 trials were required to achieve the criterion level of performance. The advantage of using this approach was that all data points in the learning process contributed to the determination of the learning function and the time constant. The learning functions enabled individual and group performance to be evaluated across trials, whereas the number of trials needed to achieve the criterion performance provided a tangible point of reference with which to characterize the effects of hearing status and listening condition.

Results

Recall that the first goal of this study was to determine the impact of noise on children's ability to learn new words. Figure 7 shows proportion correct as a function of trial for the children with NH. Results for the 8- to 9-year-old children are shown in the upper panel, and results for the 11- to 12-year-old children are shown in the lower panel. The filled and open symbols are average proportion correct for each trial block in the quiet and noise listening conditions, respectively. The average learning functions (± 1 SE) are also shown for the quiet (solid line) and noise (dashed line) listening conditions. Although the performance of the younger children was poorer than that of the older children, little difference was observed between the quiet and noise listening conditions for both groups. Figure 8 shows proportion correct as a function of trial for the children with HL using the same convention as that used in Figure 7. Overall, performance was similar across age groups, with better performance in quiet and poorer performance in noise.

Effects of hearing status and listening condition were determined using repeated measures ANOVAs. Listening condition (quiet, noise) and trial block were entered as within-subjects factors, and hearing status (NH, HL) and age group (8-9 years, 11-12 years) were entered as between-subjects factors. The variable trial block did not meet the assumption of homogeneity of variance according to Mauchly's test of sphericity (Mauchly, 1940). The degrees of freedom were adjusted using the Greenhouse-Geisser correction for this and all other analyses. Significant main effects were observed for hearing status, $F(1, 58) = 5.073$, $p = .028$, $\eta 2 = .08$, $\beta = .601$; age group, $F(1, 58) = 5.595$, $p = .021$, $\eta 2 = .088$, $\beta = .643$; listening condition, $F(1, 58) = 7.606$, $p = .008$, $\eta 2 = .116$, $b = .774$; and trial block, $F(1.157, 67.094) = 259.54$, $p < .001$, $h2 = .817$, $b = 1.0$. Significant interactions were also observed for Listening Condition ×Hearing Status, $F(1, 58) = 4.432$, $p = .040$, $h2 = .071$, $\beta = .544$;HearingStatus ×TrialBlock,$F(1.157, 67.094) = 4.466$, $p = .033$, $\eta 2 = .071$, $b = .588$; and Listening Condition ×Trial Block, $F(1.554, 90.120) = 4.997$, $p = .015$, $h2 = .079$, $\beta = .727$. All other interactions were not significant. These results indicate that, overall, performance improved significantly with each exposure to the words (main effect of trial block), the children with NH learned significantly faster than did the children with HL (main effect of hearing status), the older children learned faster than did the younger children (main effect of age group), and learning proceeded faster in quiet than in noise(main effect of listening condition). The significant Listening Condition ×Hearing Status interaction indicates that the effects of noise and hearing loss combined to further reduce the performance of the children with HL relative to that of the children with NH.

The second goal of the present study was to determine the impact of DNR on word learning in children with HL. Figure 9 shows proportion correct as a function of trial for the children with HL using the same convention as that used in Figure 8, with the results of the noise reduction condition included. These results show that the performance of the younger children was the same in noise with and withoutDNR,whereas the performance of the older children in noise improved with the use of DNR. Separate repeated measures ANOVAs were

conducted for each age group to determine whether the learning functions for the noise and noise reduction listening conditions differed significantly. For both analyses, trial blocks and listening condition (noise, noise reduction) served as within-subjects factors. The analysis for the younger children revealed a significantmain effect of trial block, $F(9.000, 12.091) = 28.182$, $p < .004$, $h2 = .701$, $\beta = .998$, but not for listening condition, $F(1, 12) = 0.124$, $p = .731$, indicating that learning in noise was unaffected by DNR. For the older children, however, the analysis revealed significant main effects of both trial block, $F(9.00, 13.76) = 50.685$, $p < .001$, $\eta 2 = .809$, $\beta = 1.0$, and listening condition, $F(1, 12) = 4.881$, $p = .047$, $\eta 2 = .289$, $\beta = .528$, indicating that word learning in noise significantly improved with the use of DNR. These results suggest an age-related benefit of DNR for word learning in children with HL. Specifically, DNR had little effect on learning for children younger than 10 years but contributed significantly to word learning in children older than 10 years.

Because word learning is governed largely by a child's receptive vocabulary, the data were also examined as a function of their performance on the PPVT-III to better appreciate the effects of hearing status and listening condition. Recall that, in addition to fitting the children's data with a learning function, the analysis also provided an estimate of the number of trials needed to achieve 70% correct performance. Figure 10 shows the number of trials required by the children with NH (upper panel) and the children with HL (lower panel) as a function of vocabulary age. The parameter in each panel is listening condition. In this configuration, lower values indicate faster learning. Data points representing >500 trials to criterion were truncated. Also note that the range of vocabulary ages differed across groups, with lower vocabulary ages for the children with HL. Regression functions for each listening condition are shown as solid and dashed lines. The results for the children with NH are consistent with a number of previous studies showing that word learning proceeds more rapidly as vocabulary knowledge increases. Also, the impact of noise on this group had little effect on their rate of word learning. The results for the children with HL show that their word-learning rate was more variable overall and decreased (more trials required) in noise relative to quiet. The use of DNR, however, improved word learning and somewhat restored the relation between age and vocabulary knowledge for these children. These data indicate that for children with mild to moderately severe HL, learning rate slowed when the acoustic signal was degraded by noise but improved to rates similar to those in quiet with the use of DNR.

Factor Analysis

Although these results suggest that the age-related benefit observed withDNRmay be due to the vocabulary knowledge of younger and older groups, other factors may have contributed to the children's performance as well, particularly given the heterogeneous characteristics of this group of children. Two factor analyses were performed to identify other characteristics that might predict which children with HL are more likely to benefit from DNR. For both analyses, Varimax rotations with Kaiser Normalization were performed, yielding two-factor solutions having Eigenvalues greater than 1.Within each solution, factor loadings greater than .80 were considered salient to the interpretation of each principal component. The resulting factor scores were correlated (Pearson's r) to the children's word-learning rate. The time constant c from Equation 1 was log-transformed and was used to represent the rate of word learning (recall that 1/c is equal to the number of trials required to reach criterion performance).

In the first analysis, seven variables representing different characteristics of the children with HL were entered: three variables associated with hearing history (age at identification of HL, age at amplification, and years of hearing aid use); overall SNR in noise without DNR; receptive vocabulary (PPVT-III age); hearing level of the right and leftears (average of 2 kHz, 4 kHz, and 8 kHz); and chronological age. The analysis reduced the data to three principal components, accounting for a total variance of 85%. The principal components were found to correspond to the children's hearing history (age of identification, age at amplification, and years of hearing aid use), which accounted for 44% of the variance; age (chronological and vocabulary age), which accounted for 28% of the variance; and overall SNR, which accounted for 13% of the variance. Pearson's r correlation coefficients revealed a significant relation between word-learning rate and age, $r = .354$, $p = .049$, but not for

hearing history, r = .249, p = .126, or overall SNR, r = -.241, p =.134. The second analysis was the same as the first, with one exception-the overall SNR achieved with DNR was entered, and the overall SNR without DNR was removed. The analysis again reduced the data to three principal components, accounting for a total variance of 85%. The principal components were found to correspond to the children's hearing history (age of identification, age at amplification, and years of hearing aid use), which accounted for 44% of the variance; age (chronological and vocabulary age), which accounted for 27% of the variance; and overall SNR, which accounted for 15% of the variance. Pearson's r correlation coefficients again revealed a significant relation between word-learning rate and age, r = .480, p = .020, but not for hearing history, r = .049, p = .837, or overall SNR, r = -.199, p = .361. These results confirmed that although the children differed along a number of parameters, word learning in noise with and without DNR was significantly related to participants' chronological and vocabulary age.

Discussion

The purpose of the present study was to determine the rate of word learning in quiet and in noise for younger and older children with HL compared to their agematched, NH peers. Of particular interest were the effects of DNR on word learning in noise for the children with HL. Performance for the multitrial, dynamic, wordlearning task showed significant effects of age for the children withNHbut not for the children withHL. Closer examination of the results revealed that, in quiet, the performance of the older children with NH was well above that of all other groups and that the performance of the remaining three groups was similar. That is, the learning rate across groups was the same with the exception of the older children with NH. These results are consistent with the vocabulary age of each group (see Figure 10). Vocabulary age was similar across groups with the exception of the higher vocabulary age of the older children with NH, who consequently learned the new words faster. These results are also in agreement with the factor analysis showing that learning rate was significantly related to vocabulary knowledge.

Conversely, significant effects of listening condition (quiet vs. noise) were observed for the children with HL but not for the children with NH. In noise, the performance of the children with NH was unchanged, whereas the performance of the children with HL decreased significantly. That is, more trials were required to learn the words presented in noise than in quiet. These results are consistent with the known effects of noise on amplification and on the perception of speech in noise by children with HL (Crandell, 1993). Therefore, these results may explain, in part, why the overall vocabulary knowledge of these children was poorer than that of their agematched peers. Specifically, the acquisition of new vocabulary may be slowed in noise, reducing the value of each exposure to a newword. Over time, one would expect that the effect would become cumulative and would result in significantly reduced vocabulary knowledge for older children with HL. But this does not appear to be the case. What, then, keeps children with mild-to-moderate HL from continuing to lose ground in vocabulary development as they mature? One possibility is that children with HL are provided with-or seek out-additional exposures to a new word (e.g., verbal repetition, rehearsal, orthographic representation) in order to adopt that word into their vocabularies. These and other possibilities are areas for further research that may advance our understanding of the relation between hearing loss and critical auditory tasks such as word learning.

DNR

With the use ofDNR, the performance of the younger children with HL was unchanged, whereas the performance of the older children improved significantly. Factor analyses confirmed that characteristics of HL in children (e.g., degree of HL, hearing history) did not contribute significantly to performance. Also, word learning was not related to the overall SNR of the stimuli in noise with or without DNR, which varied as much as 10 dB across children in each age group and for both noise conditions. Onemight expect that the children receiving amore favorable SNR would enjoy a faster word-learning rate, but this was not the case. Instead, word learning was, again, related to the vocabulary knowledge of the children.

Another possible contributor to the age-related benefits of DNR is that the older children with HL were better able to perceive the nonsense words in noise. A number of studies have shownthat the speech perception of children withNHimproves in noisewith age (Elliott, 1979; Fallon, Trehub, &Schneider, 2002; Nozza, Rossman, Bond, &Miller, 1990; Scollie, 2008; Wilson, Farmer, Gandhi, Shelburne, &Weaver, 2010). Although the relation between age and speech perception in noise is less well defined for children with HL (Scollie, 2008; Stelmachowicz et al., 2007), age appears to be a strong predictor of performance (Gravel et al., 1999; Stelmachowicz, Pittman, Hoover, &Lewis, 2001). Even so, the effect of age was observed only when the children learned the words in noise when the DNR was activated. Perhaps the improvement in overall SNR(average of 2.3 dB), the reduction in overall stimulus level (average of 5.3 dB), and the older children's greater vocabulary knowledge provided the conditions necessary for the benefits of DNR to become apparent. If so, one might expect that the use of DNR for older and younger children with HL would increase the instances of tolerable noise levels and promote better word learning.

As for the younger children with HL, word learning did not improve with DNR, but it was not adversely affected, either. This result is consistent with other studies of DNR in children with HL (Auriemmo et al., 2009; Pittman, 2011; Stelmachowicz et al., 2010) and suggests that although DNR may not facilitate improved performance for auditory tasks in noise for this age group, performance is maintained. It is possible that these children may also benefit from increased listening comfort, although the long-term effect(s) ofDNRon communication is a question for further research.

Implications of the Present Study

The results of this study suggest that DNR may provide amplification with which children can tolerate and learn in noise. This notion is supported by research showing that children with HL prefer amplification with more gain in quiet listening situations and less gain in louder, noisier listening conditions (Scollie et al., 2010). Without DNR, these preferences may be satisfied through the use of a volume control on the hearing aid or the use of multiple programs that differ in overall output. Although school-age children and adolescents are able to make appropriate volume control and programming selections (Scollie et al., 2010), younger children may not. The advantage of DNR is that it can be configured to automatically activate in the presence of noise, it requires little to no intervention by the child, and it maintains optimal amplification in quiet and in noise. Without DNR, the only recourse that a child may have against the aversive effects of noise is to remove the hearing aid(s) altogether.

Limitation of the Present Study

DNR systems differ substantially across makes and models of hearing aids. The results for the present study are based on one type of noise reduction at one SNR (0 dB) in one competitor (broadband noise). The benefits of DNR to word learning would likely differ under other presentation conditions and for other types of DNR. This places pediatric audiologists in a difficult position. They must rely on research regarding specific DNR processors thatmay be outdated due to the rapid development of new technologies and the time-consuming process of pediatric research. Instead, they may wish to refrain fromusing new technologies with children until sufficient evidence is available orwhenmethods such as rapid word learning are developed for clinical use to verify the benefits ofDNRand other forms of advanced signal processing.

Acknowledgments

Sincere thanks are extended to Samantha Gustafson, Sara Bos, Kristi Petersen, Devin Anderson, and Christine Page for their help during data collection and analysis; Bob Fanning and Tom Powers for their help with early versions of the article; Bill Cole for his assistance with hearing aid analyses; Lylis Olsen, ShelbyWilla, and the audiologists at Phoenix Children's Hospital and Children's Rehabilitative Services for their help with participant recruitment; and, most of all, the children and their families for sharing their precious time. This study was funded by a grant from the American Speech-Language- Hearing Association Foundation (Clinical Research Award).

Footnote

1Phonotactic and biphone probability is the likelihood of certain phoneme sequences occurring in a particular order within a given language (Vitevitch, Luce, Charles-Luce, &Kemmerer, 1997; Vitevitch, Luce, Pisoni, &Auer, 1999). Research has shown that word learning in children is faster for higher probability words (Storkel, 2001, 2003).

Abstract: The purpose of this study was to test the hypothesis that active listening to speech would increase medial olivocochlear (MOC) efferent activity for the right vs. the leftear. Click-evoked otoacoustic emissions (CEOAEs) were evoked by 60-dB p.e. SPL clicks in 13 normally hearing adults in 4 test conditions for each ear: (a) in quiet; (b) with 60-dB SPL contralateral broadband noise; (c) with words embedded (at -3-dB signal-to-noise ratio [SNR]) in 60-dB SPL contralateral noise during which listeners directed attention to the words; and (d) for the same SNR as in the 3rd condition, with words played backwards. There was greater suppression during active listening compared with passive listening that was apparent in the latency range of 6- to 18-ms poststimulus onset. Ear differences in CEOAE amplitudewere observed in all conditions,with right-earamplitudes larger than those for the left. The absolute difference between CEOAE amplitude in quiet and with contralateral noise, a metric of suppression, was equivalent for right and leftears. When the amplitude differences were normalized, suppression was greater for noise presented to the right and the effect measured for a probe in the leftear. The findings support the theory that cortical mechanisms involved in listening to speech affect cochlear function through the MOC efferent system.

Full text: Headnote
Purpose: The purpose of this study was to test the hypothesis that active listening to speech would increase medial olivocochlear (MOC) efferent activity for the right vs. the leftear.

Method: Click-evoked otoacoustic emissions (CEOAEs) were evoked by 60-dB p.e. SPL clicks in 13 normally hearing adults in 4 test conditions for each ear: (a) in quiet; (b) with 60-dB SPL contralateral broadband noise; (c) with words embedded (at -3-dB signal-to-noise ratio [SNR]) in 60-dB SPL contralateral noise during which listeners directed attention to the words; and (d) for the same SNR as in the 3rd condition, with words played backwards.
Results: There was greater suppression during active listening compared with passive listening that was apparent in the latency range of 6- to 18-ms poststimulus onset. Ear differences in CEOAE amplitudewere observed in all conditions,with right-earamplitudes larger than those for the left. The absolute difference between CEOAE amplitude in quiet and with contralateral noise, a metric of suppression, was equivalent for right and leftears. When the amplitude differences were normalized, suppression was greater for noise presented to the right and the effect measured for a probe in the leftear.
Conclusion: The findings support the theory that cortical mechanisms involved in listening to speech affect cochlear function through the MOC efferent system.
Key Words: Click-evoked otoacoustic emissions (CEOAEs), contralateral suppression, efferent system, medial olivocochlear bundle (MOCB), medial olivocochlear (MOC) reflex, attention
The role of the efferent auditory system in auditory perception can be investigated at cochlear and brainstem levels by recording click-evoked otoacoustic emissions (CEOAEs). Recent investigations (de Boer &Thornton, 2007, 2008; Harkrider &Bowers, 2009) report that efferent (descending) contributions affect cochlear responses early in processing and are indicative of "top-down" influences. Researchers have hypothesized that the auditory efferents, including corticofugal and brainstem portions, have an initial role in tuning the cochlea to sounds critical for speech understanding (Dolan &Nuttall, 1988; Kawase, Delgutte, &Liberman, 1993;Winslow &Sachs, 1988), and thus, perception and learning.
The medial olivocochlear (MOC) efferent loop affects cochlear function via the contralateral MOC reflex (Guinan, 2006). Interneurons in the contralateral cochlear nucleus receive input from auditory nerve fibers, then cross the brainstem in the ascending tract and innervate ipsilateral MOC neurons (Rasmussen, 1946). These neurons then descend to the ipsilateral cochlea through the uncrossed olivocochlear bundle (Liberman, 1988a, 1988b) and terminate near the base of the outer hair cells (OHCs). Efferent fibers hyperpolarize OHCs, subsequently reducing their motility. The reduced OHC motility, in turn, is thought to reduce the vibration of the basilar membrane, and thereby attenuate the cochlear amplifier effect.
Many characteristics of the MOC reflex have been determined through research using electrical neuronal stimulation in experimental animal models, such as the cat or guinea pig (Galambos, 1956; Liberman &Brown, 1986). Results from these investigations demonstrate that the MOC reflex provides sharply tuned frequency-specific feedback that inhibits the gain of the cochlear amplifier (Guinan, 2006; Liberman &Guinan, 1998). This effect has been suggested to protect from acoustic trauma (Reiter &Liberman, 1995), aid in selective attention (Scharf, Magnan, &Chays, 1997), and reduce masking (May &McQuone, 1995).
In humans, the MOC reflex has been investigated using recordings of otoacoustic emissions (OAEs) during the simultaneous presentation of contralateral broadband noise (e.g., Abdala, Ma, &Sininger, 1999; Berlin, Hood, Hurley, &Wen, 1994; Collet, 1993; Collet et al., 1990). The presence of this noise will often reduce the amplitude and change the phase of the response (Guinan, 2006) in relation to the baseline recording. In normally hearing adults, the reduction in CEOAE amplitude is on the order of 1.0-1.5 dB (Berlin et al., 1994). This reduction begins within 100 ms after the activation of the suppressor and subsides once the suppressor has ceased. This effect is thought to be a product of the MOC reflex's influence on cochlear output. The strength of the MOC reflex has been shown to vary among individuals (Backus &Guinan, 2007), and the mechanisms underlying this variability have not yet been elucidated.
MOC effects have been linked to selective attention and listening in noise (e.g., de Boer &Thornton, 2007; Froehlich,Collet,&Morgon, 1993; Giard, Collet, Bouchet, &Pernier, 1994; Giraud et al., 1997; Khalfa, Micheyl,

Veuillet, &Collet, 1998; Kumar &Vanaja, 2004; Perrot et al., 2006). MOC reflex measurements during directed attention tasks suggest that the cortical efferent system modulates the cochlea. For example, de Boer and Thornton (2007) measured CEOAE contralateral suppression during passive visual, active visual, and active auditory attention conditions. In the active auditory task, participants detected tone pips within the CEOAEevoking click train while broadband noise was presented in the opposite ear. A reduced suppression effect was observed in the active listening compared with the passive listening condition. The effect of attention on the MOC reflex was observed by measuring changes in the slope of the CEOAE amplitude input-output (I-O) function. When attention was directed to the stimulus ear, the I-Ofunctionhadthe same shapeas inthequiet condition; that is, there was a release from suppression. In the other attention conditions, the slope of the I-O function was reduced. This finding suggested that the MOC activity, specifically, suppression, was inhibited due to top-down influences during focused attention to the stimulus ear.

In contrast, Froehlich et al. (1993) and Maison, Micheyl, and Collet (2001) conducted investigations in which listeners directed attention toward the contralateral ear, that is, the suppressor side, and an increase in suppression was observed. More recently, Harkrider and Bowers (2009) reported unique findings, in that suppression was reduced when participants attended either to the click stimulus or to the contralateral broadband noise. Taken together, these studies demonstrated that active listening produced modulation of the MOC reflex as reflected in the CEOAE amplitude response compared with passive listening.

Few studies have reported findings on the laterality of MOC effects (Khalfa &Collet, 1996; Khalfa, Morlet, Micheyl, Morgon, &Collet, 1997, Philibert, Veuillet, &Collet, 1998). These investigations have shown that noise presented to the leftear during stimulation of the right CEOAE produced greater contralateral suppression effects than the reverse situation. This finding has been interpreted as evidence for a more efficient right MOC reflex, or a right-ear advantage. This asymmetry of CEOAE suppression owing to the MOC reflex effects has also been reported to exist in infants older than 36 weeks of age, indicating maturity of the efferent system leading toward the development of a right-ear advantage (Morlet et al., 1999). The source of this subcortical asymmetry has not been confirmed.

These investigations provide supportive evidence that the MOC reflex may be lateralized in nature, and that the corticofugal pathway activated during attentive listening may modulateMOC activity. However, it is not clear whether or how the effects of listening to speech may influence the MOC reflex ear differences, that is, their lateralization due to cortical control. Establishing the MOC's role in hearing and perception is important for identifying mechanisms critical for speech understanding in noise.

Purpose of the Present Study

The purpose of this study was to evaluate MOC effects while participants listened for speech in noise and to determine whether these effects are lateralized. Determining the scope of cortical modulation of the periphery would enhance our current understanding of auditory processing insofar as cortical function (e.g., listening to speech) may transformthe cochlear response to specific acoustic cues critical for speech understanding. A further motivation for this study came from the finding that adults with learning disorders exhibit a laterality of their MOC reflexes that was different from typical learners (Garinis, Glattke, &Cone-Wesson, 2008). This finding suggested that ear differences in efferent function might be a marker for an auditory-processing disorder. Lagacé, Jutras, and Gagné (2010), for example, found that speech-in-noise perception is often disordered in those with auditory-processing disorder, and others (Tervaniemi &Hugdahl, 2003) found that the right-ear advantage was diminished. The present study was undertaken to assay the effect of the MOC reflex during listening for speech in noise in the right versus the leftear. The hypotheses of this study were that (a) cortical processes engaged during active listening to speech in noise increase the suppressive effect of the MOC reflex observed as a change in CEOAE amplitude and (b) MOC reflex effects lateralize and support a rightear advantage for listening to speech. Investigating how active listening affects the MOC reflex provides insight to the descending cortical control of the central auditory system on the periphery.

Method

Participants

Women with normal hearing (M = 24.6 years of age; range = 20-33) were recruited for this study. Participants were allowed to participate if they met the following criteria: (a) were 18-38 years of age, (b) had normal tympanograms using a 226-Hz probe tone, (c) had ipsilateral and contralateral broadband noise (BBN) acoustic reflex thresholds≥60-dB SPL, (d) had normal pure-tone thresholds for 500-4000 Hz for both ears, (e) had CEOAEs present for a 60-dB p.e. SPL click for both ears, (f) had no recent history of using medications that would increase lethargy or affect cognitive function, and (g) were righthanded. Twenty participants were tested, and 13 were used in the data analyses. The criteria used to exclude data were CEOAE response amplitudes less than 6 dB in four out of five 1/3-octave bands centered at 1.0, 2.0, 3.0, 4.0, or 5.0 kHz in response to an 80-dB p.e. SPL click. A pilot study indicated that very few men in the age range of 20-33 years were able to meet the fifth criterion. It is well established that there are gender differences in the prevalence and amplitude of otoacoustic emissions (McFadden, 2009). The decision to use only female participants was made in order to control for these gender differences.

Tympanometry and Acoustic Reflex (AR) Tests

A Grason-Stadler GSI-33 middle-ear analyzer was used to perform tympanometry and ipsilateral and contralateral AR threshold tests. Tympanograms were acceptable if they demonstrated a tympanometric peak pressure of ±50 daPa and static peak compensated acoustic admittance of 0.3-1.5 mmhos. Ipsilateral AR thresholds are those for which the response is obtained from the same ear to which the eliciting stimulus is presented. Contralateral AR thresholds are those for which the response is obtained from the ear contralateral to the ear to which the eliciting stimulus is presented. The AR threshold for both testing conditions was defined as the lowest level of the BBN activator needed to elicit a .03-mmhos decrease in middle-ear admittance on two consecutive trials. Thresholds were tested using BBN stimuli so as to determine whether the contralateral noise used in the experimental paradigm would activate the AR. The initial presentation level was at 75-dB SPL, and levels were increased or decreased by 5-dB increments until the AR threshold was detected. The maximum level used for this test was 110-dB SPL to avoid exposure to excessive levels of noise. Participants were excluded if AR thresholds for BBN activators were <60-dB SPL.

CEOAE Stimuli and Tests

CEOAEs were recorded using the Otodynamics ILO-88 otoacoustic emissions (OAE) analyzer, version 4.2 B software. Participants were first tested for their CEOAE response using an 80-dB p.e. SPL "nonlinear" click train. The ILO "nonlinear" click stimulus consists of three in-phase 80-ms square wave clicks followed by a fourth out-of-phase click with a 10-dB higher level. The click rate is 50 Hz. This stimulus pattern is often used in emission testing to reduce stimulus artifact that could contaminate the desired CEOAE response (Hood, Berlin, Hurley, Cecola, &Bell, 1996). The emission waveform was recorded over a 20-ms epoch, at a digitization rate of 25 kHz. Each sample is averaged in one of two memory buffers, A or B, in alternating fashion for each click train.

If a response was present for the 80-dB condition, then the stimulus level was reduced to 60-dB p.e. SPL, and the participant was retested using a "linear" click train. The Institute of Laryngology and Otology (ILO) "linear" click train has four clicks of the same phase and sound pressure level (Velenovsky &Glattke, 2002) and is often used for CEOAE tests using stimulus levels less than 80-dB p.e. SPL. Whereas the "nonlinear" click train is used to reduce the stimulus artifact, it is also known to diminish response amplitude as it subtracts out the "linear" portion of CEOAE amplitude growth. The "linear" click train was used to obtain a better estimate of the CEOAE amplitude for the contralateral suppression conditions. The use of the "linear" click train is recommended in contralateral suppression experiments (Hood, 2007).

ACEOAEwas considered present if a response spectral peak was apparent at ≥3 dB above the noise floor for 1/3-octave bands in the 1.0 kHz-5.0 kHz range, had a response amplitude of 6-dB SPL, and had a wave

reproducibility of >85%for at least 4/5 bands. Response amplitude was estimated in two ways. First, response, or "R" amplitude, is defined as the overall level of the correlated portions of the two CEOAE waveforms held in memory buffers, A and B. For every stimulus, samples of CEOAE are allocated to the two buffers in alternating fashion. Second, A + B is the average amplitude of the waveforms stored in buffers A and B. The difference waveform, A - B, gives an estimate of the noise floor. Wave reproducibility is calculated as the point-to-point correlation of the waveforms stored in two memory buffers, A and B.

Contralateral Noise Stimuli

All participants who had CEOAEs at 60-dB p.e. SPL and met the response criteria were then tested for contralateral suppression effects in three separate noise conditions. Each noise condition was preceded by a "no noise" or control condition, for a total of seven recordings per ear (three noise, four control). The following noise conditions were measured for each participant:

* BBN alone: 60 dB SPL of continuous BBN was presented to the contralateral ear during CEOAE recordings.
* BBN + W: Spoken words were embedded in 60-dB SPL continuous BBN, at a signal-to-noise ratio (SNR) of -3 dB relative to the noise and at an interstimulus interval that averaged 1,500 ms. Participants were required to attend to the words and classify them as animal or food items using a two-interval forcedchoice button press response. This was the active listening condition.
* BBN + BW: The same words as in the previous condition were played backwards and embedded in the 60-dB SPLcontinuousBBNat an SNRof -3dBrelative to the noise. This was a passive listening condition.

Stimuli for each noise condition were constructed using MATLAB 7.4 R2007a. The BBN was then scaled so that its root-mean-square (RMS) value was 3 dB (or 1.414 ×mean) greater than the words spoken by male and female voices. This audio scaling procedure was used for both the BBN +Wand BBN +BWconditions. All stimuli for the noise conditions were played through a Maico MA 41 portable audiometer and presented to the contralateral ear at 60-dB SPL via an ER-10 insert earphone.

Calibration

All stimuli were calibrated using a Larson Davis System 824 SPL analyzer with a 1⁄2-in. microphone Model #2540 configured in a 2-cc coupler. The click stimuli were calibrated using the peak-to-peak equivalent method of equating the amplitude of a click to that of a 1000-Hz pure tone and measuring the SPL of the pure tone (Glattke, 1983).

Experimental Procedure

All tests were conducted in a sound-insulated chamber. Participants first had pure-tone threshold tests for the frequencies of 500-4000 Hz using a Maico MA 41 portable audiometer. Those who met the hearing threshold criteria (reported above) also completed tympanometry, AR threshold tests, and CEOAE tests. Only those participants who had CEOAEs present at 60-dB p.e. SPL bilaterally went on to complete the experiment testing for the MOC reflex using a CEOAE contralateral suppression paradigm.

All sevenCEOAEtests (four in quiet, three with contralateral noise) were completed for both the right and leftears separately, with the order of noise conditions randomized for each ear, and the order of ear tested randomized across participants. Participants were instructed to remain still and quiet throughout the experiment in order to avoid displacement of the ILO probe in the ear canal.

Strict criteria were used to control for noise and reduce its contamination in the experimental conditions. First, the "stability" of the stimulus, as determined by ILO software, was maintained at 70% or better. This software feature records the stimulus level in the ear canal at the onset of testing and subsequently monitors the level throughout the acquisition period (Glattke &Robinette, 2007). If the stability fell below that level during a test, then that trial was aborted and restarted. Second, an amplitude-based artifact rejection level of 35-dB SPL was used throughout testing. Third, the responses were sampled until 1,600 artifact-free samples were obtained in each test condition. Given the strict artifact rejection criterion and the oversampling used to reduce the noise levels in the averaged sample, each trial took, on average, 4 min. With seven trials for each ear, the CEOAE

experimental protocol took about 1 hr to complete for each participant.

A control trial was run after each noise condition. That is, the stability of the CEOAE amplitude, reported as bothR andA + B, and the noise (A - B) were measured with clicks alone (no contralateral noise) in order to ensure that the CEOAE amplitude and noise were constant throughout the experiment.

For the active listening (BBN + W) condition, the Direct RT-v.2007 (Jarvis, 2007) software program was used to monitor responses and measure accuracy throughout testing. It was possible for the investigator to monitor the response accuracy (the categorization of spoken words as food or animal) during the test and obtain a running score. If response accuracy fell below 85%, the trial was aborted and repeated after reinstructing the listener.

Data Analyses

CEOAE "R," A + B, and A - B amplitudes were measured. These values are calculated by the ILO-88 software in dB SPL (re: 20 mPa). Response amplitude is defined as the overall level of the correlated portions of the A and B memory waveforms. "A + B" amplitude is the RMS amplitude of the A and B memory waveforms, and "A - B" is the RMS amplitude difference between the A and B waveforms (Glattke &Robinette, 2007).

The strength of the MOC reflex using CEOAE contralateral suppression was measured in two ways: First, the difference between response amplitude in quiet and response amplitude with contralateral noise was calculated for each of the quiet (control) and noise (suppression) conditions. Second, the RMS amplitude of the difference waveform, in dB, obtained by subtracting the waveform in noise from the waveform in quiet was calculated using the EchoMaster 312 software program (Wen, Berlin, Hood, Jackson, &Hurley, 1993). The RMS amplitudes of the difference waveforms were analyzed in 2-ms time increments over a 12-ms response window, commencing at 6 ms after the click onset.

Differences inCEOAEresponseamplitude for each test condition and for each ear were analyzed using repeated measures analyses of variance (ANOVAs). Paired t tests were used in further analyses of the differencewaveforms among three noise conditions from right versus leftears.

The Human Subjects Protection Program for social and behavioral sciences at the University of Arizona approved this experiment.

Results

CEOAE Amplitude

There are two ways in which amplitude can be calculated. First, the value "R" (in dB SPL), calculated by the ILO-88 software, is the overall level of the correlated portions of the two waveforms (A and B) that are obtained during response recording (alternate sweeps are assigned to an A or a B memory buffer). Second, the summed average of the responses in the A+B memory buffers is calculated. The two estimates of CEOAE amplitude for all control (quiet) and test (noise) conditions are shown in Table 1. CEOAE response amplitudes in quiet were larger for the right ear (M= 12.62 dB SPL, SD = 3.42) compared with the leftear (M = 11.12-dB SPL, SD = 3.60). It should be noted that there were no statistically significant differences between the "R" and "A + B" estimates of CEOAE amplitude.

The amplitude estimates for the four control conditions for each ear were subjected to a paired t test to determine whether the ear-related amplitude differences were significant. The results of this test indicated a mean difference of 1.5 dB between the right and leftears, and this was statistically significant, $t(51) = 5.36$, $p < .0001$.

We also calculated the A - B values, that is, the residual noise amplitude estimates. The ILO-88 software estimates the noise amplitude as the difference between the averaged responses (waveforms) held in the A and B buffers. These estimates are shown in Table 1 for each of the control conditions.We used paired t tests to determine whether there were right- versus left-ear differences in noise level. The mean difference was -0.04, and this was not statistically significant, $t(51) = -0.29$, $p = .77$.

The results of the analyses of CEOAE amplitude in the quiet conditions indicate that the right-ear CEOAE amplitudes are larger than those for the leftear. They also suggest that there are no ear differences with respect

to noise contamination that could contribute to the right-ear amplitude advantage. That is, it is possible that one ear might be noisier than another, owing to anatomic and physiologic asymmetries in noise sources (e.g., heart, lungs, airway, and movement during testing). As all CEOAE amplitude estimates are essentially response + noise estimates, it is important to show that noise was controlled in these experiments. By using a strict artifact rejection criteria and by averaging 1,600 responses, the noise levels were equivalent for the two ears and across the four control conditions.

We also evaluated CEOAE amplitude estimates for each of the contralateral noise conditions. Themean, standard deviation, and range of response (R) and A + B amplitude estimates in each noise condition are shown in Table 1. Figure 1 displays the mean response amplitude as a function of condition (quiet or noise) for each ear. The introduction of contralateral noise caused a reduction in CEOAE amplitude, which was 2.65 dB for the right ear and 2.57 dBfor the leftear. In all noise conditions, the right-ear response amplitudes were larger than those of the leftear, $F(1, 12) = 35.1$, $p < .0001$. The CEOAE right- versus left-ear amplitude difference found in quiet is maintained in the suppressed condition.

During the active listening task, participants were required to make a two-alternative forced-choice (2AFC) response by depressing a response button as theMOC reflex was measured. It might be anticipated that this would increase the noise and thus contaminate amplitude estimates. A repeated measures ANOVA revealed no statistically significant differences in noise amplitude estimates as a function of condition.

The noise amplitude estimates do not appear to vary as a function of listening condition, and an ANOVA for the effect of condition or ear on noise levels does not allow rejection of the null hypothesis, $F(1, 2) = 0.56$, $p = .57$. Again, with the strict artifact rejection criteria and the oversampling, we controlled noise contamination across all experimental conditions.

A primary focus of this investigation was to determine whether listening to speech would modulate the MOC reflex. The CEOAE amplitude estimates for each listening condition are shown in Figure 1. Differences in the amount of suppression for passive (BBN, BBN +BW) versus active listening (BBN+W) were not evident in the CEOAEamplitude estimates. Theamount of suppression or the amplitude difference between no-noise and noise conditions was, on average, 2.6 dB for both the right and leftears. For example, the right-earCEOAEamplitude in quiet was 12.6 dB, and with a BBNsuppressor, 9.95 dB, a change of 2.65 dB, whereas for the left-ear amplitudes, they were 11.04 dB SPL in quiet and 8.47 dB SPL with contralateral BBN, a difference of 2.57 dB.

CEOAE RMS Amplitude Differences

We also calculated CEOAE contralateral suppression as the RMS amplitude of the waveform derived from the CEOAE obtained in quiet minus the CEOAE obtained when contralateral noise was present. We used the CEOAE obtained in the quiet condition preceding each noise condition for these measures of suppression. We analyzed the RMS amplitude of the difference waveform, in dB, in 2-ms intervals, using the 6- to 18-ms poststimulus portion of the waveform. The 6- to 18-ms epoch has been shown to reflect maximum suppression effects (Hood et al., 1996), and the mean RMS amplitude of the difference waveforms for this epoch is shown in Figure 2. For right-ear responses, the mean amount of suppression in this epoch was 3.14 dB (SD = 1.7) for the BBN condition, 3.11 dB (SD = 1.8) for BBN + BW, and 3.32 dB (SD = 1.9) for BBN + W. For left-ear responses, the amount of suppression was 2.8 dB (SD = 1.8) for BBN, 2.7 dB (SD = 1.9) for BBN + BW (SD = 1.9), and 3.0 dB (SD = 1.8) for BBN + W. We used the amplitudes of the difference waveforms (between 6 and 18 ms) in paired t tests to evaluate the differences in RMS amplitude (suppression) that occurred as a function of noise conditions. These comparisons made were for BBN versusBBN+ W,BBN versusBBN+BW, andBBN+Wversus BBN + BW. Greater suppression was evident in the active listening (BBN + W) condition compared with the passive listening conditions: BBN, $t(12) = 2.311$, $p < .05$; and BBN + BW, $t(25) = 2.667$, $p < .05$. There were no statistically significant differences in the amount of suppression for the two passive listening conditions, BBN versus BBN + BW, $t(12) = 0.667$, $p = .51$. This was a different result than was found for the analysis of whole

wave amplitude (see the previous section). Because this second analysis focused on the portion of the waveform in which suppressive effects were largest, it was possible to discern a difference in suppression related to active versus passive listening conditions.

There were no ear differences in the amount of suppression when considered as the RMS amplitude (in dB) of the difference waveform, or the difference in whole wave amplitudes in quiet versus noise conditions. Yet, the left-ear CEOAE amplitudes were significantly lower than those for the right ear in all conditions (quiet or contralateral noise). This suggested that there was a difference in the relative size of the suppression effect. That is, in all conditions, the right-ear CEOAE is, on average, 1.54 dB larger than those from the leftear. If the MOC reflex produced exactly the same fractional change in CEOAEs from both ears, then the values from the right ear would be 1.54 dB larger than those from the left; however, they are only 0.4-0.5 dB higher (see Figure 2). This implies that the efferent effect in the right ear is actually nearly 1 dB less than in the leftear. Another way to calculate this effect is to convert values from decibels (which expresses a ratio of two pressures on a log scale) to absolute pressure. The RMS amplitude of the difference waveform was converted from dB to absolute pressure using a 20-mPa reference. Similarly, the response amplitudes shown in Figure 1 and Table 1 were also converted to absolute pressure using the same reference. For each participant, the difference waveform pressure was divided by the whole wave pressure in order to normalize the relative amount of pressure (amplitude) change in the various noise conditions. So, for example, using one participant's response amplitude estimates, CEOAE amplitude in the no-noise condition was 16.15 dB. The RMS difference waveform (no-noise response-BBN response) had amplitude of 3.14 dB. Converting both values to pressure 3.14 dB = 28.71 mPa, and 16.15 = 128.39 mPa. The ratio of the pressure of the difference waveform and the pressure of the responsewaveform, 28.71 mPa/128.39 mPa = 0.22. So, the normalized amplitude change (suppression) was 22%. This was done for every participant individually (not just the group means).

The results of these transforms are shown in Figure 3. The values on the ordinate are the ratio of pressure change when the pressure differences are considered as a proportion of the whole wave pressure. The relative amount of pressure change (suppression) was greater for the leftear (noise right) for all conditions. On average, the relative amount of suppression was 44% for the leftear and 38% for the right ear.

Time Course of Suppression

We measured the amount of suppression as a function of time by considering the average amount of suppression in each 2-ms interval in the 4- to 18-ms interval of the CEOAE waveform. The mean values for each listening condition are plotted in Figure 4. In general, there is a linear growth in amplitude of the difference waveform (i.e., the amount of suppression) at a rate of 0.2 dB/ms over the 6- to 18-ms waveform analysis window, from 1.75 dB to 4.25 dB. The cochlear site of CEOAE generation is thought to be reflected time-domain waveform (Kemp, 2002; Norton &Neely, 1987). The earlier portion of the waveform contains high-frequency response components and the later portions, low-frequency components. Converting the time-domain waveform to a spectral analysis suggests greater suppression in the 1500- to 2000-Hz region compared with the high (4000-5000 Hz) region.Acomplementary interpretation is that all MOC effects on transient responses grow with time after the acoustic stimulus (Guinan &Cooper, 2008), no matter what their frequency content.

AR Thresholds

We performed ipsilateral and contralateral AR thresholds tests for all participants. Two participants had no measurable ARs for either ear at the maximum stimulus level of 110 dB SPL. The mean ipsilateral AR threshold was 72 dB SPL (SD = 7.97) for left-ear responses and 71.5 dB SPL (SD = 8.0) for right-ear responses. The mean contralateral reflex threshold was 76 dB SPL (SD = 8.7) for the right ear and 75 dB SPL (SD = 5.0) for the leftear. A two-way ANOVA indicated there were no significant differences in AR thresholds as a function of ear (right vs. left) or contralateral versus ipsilateral activation stimulation modes. It is important to note that the mean AR threshold for a BBN activator was 12 dB SPL above the noise levels used for the CEOAE suppression conditions.

Discussion

In the present study, we investigated the effects of listening to speech and laterality on the MOC reflex using a CEOAE contralateral suppression paradigm. We predicted that a stronger MOC reflex (more contralateral suppression) would be evident during active listening to speech, when compared with responses from the passive, contralateral BBN and BBN +BWlistening conditions. We also hypothesized that laterality effects would be present, with right-ear responses showing greater MOC activity reflecting a right-ear advantage at the level of the cochlea. The results supported the first hypothesis in that more suppression was evident in the active listening condition than in the passive listening conditions. This effectwas evidentwhen the portion of the response waveform most sensitive to suppression effects, at 6-18 ms, was analyzed. The second hypothesis was only partially supported. Right-ear CEOAE amplitudes were larger than left-ear amplitudes in all conditions. The amounts of suppression, measured as the CEOAE amplitude differences in dB, for quiet versus contralateral noise conditions, were not different for the right versus the leftears. When the noise-induced amplitude decrements (in the 6- to 18-ms waveform interval) were recalculated in absolute pressure change and normalized by each listener's CEOAE amplitude in quiet, the relative change in amplitude was proportionally greater when noise was presented to the right ear and the effect measured for a probe in the leftear.

Effects of Listening to Speech on the MOC Reflex

The phenomenon of contralateral CEOAE suppression has been linked to the function of the contralateral MOC reflex loop located in the caudal pons (Berlin et al., 1994; Collet, 1993). The MOC reflex, as it has been termed, is thought to be responsible for these changes in OAE amplitude. Measurement of MOC reflex during active listening, using an OAE contralateral suppression paradigm, provides evidence of cortical influences upon the periphery. The findings of the present study are in line with past research: Specifically, a 2- to 3-dB SPL reduction in CEOAE amplitude was evident in all contralateral noise conditions, indicative of MOC influence on OHC output. Most important, the greatest amount of contralateral suppression was evident while actively listening to speech.

The active listening condition required semantic knowledge in order to classify the spoken words as animal or food items. This requires a greater cognitive demand than the tone detection tasks used in previous research. For example, Froehlich et al. (1993) found a reduction in CEOAE amplitude when an attention task was used during CEOAE measurement. Participants pressed a button when the desired auditory toneburst (2800 Hz) was detected during the train of clicks used to evoke the CEOAE. A significant decrease in CEOAE amplitudewas measured in the 1920- to 2880-Hz response band during the attention task, but not during passive listening. Maison et al. (2001) used a CEOAE contralateral suppression paradigm, with the target stimulus embedded in the suppressor noise, to examine attention effects on the MOC reflex. The contralateral noise condition resulted in greater suppression of theCEOAE. In contrast, de Boer and Thornton (2007) found the least amount of suppression during an active listening task in comparison to passive auditory, passive visual, and active visual tasks. In the active listening task, participants detected tone pips embedded in the CEOAE-evoking click train while noise was presented to the other ear. Their attention paradigm was similar to that used by Froehlich and colleagues; however, listeners in the de Boer and Thornton study were required to direct attention to the probe (ipsilateral) ear instead of the nontest (contralateral suppressor) ear. This change in task may explain the difference in findings. More recently, Harkrider and Bowers (2009) found that CEOAE amplitudes increased slightly during active listening, indicating a release from suppression, when the participant attended to either the probe or suppressor ear. Their listening task differed for the two ears, however. When attending to the probe ear, the participants were required to count the number of pulse trains that they heard. This required vigilance to the probe stimuli, unlike other paradigms in which the target stimuli (tone pips) were embedded with the probes. When attention was directed to the suppressor (contralateral ear), listeners were told to listen for speech embedded in noise, although none was present. There are substantial differences in the methods investigators

have used to engage active listening or attention while recording CEOAEs. It may be that task difficulty influences the MOC efferent reflex (suppression) effect. This is suggested by de Boer and Thornton (2008), who showed that listeners who successfully learned to perceive speech in noise also showed changes in the amount of the suppression measured while listening to speech in noise.

The present work is consistent with previous studies suggesting that active listening modulates cochlear output through the MOC reflex. Attention directed to the probe ear from which CEOAEs are being measured appears to cause some release from suppression (e.g., de Boer &Thornton, 2007), whereas directed attention to the suppressor ear appears to enhance the suppressive effect (Maison et al., 2001; see also present results). There also appears to be some frequency selectivity of the suppression effect during active listening in that it was only possible to discern an increase in suppression when CEOAEs were filtered, that is, when the 6- to 18-ms portion of the waveform was selected for detailed analyses.

TheMOCreflex effectively reduces the output of the cochlea and raises the threshold for increased firing of auditory nerve fibers (Guinan, 2006). The psychophysical equivalent of this may be the "central masking" effect, whereby psychophysical thresholds for pure tones are increased 5-7 dB when low-level noise is introduced to the contralateral ear (Mills, Dubno, &He, 1996; Zwislocki, 1972). However, the introduction of noise would also raise the neural threshold for signals presented to the suppressor ear. Guinan suggests that the activation of the MOC reflex in a noisy environment, that is, when noise is presented binaurally, enhances the dynamic range by a mechanism known as "MOCB unmasking." Unmasking occurs because MOC efferents can inhibit the response to a noise masker, thus subsequently increasing the audibility of transient sounds like speech. Thus, the activation of the MOC efferents of the masked or suppressor ear serves to improve the dynamic range and SNR for that ear. The amount of suppression in the contralateral ear is something of an epiphenomenon for the effect of interest, which is the enhancement of SNR for the ear that is listening in a noisy environment. In the case of the present experiment, suppressor noise and words were played to one ear, and the CEOAE amplitude was monitored contralaterally. A stronger MOC reflex was evident during active listening in this condition. The MOC reflex is bilateral, and so evidence of increased suppression in the probe ear indicates that that suppression is increased in the suppressor ear, reducing the masking effects of the BBN, and perhaps improving the SNR for the target words.

This theory ofMOCefferent function has been borne out by the results of Kumar and Vanaja (2004), who reported that stimulation of the efferent system by use of contralateral noise was associated with an improvement in speech identification scores while listening in a noisy environment. As further proof of MOC involvement in improving speech-in-noise understanding and corticofugal connections, de Boer and Thornton (2008) found correlations between activation of the MOC reflex and phoneme-in-noise discrimination abilities in a group of normally hearing adults. Those with the poorest abilities on the first day of training and who subsequently showed the most improvement after training also showed an increase in MOC activity with training. Findings from these investigations provide evidence that MOCBmediated activity supports speech-in-noise perception.

Studies in which experimental animals are used have revealed that neural firing in response to tone bursts at mid-high frequencies is strongly affected by (electrical) activation of the MOC reflex (Liberman &Guinan, 1998). In a noisy environment, the activation of MOC efferents would be expected to result in greater antimasking properties in this frequency range. In humans, greater suppression is observed in the 6- to 18-ms portion of the CEOAE response (Collet et al., 1990; Hood et al., 1996), which corresponds to the 1 kHz-4 kHz frequency range (Kemp, 2002; Norton &Neely, 1987). Again, in a noisy environment, the activation of the MOC efferents could subsequently enhance mid-high frequency sound information for cortical processing (Giraud, Collet, Chéry-Croze, Magnan, &Chays, 1995). This improvement in SNR produced by MOC activation is thought to improve the understanding of speech (Kawase et al., 1993; Kawase &Liberman, 1992; Liberman, 1988b) and perceptual intensity discrimination (Micheyl, Perrot, &Collet, 1997) in the presence of ambient noise. Although

the broadband nature of MOC reflex activation has recently been demonstrated (Lilaonitkul &Guinan, 2009) for passive listening conditions, it is possible that frequency-specific effects are engaged during active listening. The present investigation supports the theory of top-down modulation, that is, corticofugal influences, on the peripheral auditory system, particularly while listening for speech in noise. Participants had greater suppression in the active attention listening condition compared with the passive listening (BBN or BBN + BW) conditions. Even more compelling is the complexity of the attention task used. In past investigations, the attention task was usually detection of tonebursts embedded in noise, or a sham speech condition (Harkrider &Bowers, 2009). We used semantically meaningful stimuli in the present study requiring directed attention during MOC reflex testing. We found more contralateral suppression in this investigation during active listening condition when participants were asked to respond to semantically meaningfully stimuli.

The present results may be a reflection of cortical influences on the periphery that are specific to language. The ability to categorize between food versus animal items required a semantic understanding of speech stimuli, and an ability to categorize words. It may be that cortical efferents from left-hemisphere language centers, such as planum temporale (Alain, 2007; Zheng, 2009) and that project to brainstem were more strongly activated forBBN+W. Although theMOCefferents have a primarily inhibitory function once stimulated, input from the cortex may adapt the amount of inhibition occurring at the level of the cochlea. The present findings provide evidence for an adaptiveMOC function via cortical inputs. Thus, the type of stimuli used to engage attentionmay influence the magnitude of this effect. An investigation of MOC reflex during active listening using nonsense words and nonspeech items with temporal and spectral complexity appears warranted to further clarify the role of corticofugal modulation of cochlear function.

Lateralities (or Asymmetries) in the Auditory System

Lateralities, or asymmetries, in the auditory system have been established at peripheral, brainstem, and cochlear levels. At the cochlear level, asymmetries have been established for OAE responses (Khalfa &Collet, 1996; Morlet et al., 1999; Sininger &Cone-Wesson, 2004): OAEs for the right-ear OAEs are consistently larger than for the left. This was also observed in the present investigation with larger response amplitudes for right-ear CEOAEs versus left-ear responses in all conditions. Several theories have been proposed for this asymmetry, including anatomical differences in cochlear structure and/or differences in afferent and efferent innervations (Xiao &Suga, 2005). For example, gender differences in CEOAE amplitudes have been observed pertaining to cochlear structure and function (McFadden, 2009). Male versus female differences in cochlear length have been cited as a factor contributing to OAE differences observed in females versus males (Bowman, Brown, &Kimberley, 2000; Don, Ponton, Eggermont, &Masuda, 1993; Morlet et al., 1996). Investigations of animals have indicated that longer cochleae appear to have more inner and outer hair cells than do shorter cochleae (Bohne&Carr, 1979). It may be that cochlear length contributes directly to the number of sensory cells aligning the basilar membrane. The number of hair cells may have a direct effect on OAE asymmetries observed. A thorough understanding of the anatomical and the physiological mechanisms contributing to asymmetries of OAE amplitudes remains elusive at present. The contribution of the MOC efferents to these asymmetries is yet unknown. The results of the present study are in conflict with past work regarding asymmetries observed during contralateral CEOAE suppression. Khalfa and Collet (1996) reported greater suppression for CEOAEs evoked from right (, 1.4 dB) versus left(, 0.7 dB) ears in the presence of 30-dB SL contralateral noise. In the present study, an equal amount of suppression, , 2 dB, was observed for right- and left-ear responses. Again, differences in methodology likely contribute to differences in results. In the present study, we used 60-dB SPL of contralateral BBN to stimulate efferent effects, whereas Khalfa and Collet's noise levels were 30 dB SL. Also, only right-handed women were tested in the present investigation, whereas males and females participated in the Khalfa and Collet experiment. In that men and women show differences in CEOAE amplitude (McFadden, 1993; McFadden, Martin, Stagner, &Maloney, 2009), this may also pertain to suppression effects, and so the present results would vary from those studies in which both genders were used

as participants. Both the present investigation and Khalfa et al. (1998) are in agreement that CEOAE amplitude asymmetries observed in quiet do not predict the size of the MOC suppression effect. The present study showed that CEOAE amplitudes in quiet were larger from rightcompared with left-ear responses. The amount of suppression, measured as the difference in response amplitude or the amplitude of a difference waveform, was equivalent for the right and leftears. Yet, when considered as a normalized proportion of the unsuppressed response, the leftear had greater contralateral suppression than the right ear. The greater suppression for the leftear, effectively decreasing the neural input to higher levels of the auditory system, would result in an advantage for information from the right ear (e.g., words embedded in suppressor noise). This would result in a "right-ear advantage" in this type of listening situation.

There are a number of complexities, however, in determining whether one ear demonstrates an "advantage" over the other. Right-ear CEOAE amplitudes are larger in all listening conditions. If suppressor noise is presented to the leftear with the probe stimulus in the right, is there relatively less effect because the output of the leftear is lower to begin with? Is the larger proportional suppression observed when noise is right and probe is leftdue to the effect of the "stronger" right-ear response to the noise suppressor or the weaker left-ear response to the probe? Further experimentation is needed to evaluate the absolute and relative amount of suppression measured when the ears are tested with probe stimuli that yield equal amplitude responses.

AR

ARs, another indicator of efferent function, were measured for each participant. All participants had AR thresholds that exceeded the level of BBN noise used to produce suppression (60-dB SPL). It is not possible to completely rule out the contribution of ARs to the CEOAE effects obtained. It is well established that the stapedius muscle effects cochlear input and output at levels of stimulation that are well below those that cause a change in middle-ear impedance (Eliasson &Gisselson, 1955; Simmons&Beatty, 1962). Concomitant recording of CEOAEs with acoustic reflectance measures may shed light on the contribution of the stapedius muscle reflex to cochlear input-output functions.

Conclusions

The MOC reflex is modulated by active listening requiring attention to semantically meaningful speech. This finding provides evidence of descending cortical control at the cochlear level and suggests that the efferent systemmay have a role in filtering irrelevant acoustic informationwhenattention is directed to speech.Whether or not the same effects would be found for active listening to temporally and/or spectrally complex nonspeech stimuli should be tested empirically. A direct comparison of suppression effects during active listening to probe versus suppressor ear and also for conditions in which noise may be present in both ears would contribute to the understanding of MOCB mechanisms subserving auditory attention, specifically for "figure-ground" problems such as speech perception in noise.

The experimental protocol used for the present investigation of CEOAE suppression has also been used for recording auditory brainstem responses and obligatory cortical auditory-evoked potentials to determine whether the effects of contralateral suppression and active listening observed at the cochlear level were evident at higher levels of the auditory system. The findings will be presented in a subsequent article.

Acknowledgments

Andrew Lotto, Brad Story, David Velenovsky, and Mark Bergstrom provided useful discussion, critique, and technical assistance for this investigation and present article. We gratefully acknowledge their contributions. Portions of this work were presented at the Association for Research in Otolaryngology (ARO), 31st Annual Midwinter Meeting (February 2008; Phoenix, AZ) and at the American Auditory Society Annual Meeting (March 2008; Phoenix, AZ).

Abstract: In this study, the authors evaluated a processing algorithm aimed at improving speech recognition via the telephone among older adults with sensorineural hearing loss (SNHL). Thirty older adults with SNHL participated. Speech recognition was measured in quiet using the Modified Rhyme Test (MRT; Kreul et al., 1968) and the Speech Perception in Noise (SPIN; Bilger et al., 1984) sentences, and in noise using the Quick Speech in Noise (QSIN; Killion et al., 2004) test. Each test was presented via the telephone with and without processing. Significant improvements in recognition performance due to processing were observed for the SPIN and QSIN. The improvement on the QSIN was significantly greater than on the MRT and SPIN, likely because the MRT and SPIN sentences were presented in quiet, whereas the QSIN was presented in noise. Significant improvements in recognition performance were observed for both an offline version and a real-time version of the algorithm relative to the unprocessed condition, although no difference was noted between the 2 versions. Results indicate that preprocessing the acoustic signal is a viable method of improving speech recognition via the telephone. The algorithm has the potential to benefit older adults with SNHL who struggle to communicate via the telephone with or without hearing aids.

Purpose: In this study, the authors evaluated a processing algorithm aimed at improving speech recognition via the telephone among older adults with sensorineural hearing loss (SNHL).
Method: Thirty older adults with SNHL participated. Speech recognition was measured in quiet using the Modified Rhyme Test (MRT; Kreul et al., 1968) and the Speech Perception in Noise (SPIN; Bilger et al., 1984)

sentences, and in noise using the Quick Speech in Noise (QSIN; Killion et al., 2004) test. Each test was presented via the telephone with and without processing.
Results: Significant improvements in recognition performance due to processing were observed for the SPIN and QSIN. The improvement on the QSIN was significantly greater than on the MRT and SPIN, likely because the MRT and SPIN sentences were presented in quiet, whereas the QSIN was presented in noise. Significant improvements in recognition performance were observed for both an offline version and a real-time version of the algorithm relative to the unprocessed condition, although no difference was noted between the 2 versions.
Conclusions: Results indicate that preprocessing the acoustic signal is a viable method of improving speech recognition via the telephone. The algorithm has the potential to benefit older adults with SNHL who struggle to communicate via the telephone with or without hearing aids.
Key Words: hearing impairment, speech recognition, telephone
For older adults, communication via the telephone may be complicated by reduced audibility of the telephone signal due to hearing loss (Cruickshanks et al., 1998).This complication can be further exacerbated by two limitations inherent to telephone communication itself: a limited acoustic signal from the telephone and total reliance on the auditory signal due to a lack of visual cues.The frequency response range of a landline telephone is commonly accepted as 300-3300 Hz (Rodman, 2003). The reduced bandwidth of the telephone signal results in missing acoustic energy needed to correctly recognize speech. The dynamic range of the telephone is also limited in that an amplified acoustic signal will likely be peak clipped, thereby introducing nonlinearity and/or distortion. In addition, communication via the telephone forces the listener to rely solely on the auditory signal without the benefit of visual cues. Considerable improvement in speech recognition occurs when visual speech cues are available to supplement the auditory information (Helfer, 1998; MacLeod &Summerfield, 1987). The lack of visual cues, reduced audibility due to hearing loss, and a limited acoustic signal all interact, causing difficulty understanding speech over the telephone.
Existing options available for improving the audibility of the telephone signal for listeners with hearing impairment (HI; e.g., amplified telephones, telephones with a volume control, hearing aids with and without telecoils) are dependent on their use by the individual with HI. Another option is to preprocess the acoustic signal before it reaches the listener with HI. The option of amplifying the telephone signal through preprocessing is particularly relevant for community service agencies (e.g., community assistance programs) and medical organizations (e.g., telehealth) that experience difficulty communicating with older adults with HI. The idea of preprocessing a telephone signal is not new. For example, Terry et al. (1992) used digital signal processing to provide frequency shaping and compression to improve the audibility and intelligibility of the telephone signal for listeners with HI. Results revealed significant improvements in speech intelligibility for the frequency shaping with and without compression compared with the control condition. Terry et al. also obtained preference judgments regarding processing strategies presented through the telephone. The majority of subjects preferred a form of preprocessing over linear amplification. The results from Terry et al. suggest that preprocessing of the telephone signal is a viable method of improving speech recognition for listeners with HI.
The Departments of Speech andHearing Science and Electrical and Computer Engineering at The Ohio State University have collaborated to develop a computerbased telephone speech-enhancement algorithm (TSEA; Komattil, 2004; Natarajan, 2002; Poling, 2004; Sheffield, 2000). The TSEA is based on a hearing aid compressionprocessing algorithm aimed at preserving spectral contrast within the speech signal (Tejero-Calado, Rutledge, &Nelson, 2001) that was chosen, in part, to amplify the signal without introducing peak clipping. Motivation for development of the TSEA stems from the need to improve telephone communication between community service agencies (e.g., community assistance programs, telehealth) and older adults with HI. In a community assistance program situation, the TSEA is intended to be activated on the "counselor end" in order to assist with speech recognition on the "client end." The TSEA can also be implemented in this manner within the emerging telehealth domain, which has become increasingly utilized over the past decade (Koch,

2006). Difficulty communicating with health care professionals via the telephone has been reported as a concern by older adults (Iezzoni,O'Day, Killeen,&Harker, 2004). The ability of a health care professional to enhance the speech signal via the telephone has the potential to greatly improve communication with older adults with HI. The purpose of the present study, therefore, was to evaluate the effectiveness of the TSEA at improving speech recognition of older adult listeners with HI via the telephone in a group of older adults with sensorineural hearing loss (SNHL). A secondary purpose of the study was to compare telephone recognition performance between the original offline version of the algorithm and an updated version that can be run in real time.

Method

Subjects

Thirty older adults (16 female, 14 male), ranging in age from 55 to 70 years, participated in the present study. Twenty of the subjects (11 female, 9 male) participated in Experiment 1, and all 30 participated in Experiment 2. Inclusion criteria included (a) a bilateral, moderate to severe SNHL (i.e., air and bone conduction thresholds within 10 dB at 250-4000 Hz); (b) normal otoscopic findings; (c) tympanometry within normal limits (Wiley et al., 1996); and (d) English as a first language. Figure 1 presents mean pure-tone thresholds for all subjects. All subjects were recruited from The Ohio State University Speech-Language-Hearing Clinic research database and employee e-mail advertisements. The present study was approved by the Behavioral and Social Sciences Institutional Review Board at The Ohio State University.

TSEA

The TSEA is based on a hearing aid compressionprocessing algorithm (Tejero-Calado et al., 2001) adapted by Natarajan (2002) for the present study. The TSEA is a multichannel compression algorithm aimed at preserving spectral contrast within the speech signal. The processing reduces the typical amplitude variations in speech, allowing relatively low-amplitude consonant sounds to be amplified to audible levels while higher amplitude vowel sounds remain comfortably loud. It also preserves the spectral contrast by maintaining spectral peak-to-valley ratios between loud and softvariations in speech. Specifically, the speech signal sampled at 8000 Hz is split into frames of 32 ms with 50% overlap between the frames. Each frame is then passed through a Hamming window, and a 512-point fast Fourier transform is used to compute the spectral content of each frame. Further processing of the frame is done only if the spectral content of the frame is above a noise threshold.

Each non-noise frame is divided into three channels on the basis of its spectral content. The gain applied to each channel is computed independently from the input audiogram and the frequency response characteristics of the telephone1 receiver so as to raise the signal level above the threshold of audibility while maintaining the spectral peak-to-valley ratio. In a given channel, let DNH and DHI be the dynamic ranges of a listener with normal hearing (NH) and a listener with HI, respectively. Assume that the relative threshold of the listener with HI is T and that the relative SPL in the channel before gain is SN. Gain (g) is computed as g=DHI/DNH, and the relative sensation level (SL) is computed as SLHI = g ×SLNH + T. The determination of gain by the algorithm is further illustrated in Figure 2. Specifically, the unprocessed (original) spectrum is shown as a dashed curve, and the processed spectrum is shown as a solid curve. The threshold of audibility for the average hearing loss implemented by the algorithm is depicted as a solid line. Point A in Figure 2 at approximately 2000 Hz would be audible for a listener with normal thresholds, but it falls below the threshold for the average listener with HI. At 2000 Hz, the algorithm calculates a ratio of the dynamic range of the HI ear (DHI) to the dynamic range of the NH ear (DNH). Then, the level of A is expressed in dB SL (above normal threshold). The algorithm determines the desired SL for the HI ear as SLHI/SLNH = DHI/DNH. To determine the gain to be applied to level A, the value of A is multiplied by DHI/DNH and is added to the threshold value at 2000 Hz. Thus, A* = (DHI/DNH) ×A + threshold.

To avoid any audible distortion due to discontinuities in the signal, the gain variation between adjacent frames is smoothed. The processed speech is synthesized by performing an inverse fast Fourier transform, and the

individual frames are recombined by an overlap add method to smooth the discontinuities at the frame boundaries. Compression characteristics of the TSEA included (a) an attack time of 5 ms with a release time of 100 ms and (b) a compression threshold of 50 dB SPL. There is no fixed compression ratio in the TSEA. Rather, the compression ratio is determined frame by frame on the basis of the input signal.

For the purposes of the present study, average hearing thresholds were used to define the gain within each channel of the algorithm. The intended purpose of the TSEA is to enhance the speech signal before it reaches the listener with HI, and the device would therefore be activated by a service provider. In this scenario, the service provider would have no prior knowledge of the individual's audiogram. Therefore, the average audiogram was based on hearing thresholds (250-8000 Hz) compiled from 100 individuals over the age of 60 years tested at the Columbus Speech and Hearing Center (Columbus, OH) between 1996 and 2000 (see Figure 1).

There are two versions of the TSEA: (a) Version 1, a preliminary version coded in MATLAB that cannot be run in real time, and (b) Version 2, written in C code to run on a real-time signal processing server platform developed by FutureCom Technologies. Specifically, the real-time signal processing system was an implementation of the algorithm on telephone interface cards as part of a commercial interactive voice response platform.

Stimuli

Speech recognition was measured in each of the following categories: (a) phoneme discrimination, (b) word recognition, and (c) sentence recognition. Phoneme discrimination was measured with the Modified Rhyme Test (MRT; Kreul et al., 1968). The MRT is a closed-set, 50-item test, with each item consisting of a set of six monosyllabic words that vary in either the initial or final consonant. Word recognition was measured with the revised Speech Perception in Noise (SPIN) test sentences (Bilger, Nuetzel, Rabinowitz, &Rzeczkowski, 1984). The SPIN includes eight lists of 50 sentences, with each list divided into 25 high-predictability and 25 low-predictability sentences. Although the SPIN was designed to be given in the presence of background noise, the sentences were given in quiet for this experiment. In addition, for the purposes of the present study, the number of correct responses was collapsed across SPIN sentence type to determine an overall percent correct. And finally, sentence recognition was measured with the Quick Speech-in-Noise (QSIN) test (Killion, Niquette, Gudmundsen, Revit, &Banerjee, 2004). The QSIN is a test of speech recognition in background noise (i.e., four-talker babble). Multiple signal-to-noise ratios (SNRs) are used to determine a measure of SNR loss. Specifically, six sentences are presented, each at a different SNR. The SNRs decrease in 5-dB steps from 25 dB to 0 dB for each successive sentence. Listeners are asked to repeat the entire sentence, and five key words are scored. For the purposes of the present study, the number of correct responses was collapsed across all SNRs to determine an overall percent correct.

Recordings of each speech test (MRT, SPIN, and QSIN) were obtained from commercially available CDs. The audio files for each test were extracted from their respective CDs, digitized at a sampling rate of 44.1 kHz (quantization bit rate of 16), and down-sampled to 8 kHz to be compatible with the TSEA. The stimuli were then stored on a desktop PC hard drive.

Procedure \ For Experiment 1, speech recognition was measured for the three tests (MRT, SPIN, and QSIN) under two listening conditions-unprocessed and processed-with the offline version of the TSEA. The order of test delivery (type of test) was randomized, and the listening conditions (unprocessed vs. processed) were counterbalanced to minimize order effects. The MRT and the SPIN test were presented in quiet, with 50 trials per condition. The QSIN was presented as intended, in a multitalker babble with six sentences (30 key words) per condition. For Experiment 2, speech recognition was measured using the QSIN under three listening conditions: unprocessed, processed with Version 1 (original), and processed with Version 2 (real time). For Experiments 1 and 2, the QSIN sentences were processed through the algorithm, and the multitalker babble was mixed with the speech after processing. The decision not to process the multitalker babble was based on

the assumption of noise present on the HI listener's end. The multitalker babble was attenuatedmanually (PA4 attenuator, Tucker Davis Technologies) between each sentence to create the various SNRs (25-0 dB). All speech stimuli as well as the multitalker babble for the QSIN were presented (a) through an Audigy 2NX sound card (Creative Technology) from a desktop PC that was coupled to a portable telephone interface (Microtel, Gentner Communications Corporation); (b) through a telephone landline; and (c) to a telephone receiver (Model T-905C, Cortel). Participants were seated in a sound-treated booth (Model 402ATR, IAC) and were familiarized with each test before administration. All stimuli were presented to the ear that the listener used for everyday telephone communication. Subjects responded verbally to the speech stimuli, and their responses were recorded as percent correct or incorrect. All speech-recognition testing was completed unaided.

The unprocessed speech stimuli were digitized at the 8-kHz sampling rate to match the sampling rate used on the telephone network. To maximize waveform fidelity and minimize quantization errors, the sample amplitudes were normalized. For each sample, the peak value of the amplitude was rescaled so that it was just less than the maximum output available from the sound card. This resulted in an average presentation level of 70-74 dB SPL. The presentation levels were monitored acoustically from the telephone receiver placed directly over the external ear canal on the pinna of a Knowles electronics manikin for acoustic research (KEMAR) and held in place with adhesive strapping. The compressive processing of these speech samples reduced the peak factor of eachwaveform.Thus,when the processed waveform was normalized before being delivered to the telephone network, the average level measured was 82-85 dB SPL.

Results

Experiment 1. Table 1 includes Ms and SDs for recognition performance for the three speech tests (MRT, SPIN, and QSIN) across the two listening conditions (unprocessed and processed). As seen in Table 1, small improvements in telephone speech recognition due to TSEA processing were seen for the phonemediscrimination task (MRT) and the word-recognition task (SPIN). The greatest improvement occurred for the sentence-based speech-in-noise task (QSIN).

The percentage data were transformed into rationalized arcsine units before statistical analysis (Studebaker, 1985). To determine whether the TSEA resulted in a significant ($p < .05$) improvement in telephone speech recognition, the transformed data were subjected to a twoway repeated measures analysis of variance (ANOVA) with processing condition and speech type as withinsubjects factors. Results revealed a significantmain effect for processing condition, $F(1, 19) = 100.7$, $p < .05$. Post hoc Bonferroni t tests revealed significant improvements in telephone speech recognition for the SPIN and the QSIN due to the processing algorithm. The difference in phoneme discrimination between the unprocessed and processed conditions for the MRT was not significant. The ANOVA also revealed a significant main effect for speech type, $F(2, 38) = 144.5$, $p < .05$. Post hoc Bonferroni t tests revealed significantly better processed recognition performance for both the MRT and SPIN as compared with the QSIN. The difference in processed performance between the MRT and SPIN was not significant.

Mean difference scores (processed vs. unprocessed) were also calculated (see Table 1) and compared across the three speech types using a one-way ANOVA. Results revealed a significant main effect, $F(2, 57) = 24.9$, $p < .05$. Tukey's honestly significant difference post hoc analysis revealed significantly more improvement in QSIN performance relative to both MRT and SPIN performance. No significant differences were found in improvement between the MRT and SPIN.

Experiment 2. Table 2 includes means and SDs for the QSIN across the three listening conditions: unprocessed, processed with Version 1, and processed with Version 2. As can be seen in Table 2, both versions of the TSEA resulted in improved sentence recognition as compared with the unprocessed condition. The difference in speech recognition performance between the algorithm versions, however, was minimal (63.8% and 69.0%, respectively).

In order to determine whether the improvement in sentence recognition differed across conditions, the

arcsinetransformed (Studebaker, 1985) data were subjected to a one-way ANOVA. Results revealed a significant main effect of condition, $F(2, 87) = 30.4$, $p < .05$. Tukey's honestly significant difference post hoc analysis on the effect of condition revealed significant ($p < .05$) improvements between the unprocessed condition and the two algorithm versions. Significant differences in recognition performance were not present between the two algorithm versions ($p > .05$).

Discussion

The purpose of Experiment 1 was to evaluate the effectiveness of a processing algorithmdesigned to enhance communication via the telephone. Results of Experiment 1 revealed significant improvements in speech recognition due to processing by the TSEA. Specifically, mean performance improved by 10.9% for the SPIN test and 31.9% for the QSIN test. Mean performance improved by 4.7% for the MRT; however, this difference was not significant. Similar results were reported by Terry et al. (1992), who used frequency shaping to improve audibility of a speech signal filtered to mimic the frequency response of a telephone (i.e., 300-3000 Hz). The authors reported improvements in phoneme discrimination on the order of 11.8% for frequency shaping alone and 15.8% for frequency shaping plus compression in a group of listeners with SNHL. The results from the present study and those from Terry et al. (1992) suggest that preprocessing the speech signal is a viable method of improving speech recognition via the telephone.

The amount of improvement observed in the present study was not equal across the levels of speech assessed (i.e., phoneme, word, and sentence). Specifically, the difference in mean improvement due to processing between the MRT and the SPIN test was not significantly different. However, the QSIN test resulted in significantly greater improvement due to processing than either the MRTor the SPINtest.Agreater improvement due to processing on theQSIN test is unsurprising given that it was presented in the presence of multitalker babble. The fact that equal amounts of improvement due to processing were not seen across the three levels of speech tested may be a reflection of different levels of test difficulty.

As part of the development of the TSEA, Version 1 tested in Experiment 1 was programmed in C code to run in real time on a signal processing server platform developed by FutureCom Technologies (i.e., Version 2). It was expected that no differences would be observed in speech recognition performance between the two versions of the TSEA. Results of Experiment 2 verified that, indeed, similar levels of improvement were observed for both versions of the TSEA relative to the unprocessed condition. Performance differences between the two algorithm versions were small and not significant. Version 2 of the TSEA, therefore, was as effective at improving speech recognition via the telephone as the original algorithm. Version 2 has the added benefits of real-time implementation and multichannel capabilities. Specifically, the speech signal can be processed as it is presented or spoken. In addition, this real-time system is capable of handling multiple calls simultaneously.

The ability to communicate effectively via the telephone in today's society is vital formanyreasons, including avoiding isolation, maintaining independence, and ensuring safety and security (Dimmick, Sikand, &Patterson, 1994; Murphy, 1999). The issue of effective telephone communication takes on even greater importance when considering the evolution of telehealth. Telehealth allows in-home patient care by health care providers, overcoming common issues for older adults such as difficulty with transportation (Mormer &Mack, 2003; Wakefield, 2003). Many older adults with hearing loss, however, have expressed concerns regarding their ability to effectively communicate about their health care via the telephone (Iezzoni et al., 2004). Options for improving telephone communication currently focus on the HI user's end (i.e., amplified telephones or hearing aids). The success of these strategies, however, depends on the individual with HI having knowledge of and access to such devices. The focus of the present study, therefore, was to examine the efficacy of a system that can be implemented by community service agencies and health care providers that routinely communicate with older adults with HI. The development of a preprocessing algorithm such as the TSEA is an important first step toward the long-term goal of providing improved communication via the telephone for older adults with HI. Other telecommunication technologies, such as mobile telephones and voice-over-Internet protocols (VoIP),

such as Skype, also may potentially benefit from a preprocessing algorithm. Mobile telephone signals can be affected by the same limited bandwidth as landline telephone signals and may therefore benefit from a preprocessing strategy such as the TSEA. VoIP technology, on the other hand, takes advantage of web camera technology, allowing the listener to use lip and facial cues during communication. A preprocessing strategy such as the TSEA may not be as beneficial in this situation. Future research efforts will also be aimed at evaluating the algorithm with additional communication technologies, such as mobile telephones and VoIP.

Acknowledgments

Funding for this project was provided by the Franklin County Office on Aging, an Ameritech Faculty Research Grant, a National Institute on Aging Phase I Small Business Innovation Research grant, and a Battelle Endowment for Technology and Human Affairs award. Portions of this research were presented at the 1999 and 2000 Acoustical Society of America meetings (Columbus, OH, and Atlanta, GA, respectively) and the 2007 Ohio Audiology Conference (Columbus, OH). We would like to thank FutureCom Technologies (Gahanna, OH) for their contributions to this project.We would also like to thank Evelyn Hoglund for her helpful comments on an earlier draftof this article.

Footnote

1The frequency characteristics of the telephone network used in the present study were measured using a type 2 frequency response in which the input varied in order to achieve a constant output. The output was set to the maximum possible before clipping occurred. The frequency response characteristics of the telephone network were incorporated into the algorithm with the average audiogram in order to shape the output.

Endangered and Threatened Wildlife and Plants; Partial 90-Day Finding on a Petition To List 404 Species in the Southeastern United States as Endangered or Threatened With Critical Habitat

Publication info: The Federal Register / FIND 76. 187. (Sep 27, 2011).

Abstract (Abstract): Notice of petition finding and initiation of status review.
CFR Part: "50 CFR Part 17"
Citation: "76 FR 59836"
Document Number: "Docket No. FWS-R4-ES-2011-0049; MO 92210-0-0009"
Page Number: "59836"
"Proposed Rules"
SUMMARY: We, the U.S. Fish and Wildlife Service (Service), announce a partial 90-day finding on a petition to list 404 species in the southeastern United States as endangered or threatened under the Endangered Species Act of 1973, as amended (Act). Based on our review, we find that for 374 of the 404 species, the petition presents substantial scientific or commercial information indicating that listing may be warranted. Therefore, with the publication of this notice, we are initiating a status review of the 374 species to determine if listing is warranted. To ensure that the review is comprehensive, we are soliciting scientific and commercial information regarding these 374 species. Based on the status reviews, we will issue 12-month findings on the petition, which will address whether the petitioned action is warranted, as provided in section 4(b)(3)(B) of the Act. Of the 30 other species in the petition, 1 species--Alabama shad--has had a 90-day finding published by the National Marine Fisheries Service, and 18 species are already on the Service's list of candidate species or are presently the subject of proposed rules to list. We have not yet made a finding on the remaining 11 species, but anticipate doing so no later than September 30, 2011.

We have not yet made a finding on the remaining 11 species, but anticipate doing so no later than September 30, 2011.
EFFECTIVE DATE: To allow us adequate time to conduct a status review, we request that we receive information on or before November 28, 2011. The deadline for submitting an electronic comment using the Federal eRulemaking Portal (see ADDRESSES section below) is 11:59 p.m. Eastern Standard Time on this date. After November 28, 2011, you must submit information directly to the Regional Office (see FOR FURTHER INFORMATION CONTACT section below). Please note that we may not be able to address or incorporate information that we receive after the above requested date.

ADDRESSES: You may submit information by one of the following methods:
(1) Electronically: Go to the Federal eRulemaking Portal: http://www.regulations.gov. In the Enter Keyword or ID box, enter Docket No. FWS-R4-ES-2011-0049, which is the docket number for this action. Then click on the Search button.
(2) By hard copy: Submit by U.S. mail or hand-delivery to: Public Comments Processing, Attn: FWS-R4-ES-2011-0049; Division of Policy and Directives Management; U.S. Fish and Wildlife Service; 4401 N. Fairfax Drive, MS 2042-PDM; Arlington, VA 22203.
We will not accept e-mail or faxes. We will post all information received on http://www.regulations.gov. This generally means that we will post any personal information you provide us (see Request for Information section below for more details).
FOR FURTHER INFORMATION CONTACT: Janet Mizzi, Chief, Division of Endangered Species, Ecological Services, Southeast Regional Office, U.S. Fish and Wildlife Service, 1875 Century Blvd., Atlanta, GA 30345; by telephone at 404-679-7169; or by facsimile at 404-679-7081. If you use a telecommunications device for the deaf (TDD), please call the Federal Information Relay Service (FIRS) at 800-877-8339.
SUPPLEMENTARY INFORMATION: When we make a finding that a petition presents substantial information indicating that a species may be warranted for listing, we are required to promptly review the status of the species (status review). For the status reviews to be complete and based on the best available scientific and commercial information, we request information on the 374 species from governmental agencies, Native American tribes, the scientific community, industry, or any other interested parties concerning the status of the species. We seek information on:
(1) The species' biology, range, and population trends, including:
(a) Habitat requirements for feeding, breeding, and sheltering;
(b) Genetics and taxonomy;
(c) Historical and current range, including distribution patterns;
(d) Historical and current population levels, and current and projected trends; and
(e) Past and ongoing conservation measures for the species, its habitat, or both.
(2) The factors that are the basis for making a listing determination for a species under section 4(a) of the Act (16 U.S.C. 1531 et seq.), which are:
(a) The present or threatened destruction, modification, or curtailment of its habitat or range;
(b) Overutilization for commercial, recreational, scientific, or educational purposes;
(c) Disease or predation;
(d) The inadequacy of existing regulatory mechanisms; or
(e) Other natural or manmade factors affecting its continued existence.
(3) The potential effects of climate change on the species and their habitat.
If, after the status review, we determine that listing any of these species is warranted, it is our intent to propose critical habitat under section 4 of the Act, to the maximum extent prudent and determinable at the time we propose to list the species. Therefore, we also request data and information on:
(1) What may constitute "physical or biological features essential to the conservation of the species," within the geographical range currently occupied by the species;
(2) Where these features are currently found;
(3) Whether any of these features may require special management considerations or protection;
(4) Specific areas outside the geographical area occupied by the species that are "essential for the conservation of the species;" and
(5) What, if any, critical habitat you think we should propose for designation if the species is proposed for listing, and why such habitat meets the requirements of section 4 of the Act.
Please include sufficient information with your submission (such as scientific journal articles, other supporting

publications, or data) to allow us to verify any scientific or commercial information you include.
Submissions merely stating support for or opposition to the action under consideration without providing supporting information, although noted, will not be considered in making a determination. Section 4(b)(1)(A) of the Act directs that determinations as to whether any species is an endangered or threatened species must be made "solely on the basis of the best scientific and commercial data available."
You may submit your information concerning the status reviews or the 404 species by one of the methods listed in the ADDRESSES section. If you submit information via http://www.regulations.gov, your entire submission--including any personal identifying information--will be posted on the Web site. If your submission is made via a hardcopy that includes personal identifying information, you may request at the top of your document that we withhold this information from public review. However, we cannot guarantee that we will be able to do so. We will post all hardcopy submissions on http://www.regulations.gov.
Information and supporting documentation that we received and used in preparing this finding is available for you to review at http://www.regulations.gov, or by appointment, during normal business hours, at the U.S. Fish and Wildlife Service, Southeast Ecological Services Regional Office (see FOR FURTHER INFORMATION CONTACT).
Background
Section 4(b)(3)(A) of the Act requires that we make a finding on whether a petition to list, delist, or reclassify a species presents substantial scientific or commercial information indicating that a petitioned action may be warranted. We are to base this finding on information found in the petition, supporting information submitted with the petition, and information otherwise available in our files. To the maximum extent practicable, we are to make this finding within 90 days of our receipt of the petition, and publish our notice of this finding promptly in the Federal Register .
Our standard for substantial scientific or commercial information within the Code of Federal Regulations (CFR) with regard to a 90-day petition finding is "that amount of information that would lead a reasonable person to believe that the measure proposed in the petition may be warranted" (50 CFR 424.14(b)). If we find that substantial scientific or commercial information was presented, we are required to promptly conduct a species status review, which we subsequently summarize in our 12-month finding.
Petition History
On April 20, 2010, we received, via electronic mail, a petition from the Center for Biological Diversity (CBD), Alabama Rivers Alliance, Clinch Coalition, Dogwood Alliance, Gulf Restoration Network, Tennessee Forests Council, West Virginia Highlands Conservancy, Tierra Curry, and Noah Greenwald (referred to below as the CBD petition) to list 404 aquatic, riparian, and wetland species from the southeastern United States as endangered or threatened species and to designate critical habitat concurrent with listing under the Act. The petition clearly identified itself as a petition, was dated, and included the identification information required at 50 CFR 424.14(a). On April 21, 2010, via electronic mail to Noah Greenwald at CBD, we acknowledged receipt of the petition. On May 10, 2010, the Southeast Region of the Service, to which the petition had been assigned, provided additional formal written acknowledgement of receipt of the petition.
The petitioners developed an initial list of species by searching NatureServe for species that "occur in the twelve states typically considered the Southeast, occur in aquatic, riparian, or wetland habitats and appeared to be imperiled." Species were considered imperiled if they were classified as G1 or G2 by NatureServe, near threatened or worse by the International Union for Conservation of Nature (IUCN), or a species of concern, threatened, or endangered by the American Fisheries Society.
NatureServe conservation status ranks range from critically imperiled (1) to demonstrably secure (5). Status is assessed and documented at three distinct geographic scales: Global (G), national (N), and subnational (S) (i.e., state/province/municipal). Subspecies are similarly assessed with a subspecific (T) numerical assignment. Assessment by NatureServe of any species as being critically imperiled (G1), imperiled (G2), or vulnerable (G3)

does not constitute a recommendation by NatureServe for listing under the Act. NatureServe status assessment procedures have different criteria, evidence requirements, purposes, and taxonomic coverage than government lists of endangered and threatened species, and therefore these two types of lists should not be expected to coincide. For example, an important factor in many legal listing processes is the extent to which a species is already receiving protection of some type--a consideration not included in the NatureServe conservation status ranks. Similarly, the IUCN and American Fisheries Society do not apply the same criteria to their ranking determinations as those encompassed in the Act and its implementing regulations.

On May 7, 2010, the Service received correspondence from the Southeastern Fishes Council, dated May 2, 2010, with an explanation of its involvement in formulation of the petition. The Council was contacted by CBD, which solicited the Council's involvement in the preparation of the subject petition. The Southeastern Fishes Council's members provided expertise in review of the CBD's list of fishes in the draft petition.

On May 27, 2010, the Freshwater Mollusk Conservation Society submitted a letter to the Regional Director, Fish and Wildlife Service, Southeast Region, in support of the CBD petition's inclusion of a large number of freshwater mollusks. On September 1, 2010, and again on October 1, 2010, CBD forwarded to the Regional Director, Service, Southeast Region, a letter of support for the subject petition from 35 conservation organizations.

The CBD submitted supplemental comments and information on October 6, 2010, in support of protecting the Panama City crayfish (Procambarus econfinae) under the Act. On December 13, 2010, we received a second petition, from Wild South, to list the Carolina hemlock (Tsuga caroliniana), as endangered and to designate its critical habitat. We acknowledged receipt of the petition in a letter dated December 20, 2010, and identified it as a second petition for the same species' as Tsuga caroliniana was one of the species identified in the CBD petition.

The CBD petition included 404 species for which the petitioners requested listing as endangered or threatened under the Act, and designation of critical habitat concurrent with the listing. It is our practice to evaluate all species petitioned for listing for the potential need to emergency list the species under the emergency provisions of the Act at section 4(b)(7) and as outlined at 50 CFR 424.20. We have carefully considered the information provided in the petition and in our files and have determined that emergency listing is not indicated for any of the 404 species in the petition.

The petition included 18 species that were already on the Service's list of candidate species at the time of receipt of the petition, including five that have since been proposed to be listed as endangered. A candidate species is one for which we have on file sufficient information on biological vulnerability and threats to support a proposal to list as endangered or threatened, but for which preparation and publication of a proposal is precluded by higher priority listing actions. We may identify a species as a candidate for listing based on an evaluation of its status that we conducted on our own initiative, or as a result of making a finding on a petition to list a species that listing is warranted but precluded by other higher priority listing actions. Of the 404 species that are the subjects of the petition, 18 had already been placed on the candidate list as a result of our own review and evaluation. These include: sicklefin redhorse (Moxostoma sp. 2 (the 2 refers to one of two species within the genus that have not yet been officially classified)), laurel dace (Phoxinus saylori) ((currently proposed for listing as endangered (June 24, 2011; 75 FR 36035)), spectaclecase (Cumberlandia monodonta) ((currently proposed for listing as endangered (January 19, 2011; 76 FR 3392)), narrow pigtoe (Fusconaia escambia), round ebonyshell (Fusconaia rotulata), southern sandshell (Hamiota australis), sheepnose (Plethobasus cyphyus) ((currently proposed for listing as endangered (January 19, 2011; 76 FR 3392)), fuzzy pigtoe (Pleurobema strodeanum), southern kidneyshell (Ptychobranchus jonesi), rabbitsfoot (Quadrula cylindrica cylindrica), tapered pigtoe (Fusconaia burkei), Choctaw bean (Villosa choctawensis), rayed bean (Villosa fabalis) ((currently proposed for listing as endangered (November 2, 2010; 75 FR 67552)), black mudalia (Elimia melanoides), Coleman cave beetle (Pseudanophthalmus colemanensis), Black Warrior waterdog (Necturus

alabamensis), and Yadkin River goldenrod (Solidago plumosa). We proposed to list the snuffbox (Epioblasma triquetra) as endangered on November 2, 2010 (75 FR 67552).

We conduct a review of all candidate species annually to ensure that a proposed listing is justified for each species, and reevaluate the relative listing priority number assigned to each species. We also evaluate the need to emergency list any of these species, particularly species with high priorities. Through this annual review we also add new candidate species and remove those that no longer warrant listing. This review and reevaluation ensure that we focus conservation efforts on those species at greatest risk first.

Because we have already made the equivalent of a 90-day and a 12-month finding on the species listed above, and they have already been identified as warranting listing, including five that we have proposed to list as endangered, we find the petition provides substantial scientific or commercial information indicating that these species may be warranted for listing.

The CBD petition includes one species, the Alabama shad (Alosa alabamae), that falls under the jurisdiction of the NMFS. According to the 1974 Memorandum of Understanding regarding jurisdictional responsibilities and listing procedures between the Service and NMFS, the NMFS has jurisdiction over species which either (1) Reside the majority portion of their lifetimes in marine waters, or (2) are species which spend part of their lifetimes in estuarine waters, if the majority portion of the remaining time (the time which is not spent in estuarine waters) is spent in marine waters. Based on this definition, NMFS has jurisdiction for the Alabama shad, and, accordingly, NMFS provided a letter to the Service, dated April 30, 2010, proposing to evaluate the subject petition, for the Alabama shad only, for the purpose of the 90-day finding and any required subsequent listing action. The NMFS published the 90-day finding for the Alabama shad on February 17, 2011 (76 FR 9320), and in that document announced its finding that the petition did not present substantial scientific or commercial information indicating that listing may be warranted for the Alabama shad.

Previous Federal Actions

A large number of the petitioned species have previously been considered for listing under the Act and were at one time or another assigned status as a category 1, 2, or 3C candidate species. A category 1 candidate species was one for which the Service had substantial information on hand to support the biological appropriateness of proposing to list as endangered or threatened, and for which development and publication of such a proposal was anticipated. A category 2 candidate species was one for which there was some evidence of vulnerability, but for which additional biological information was needed to support a proposed rule to list as endangered or threatened. A category 3C candidate was one that was proven to be more widespread than was previously believed and/or those that were not subject to any identifiable threats. These categories were discontinued in 1996 (December 5, 1996; 61 FR 64481) in favor of maintaining a list that only represented those species for which we have on file sufficient information on biological vulnerability and threats to support a proposal to list as endangered or threatened, but for which preparation and publication of a proposal is precluded by higher priority listing actions.

The Service was previously petitioned to list two of the subject petitioned species, the Say's spiketail dragonfly (February 15, 1994) and the orangefin madtom (October 6, 1983), as endangered species. We published 90-day findings for Say's spiketail dragonfly on October 26, 1994 (59 FR 53776), and the orangefin madtom on January 16, 1984 (49 FR 1919), respectively, and 12-month findings on July 17, 1995 (60 FR 36380), and July 18, 1985 (50 FR 29238), respectively. Similarly, we previously proposed to list as endangered the Barrens topminnow (December 30, 1977; 42 FR 65209). However, that proposal was never finalized.

Species Information

The petition identified 404 aquatic, riparian, and wetland species from the southeastern United States as needing protection under the Act. This list included 15 amphibians, 6 amphipods, 18 beetles, 3 birds, 4 butterflies, 9 caddisflies, 83 crayfish, 14 dragonflies, 48 fish, 1 springfly, 1 fairy shrimp, 2 isopods, 4 mammals, 1 moth, 48 mussels, 6 non-vascular plants, 13 reptiles, 44 snails, 8 stoneflies, and 76 vascular plants. Of these 404 species, 374 species are addressed in this finding (listed in Table 2 in the Summary of Threats as Identified in the Petition section below). We have not yet made a finding on the following 11 species: South Florida rainbow snake (Farancia erytrogramma seminola), Sarah's hydroptila caddisfly (Hydroptila sarahae), Rogue

Creek hydroptila caddisfly (Hydroptila okaloosa), Florida brown checkered summer sedge (Polycentropus floridensis), Florida fairy shrimp (Dexteria floridana), Ouachita creekshell (Villosa arkansasensis), crystal darter (Crystallaria asprella), spotted darter (Etheostoma maculatum), Florida bog frog (Rana okaloosae), Greensboro burrowing crayfish (Cambarus catagius), and Blood River crayfish (Orconectes burri).

The nature of this petition finding, that is, the large number of species evaluated, necessitates our limiting a discussion of species information to a general one; only where there is a clarification necessary do we provide specific species information below.

The petition identified 15 amphibians and requested that they be added to the List of Endangered and Threatened Wildlife (List). Thirteen of these are subjects of this finding, including the following: Streamside salamander (Ambystoma barbouri), one-toed amphiuma (Amphiuma pholeter), hellbender (Cryptobranchus alleganiensis), Cumberland dusky salamander (Desmognathus abditus), seepage salamander (Desmognathus aeneus), Chamberlain's dwarf salamander (Eurycea chamberlaini), Oklahoma salamander (Eurycea tynerensis), Tennessee cave salamander (Gyrinophilus palleucus), West Virginia spring salamander (Gyrinophilus subterraneus), Georgia blind salamander (Eurycea wallacei, formerly known as, and identified by petitioners as, Haideotriton wallacei), Neuse River waterdog (Necturus lewisi), Gulf hammock dwarf siren (Pseudobranchus striatus lustricolus), and patch-nosed salamander (Urspelerpes brucei). The Black Warrior waterdog (Necturus alabamensis) is already on the Service's candidate species list. The seepage salamander, Oklahoma salamander, Tennessee cave salamander, West Virginia Spring salamander, Georgia blind salamander, Neuse River waterdog, hellbender, and Gulf hammock dwarf siren were previous C2 candidates for Federal listing, until that category was discontinued in 1996.

Chamberlain's dwarf salamander is given a NatureServe global ranking of G5; however, its status in Georgia is S1, indicating it is considered critically imperiled in that State. The streamside salamander is given the G4 conservation status by NatureServe; however, it is considered critically imperiled (S1) in West Virginia, imperiled (S2) in Tennessee, and vulnerable (S3) in Indiana. The one-toed amphiuma maintains a global G3 ranking by NatureServe; however, it is also considered critically imperiled by NatureServe in Mississippi, Alabama, and Georgia, and vulnerable in Florida. The Tennessee cave salamander maintains a NatureServe global ranking of G2 with State rankings of S2 (AL and TN) and S1 (GA). The hellbender maintains a NatureServe global ranking of G3. Its State status ranges from S1 to S3. The subspecies bishopi, or Ozark hellbender, was proposed for Federal listing as endangered on September 8, 2010 (75 FR 54561). The Cumberland dusky salamander and Georgia blind salamander each have a NatureServe conservation status of imperiled (G2), with State rankings varying from possibly extirpated, to critically imperiled, to imperiled. The seepage salamander, Oklahoma salamander, and Neuse River waterdog each have a NatureServe global conservation ranking of G3, with individual State rankings of S1 to S3. The West Virginia spring salamander and patch-nosed salamander each have a NatureServe conservation ranking of G1. The Gulf hammock dwarf siren is given a NatureServe global ranking of T1. The dwarf siren has not been documented since its description in 1951.

The petition identified six amphipods and requested that they be added to the List, including the following: Florida cave amphipod (Crangonyx grandimanus), Hobbs cave amphipod (Crangonyx hobbsi), Cooper's cave amphipod (Stygobromus cooperi), tidewater amphipod (Stygobromus indentatus), Morrison's cave amphipod (Stygobromus morrisoni), and minute cave amphipod (Stygobromus parvus).

These six amphipods are each assigned a NatureServe Global ranking of either G2 or G3, indicating they are considered imperiled or vulnerable across their entire range. Cooper's cave amphipod, tidewater amphipod, Morrison's cave amphipod and the minute cave amphipod were each previous Service category 2 candidate species for listing (species for which there was some evidence of vulnerability, but for which additional biological information was needed to support a proposed rule to list as endangered or threatened).

The petition identified 18 beetles and requested that they be added to the List. Seventeen of these are included

in this finding, including the following: Cobblestone tiger beetle (Cincindela marginipennis), Avernus cave beetle (Pseudanophthalmus avernus), Little Kennedy cave beetle (Pseudanophthalmus cordicollis), New River Valley cave beetle (Pseudanophthalmus egberti), Cumberland Gap cave beetle (Pseudanophthalmus hirsutus), Hubbard's cave beetle (Pseudanophthalmus hubbardi), Hubricht's cave beetle (Pseudanophthalmus hubrichti), Crossroad's cave beetle (Pseudanophthalmus intersectus), Madden's cave beetle (Pseudanophthalmus limicola), Dry Fork Valley cave beetle (Pseudanophthalmus montanus), Natural Bridge cave beetle (Pseudanophthalmus pontis), South Branch Valley cave beetle (Pseudanophthalmus potomaca), overlooked cave beetle (Pseudanophthalmus praetermissus), Saint Paul cave beetle (Pseudanophthalmus sanctipauli), silken cave beetle (Pseudanophthalmus sericus), Thomas's cave beetle (Pseudanophthalmus thomasi), and Maiden Spring cave beetle (Pseudanophthalmus virginicus). The Coleman's cave beetle (Pseudanophthalmus colemanensis) is already a Federal candidate species.

These cave beetles are locally endemic to small cave systems in Virginia, West Virginia, and Tennessee. Sixteen of them are afforded a NatureServe ranking of G1, with a population size of 1,000 or fewer, and many have not been documented since their description. One cave beetle, the South Branch Valley cave beetle, has a slightly wider range and is afforded a NatureServe ranking of G3. All of these beetles were previous category 2 candidates for Federal listing, until that category was discontinued in 1996.

The petition identified three birds and requested that they be added to the List, including the following: MacGillivray's seaside sparrow (Ammodrammus maritimus macgillivraii), Florida sandhill crane (Grus canadensis pratensis), and black rail (Laterallus jamaicensis). MacGillivray's seaside sparrow and the Florida sandhill crane are given a NatureServe ranking of T2, while the black rail is more widely distributed and given a NatureServe ranking of G4. The black rail is a previous category 2 candidate species.

The petition identified four butterflies and requested that they be added to the List, including the following: Linda's roadside-skipper (Amblyscirtes linda), Duke's skipper (Euphyes dukesi calhouni), Palatka skipper (Euphyes pilatka klotsi), and rare skipper (Problema bulenta). Linda's roadside skipper and the rare skipper are afforded a NatureServe ranking of G2. Duke's and Palatka's skippers are afforded NatureServe rankings of T2 and T1, respectively. The rare skipper was previously considered a category 2 candidate, until that category was discontinued by the Service in 1996.

The petition identified nine caddisflies and requested that they be added to the List. Six of these are included in this finding, including the following: Logan's agarodes caddisfly (Agarodes logani), Sykora's hydroptila caddisfly (Hydroptila sykorae), Morse's little plain brown sedge (Lepidostoma morsei), little oecetis longhorn caddisfly (Oecetis parva), Setose cream and brown mottled microcaddisfly (Oxyethira setosa), and three-toothed triaenodes caddisfly (Triaenodes tridontus).

Of these caddisflies, two are assigned a NatureServe ranking of G1, and four are assigned a G2. There is very little known about these species except that they appear to be very narrow endemics. The little oecetis longhorn caddisfly and three-toothed triaenodes caddisfly are previous category 2 candidate species.

The petition identified 83 crayfish and requested that they be added to the List. Eighty-one of these are included in this finding: Bayou Bodcau crayfish (Bouchardina robisoni), Dougherty Plain cave crayfish (Cambarus cryptodytes), Obey crayfish (Cambarus obeyensis), cypress crayfish (Cambarellus blacki), least crayfish (Cambarellus diminutus), angular dwarf crawfish (Cambarellus lesliei), Big South Fork crayfish (Cambarus bouchardi), New River crayfish (Cambarus chasmodactylus), Chauga crayfish (Cambarus chaugaensis), Coosawattae crayfish (Cambarus coosawattae), slenderclaw crayfish (Cambarus cracens), Conasauga blue burrower (Cambarus cymatilis), Grandfather Mountain crayfish (Cambarus eeseeohensis), Elk River crayfish (Cambarus elkensis), Chickamauga crayfish (Cambarus extraneus), Etowah crayfish (Cambarus fasciatus), Little Tennessee crayfish (Cambarus georgiae), Piedmont blue burrower (Cambarus harti), spiny scale crayfish (Cambarus jezerinaci), Alabama cave crayfish (Cambarus jonesi), Greenbrier cave crayfish (Cambarus nerterius), Hiwassee headwater crayfish (Cambarus parrishi), pristine crayfish (Cambarus pristinus), Chattooga

River crayfish (Cambarus scotti), beautiful crayfish (Cambarus speciosus), Broad River spiny crayfish (Cambarus spicatus), lean crayfish (Cambarus strigosus), blackbarred crayfish (Cambarus unestami), Big Sandy crayfish (Cambarus veteranus), Brawley's Fork crayfish (Cambarus williami), mimic crayfish (Distocambarus carlsoni), Broad River burrowing crayfish (Distocambarus devexus), Newberry burrowing crayfish (Distocambarus youngineri), burrowing bog crayfish (Fallicambarus burrisi), speckled burrowing crayfish (Fallicambarus danielae), Jefferson County crayfish (Fallicambarus gilpini), Ouachita burrowing crayfish (Fallicambarus harpi), Hatchie burrowing crayfish (Fallicambarus hortoni), slenderwrist burrowing crayfish (Fallicambarus petilicarpus), Saline burrowing crayfish (Fallicambarus strawni), Crested riverlet crayfish (Hobbseus cristatus), Oktibbeha riverlet crayfish (Hobbseus orconectoides), Tombigbee riverlet crayfish (Hobbseus petilus), Yalobusha riverlet crayfish (Hobbseus yalobushensis), Calcasieu crayfish (Orconectes blacki), Coldwater crayfish (Orconectes eupunctus), Yazoo crayfish (Orconectes hartfieldi), Tennessee cave crayfish (Orconectes incomptus), Sucarnoochee River crayfish (Orconectes jonesi), Kisatchie painted crayfish (Orconectes maletae), Mammoth Spring crayfish (Orconectes marchandi), Appalachian cave crayfish (Orconectes packardi), Shelta cave crayfish (Orconectes sheltae), Chowanoke crayfish (Orconectes virginiensis), Hardin crayfish (Orconectes wrighti), Orlando cave crayfish (Procambarus acherontis), Coastal flatwoods crayfish (Procambarus apalachicolae), Silver Glen Springs crayfish (Procambarus attiguus), Jackson Prairie crayfish (Procambarus barbiger), Mississippi flatwoods crayfish (Procambarus cometes), bigcheek cave crayfish (Procambarus delicatus), Panama City crayfish (Procambarus econfinae), Santa Fe cave crayfish (Procambarus erythrops), spinytail crayfish (Procambarus fitzpatricki), Orange Lake cave crayfish (Procambarus franzi), Big Blue Springs cave crayfish (Procambarus horsti), lagniappe crayfish (Procambarus lagniappe), coastal lowland cave crayfish (Procambarus leitheuseri), Florida cave crayfish (Procambarus lucifugus), Alachua light-fleeing cave crayfish (Procambarus lucifugus alachua), Florida cave crayfish (Procambarus lucifugus lucifugus), Shutispear crayfish (Procambarus lylei), Miami cave crayfish (Procambarus milleri), Putnam County cave crayfish (Procambarus morrisi), Woodville Karst cave crayfish (Procambarus orcinus), pallid cave crayfish (Procambarus pallidus), Black Creek crayfish (Procambarus pictus), bearded red crayfish (Procambarus pogum), regal burrowing crayfish (Procambarus regalis), Irons Fork burrowing crayfish (Procambarus reimeri), and spider cave crayfish (Troglocambarus maclanei).

The petition identified the Florida cave crayfish twice in its list of 404 species, once at the species level, Procambarus lucifugus, and once at the subspecific level, Procambarus lucifugus lucifugus. We include both in this finding with the intent that a further status review will assess the status at both the species and subspecies levels.

We received an amended petition from CBD providing supplemental comments in support of listing the Panama City crayfish. The petition identified threats from habitat loss and degradation, predation, overharvest from collections for use as fishing bait, drought, its limited range and isolated distribution, pollution from pesticides and fertilizers, invasive species of introduced crayfish, and the inadequacy of existing regulatory mechanisms. The Panama City crayfish only occurs in Bay County, Florida, where it is considered a species of special concern by the State of Florida. The Service has worked with the State and the St. Joe Company to develop a Candidate Conservation Agreement with Assurances, but the Agreement has not been finalized.

Almost all of the petitioned crayfish are restricted to narrow ranges encompassing small cave or stream systems, which places them in the G1 or G2 NatureServe ranking due to their restricted ranges. Two exceptions to this are the Woodville Karst cave crayfish (Procambarus orcinus), which receives a G3 ranking, and the regal burrowing crayfish (Procambarus regalis), which is given a G2G3 ranking. Their narrow ranges make these crayfish vulnerable to any event that would result in habitat degradation. A number of the crayfish (26) were previously considered category 2 candidates until that category was discontinued by the Service in 1996.

The petition identified 14 dragonflies and requested that they be added to the List, including the following: Say's spiketail (Cordulegaster sayi), Cherokee clubtail (Gomphus consanguis), Tennessee clubtail (Gomphus

sandrius), Septima's clubtail (Gomphus septima), Westfall's clubtail (Gomphus westfalli), purple skimmer (Libellula jesseana), Mountain River cruiser (Macromia margarita), southern snaketail (Ophiogomphus australis), Edmund's snaketail (Ophiogomphus edmundo), Appalachian snaketail (Ophiogomphus incurvatus), Calvert's emerald (Somatochlora calverti), Texas emerald (Somatochlora margarita), Ozark emerald (Somatochlora ozarkensis), and yellow-sided clubtail (Stylurus potulentus).

The Service was previously (February 15, 1994) petitioned to list the Say's spiketail dragonfly as an endangered species. We published a 90-day finding on October 26, 1994 (59 FR 53776) indicating that because the species was already a category 2 candidate for listing we would proceed with a full status review. The 12-month finding was published on July 17, 1995 (60 FR 36380). The Service found that listing the species was not warranted but retained the designation of the Say's spiketail as a category 2 candidate species. An additional eight of the petitioned dragonflies held previous designations of category 2 candidate species, including the Cherokee clubtail, Tennessee clubtail, Septima's clubtail, Westfall's clubtail, Mountain River cruiser, Edmund's snaketail, Appalachian snaketail, and the Texas emerald. The NatureServe global ranking of the petitioned dragonflies ranges from G1, critically imperiled, to G3, vulnerable.

The petition identified 47 fish (not including the Alabama shad (Alosa alabamae), which has already been the subject of a 90-day finding by NMFS) to be added to the List. Forty-three of these are included in this finding, including the following: Northern cavefish (Amblyopsis spelaea), bluestripe shiner (Cyprinella callitaenia), Altamaha shiner (Cyprinella xaenura), Carolina pygmy sunfish (Elassoma boehlkei), Ozark chub (Erimystax harryi), Warrior darter (Etheostoma bellator), holiday darter (Etheostoma brevirostrum), ashy darter (Etheostoma cinereum), Barrens darter (Etheostoma forbesi), smallscale darter (Etheostoma microlepidum), candy darter (Etheostoma osburni), paleback darter (Etheostoma pallididorsum), egg-mimic darter (Etheostoma pseudovulatum), striated darter (Etheostoma striatulum), Shawnee darter (Etheostoma tecumsehi), Tippecanoe darter (Etheostoma tippecanoe), trispot darter (Etheostoma trisella), Tuscumbia darter (Etheostoma tuscumbia), Barrens topminnow (Fundulus julisia), robust redhorse (Moxostoma robustum), popeye shiner (Notropis ariommus), Ozark shiner (Notropis ozarcanus), peppered shiner (Notropis perpallidus), rocky shiner (Notropis suttkusi), saddled madtom (Noturus fasciatus), Carolina madtom (Noturus furiosus), orangefin madtom (Noturus gilberti), piebald madtom (Noturus gladiator), Ouachita madtom (Noturus lachneri), frecklebelly madtom (Noturus munitus), Caddo madtom (Noturus taylori), Chesapeake logperch (Percina bimaculata), coal darter (Percina brevicauda), Halloween darter (Percina crypta), bluestripe darter (Percina cymatotaenia), bridled darter (Percina kusha), longhead darter (Percina macrocephala), longnose darter (Percina nasuta), bankhead darter (Percina sipsi), sickle darter (Percina williamsi), broadstripe shiner (Pteronotropis euryzonus), bluehead shiner (Pteronotropis hubbsi), and blackfin sucker (Thoburnia atripinnis). The NatureServe global ranking of these fish ranges from G1 to G4.

Since receipt of the CBD petition, the laurel dace was proposed for listing as endangered (75 FR 36035; June 24, 2010). The sicklefin redhorse has already been found to be warranted for listing and is a current Federal candidate species.

On December 30, 1977, the Barrens topminnow was proposed for listing as endangered with critical habitat (42 FR 65209). On March 6, 1979, the critical habitat portion of the proposal was withdrawn due to the procedural and substantive changes made to the Act in 1978 (44 FR 12382). On July 27, 1979, the Service published a reproposal of critical habitat for the Barrens topminnow (44 FR 44418). A final listing was never published, and the species was subsequently classified as a category 2 candidate for Federal listing until that category was discontinued in 1996.

On October 6, 1983, the Service was petitioned to list the orangefin madtom and a substantial finding was published on January 16, 1984 (49 FR 1919). On completion of the status review on October 12, 1984, a 12-month finding was made that listing the orangefin madtom was warranted but precluded by other efforts to revise the Lists. This finding was announced in a July 18, 1985, Federal Register notice (50 FR 29238). The

species remained a candidate species until its removal from the candidate list in 1996.
In addition to the above species, 24 of the petitioned fish were at one time candidates for listing under the Act. The peppered shiner, paleback darter, and Ouachita madtom were category 1 candidates (47 FR 58454). However, they were subsequently removed from the candidate list. Twenty-one of the petitioned fish were category 2 candidates for listing, including the following: Northern cavefish, bluestripe shiner, Carolina pygmy sunfish, Warrior darter, holiday darter, ashy darter, Barrens darter, candy darter, egg-mimic darter, striated darter, trispot darter, Tuscumbia darter, robust redhorse, Ozark shiner, Carolina madtom, frecklebelly madtom, Caddo madtom, bluestripe darter, longhead darter, longnose darter, and Halloween darter.
In 1995, the Service entered into a cooperative voluntary partnership, the Robust Redhorse Conservation Committee, to conserve the robust redhorse through a Memorandum of Understanding between State and Federal resource agencies, private industry, and the conservation community. In 2002, the Service entered into a Robust Redhorse Candidate Conservation Agreement with Assurances with the Georgia Department of Natural Resources and the Georgia Power Company to restore the species to the Ocmulgee River.
The petition identified one springfly, the Blueridge springfly (Remenus kirchneri), and one moth, the Louisiana eyed silkmoth (Automeris louisiana), and requested that they be added to the List. These species hold NatureServe global rankings of G2.
The petition identified four mammals and requested that they be added to the List, including the following: Sherman's short-tailed shrew (Blarina carolinensis shermani), Pine Island oryzomys or marsh rice rat (Oryzomys palustris, pop. 1), Sanibel Island oryzomys or marsh rice rat (Oryzomys palustris, pop. 2), and insular cotton rat (Sigmodon hispidus insulicola). All four of these mammals are afforded a ranking of G1 or T1 by NatureServe. The insular cotton rat was previously a category 2 candidate species but was removed from the candidate list in 1996 when the category was discontinued.
The petition identified two isopods and requested that they be added to the List: The Caecidotea cannula (no common name) and Rye Cove isopod (Lirceus culveri). These isopods are given NatureServe rankings of G2 (Caecidotea cannula) and G1 (Rye Cove isopod). Both species were former category 2 candidates for listing, until that category was discontinued in 1996.
The petition identified 48 mussels and requested that they be added to the List. Thirteen species of mussels identified in the petition are not evaluated in this finding; twelve have previously been found by the Service to warrant listing, and one, the Ouachita creekshell (Villosa arkansasensis) has not yet been evaluated. Thirty-five of the petitioned species are included in this finding, including the following: Altamaha arcmussel (Alasmidonta arcula), southern elktoe (Alasmidonta triangulata), brook floater (Alasmidonta varicosa), Apalachicola floater (Anodonta heardi), rayed creekshell (Anodontoides radiatus), western fanshell (Cyprogenia aberti), southern lance (Elliptio ahenea), Alabama spike (Elliptio arca), delicate spike (Elliptio arctata), brother spike (Elliptio fraterna), yellow lance (Elliptio lanceolata), St. Johns elephant ear (Elliptio monroensis), inflated spike (Elliptio purpurella), Tennessee pigtoe (Pleuronaia barnesiana), Atlantic pigtoe (Fusconaia masoni), longsolid (Fusconaia subrotunda), Waccamaw fatmucket (Lampsilis fullerkati), Tennessee heelsplitter (Lasmigona holstonia), green floater (Lasmigona subviridis), Cumberland moccasinshell (Medionidus conradicus), Suwannee moccasinshell (Medionidus walkeri), round hickorynut (Obovaria subrotunda), Alabama hickorynut (Obovaria unicolor), Canoe Creek pigtoe (Pleurobema athearni), Tennessee clubshell (Pleurobema oviforme), Warrior pigtoe (Pleurobema rubellum), pyramid pigtoe (Pleurobema rubrum), inflated floater (Pyganodon gibbosa), Tallapoosa orb (Quadrula asperata archeri), salamander mussel (Simpsonaias ambigua), purple lilliput (Toxolasma lividus), Savannah lilliput (Toxolasma pullus), Alabama rainbow (Villosa nebulosa), Kentucky creekshell (Villosa ortmanni), and Coosa creekshell (Villosa umbrans).
These mussels have NatureServe rankings ranging from G1, critically imperiled, to G3, vulnerable, with one mussel, the round hickorynut, having a ranking of G4, apparently stable. The Atlantic pigtoe, Waccamaw fatmucket, Tennessee heelsplitter, green floater, Suwannee moccasinshell, Tennessee clubshell, warrior pigtoe,

salamander mussel, purple lilliput, Savannah lilliput, and Kentucky creekshell, are previous category 2 candidates for listing, but were removed when the category was discontinued in 1996.

The snuffbox (Epioblasma triquetra) and rayed bean (Villosa fabalis) were proposed for listing as endangered on November 2, 2010 (75 FR 67552). The spectaclecase (Cumberlandia monodonta) and sheepnose (Plethobasus cyphyus) were proposed as endangered on January 19, 2011 (76 FR 3392). The other eight are current candidates for Federal listing and subjects of a draft proposed rule to list, including the narrow pigtoe (Fusconaia escambia), round ebonyshell (Fusconaia rotulata), southern sandshell (Hamiota australis), fuzzy pigtoe (Pleurobema strodeanum), southern kidneyshell (Ptychobranchus jonesi), rabbitsfoot (Quadrula cylindrica cylindrica), tapered pigtoe (Fusconaia burkei), and Choctaw bean (Villosa choctawensis).

The petition identified six non-vascular plants and requested that they be added to the List of Endangered and Threatened Plants, including the following: Fissidens appalachensis (Appalachian fissidens moss), Fissidens hallii (Hall's pocket moss), Megaceros aenigmaticus (hornwort), Phaeophyscia leana (Lea's bog lichen), Plagiochila caduciloba (Gorge leafy liverwort), and Plagiochila sharpii ssp. sharpii (Sharp's leafy liverwort). The NatureServe Global ranking for these plants ranges from G2, imperiled (Fissidens appalachensis, Fissidens hallii, Phaeophyscia leana, and Megaceros aenigmaticus), to G3, vulnerable (Plagiochila caduciloba), to T3, vulnerable (Plagiochila sharpii ssp. sharpii). Plagiochila caduciloba and Plagiochila sharpii ssp. sharpii held prior Federal category 2 candidate status, but were removed from that list when we discontinued use of the category 2 and 3C lists in 1996.

The petition identified 13 reptiles and requested that they be added to the List. Twelve of these are subjects of this finding, including the following: Kirtland's snake (Clonophis kirtlandii), western chicken turtle (Deirochelys reticularia miaria), Florida keys mole skink (Eumeces egregius egregius), Barbour's map turtle (Graptemys barbouri), Escambia map turtle (Graptemys ernsti), Pascagoula map turtle (Graptemys gibbonsi), black-knobbed map turtle (Graptemys nigrinoda), Alabama map turtle (Graptemys pulchra), Lower Florida Keys striped mud turtle (Kinosternon baurii, pop. 1), Florida Panhandle Florida red-bellied turtle (Pseudemys nelsoni, pop. 1), northern red-bellied cooter (Pseudemys rubriventris), and Lower Florida Keys eastern ribbonsnake (Thamnophis sauritus, pop. 1).

The Kirtland's snake, Barbour's map turtle, Escambia map turtle, and Pascagoula map turtle have a NatureServe conservation status of G2, with State rankings varying from possibly extirpated, to S1, to S2. The black-knobbed map turtle has a NatureServe ranking of G3. The Alabama map turtle has a NatureServe ranking of G4, but State rankings vary from S1 to S3. The Florida Keys mole skink and Lower Florida Keys eastern ribbonsnake are given a NatureServe global ranking of T1. The western chicken turtle is considered secure by NatureServe with a global ranking of T5. The Lower Florida Keys striped mud turtle and the Florida Panhandle population of the Florida red-bellied turtle are given a T2 NatureServe ranking. We proposed to list the striped mud turtle as endangered on May 19, 1978 (43 FR 21702) but never finalized the listing. The species was placed on the category 2 candidate list on December 30, 1982 (47 FR 58454). The northern red-bellied cooter is given a NatureServe ranking of G4 or apparently stable with State rankings ranging from S2 (imperiled) to S5 (stable). In addition to the striped mud turtle, Kirtland's snake, Florida Keys mole skink, and Barbour's map turtle were each prior Federal category 2 candidate species. The black-knobbed map turtle was a prior category 3C candidate species (taxa that were proven to be more widespread than was previously believed and/or those that were not subject to any identifiable threat).

The petition identified 44 snails and requested that they be added to the List, of which 43 are subjects of this finding, including the following: Manitou cavesnail (Antrorbis breweri), Blue Spring hydrobe snail (Aphaostracon asthenes), freemouth hydrobe snail (Aphaostracon chalarogyrus), Wekiwa hydrobe snail (Aphaostracon monas), dense hydrobe snail (Aphaostracon pycnus), Clifton Spring hydrobe snail (Aphaostracon theiocrenetum), acute elimia (Elimia acuta), mud elimia (Elimia alabamensis), ample elimia (Elimia ampla), Lilyshoals elimia (Elimia annettae), spider elimia (Elimia arachnoidea), princess elimia (Elimia bellacrenata),

walnut elimia (Elimia bellula), prune elimia (Elimia chiltonensis), cockle elimia (Elimia cochliaris), cylinder elimia (Elimia cylindracea), nodulose Coosa River snail (Elimia lachryma), round-rib elimia (Elimia nassula), caper elimia (Elimia olivula), engraved elimia (Elimia perstriata), compact elimia (Elimia showalteri), elegant elimia (Elimia teres), cobble elimia (Elimia vanuxemiana), Ichetucknee siltsnail (Floridobia mica), Enterprise siltsnail (Floridobia monroensis), pygmy siltsnail (Floridobia parva), Ponderosa siltsnail (Floridobia ponderosa), Wekiwa siltsnail (Floridobia wekiwae), spiny riversnail (Io fluvialis), Arkansas mudalia (Leptoxis arkansasensis), spotted rocksnail (Leptoxis picta), smooth mudalia (Leptoxis virgata), knobby rocksnail (Lithasia curta), helmet rocksnail (Lithasia duttoniana), Ocmulgee marstonia (Marstonia agarhecta), beaverpond marstonia (Marstonia castor), Ozark pyrg (Marstonia ozarkensis), magnificant rams-horn (Planorbella magnifica), corpulent hornsnail (Pleurocera corpulenta), shortspire hornsnail (Pleurocera curta), skirted hornsnail (Pleurocera pyrenella), domed ancylid (Rhodacme elatior), and reverse pebblesnail (Somatogyrus alcoviensis).

These 43 snails each maintain a NatureServe ranking of either G1, critically imperiled, or G2, imperiled. Several are previous Federal category 2 candidates, including the magnificent rams-horn, beaverpond marstonia, Ocmulgee marstonia, and the skirted hornsnail, until that category was discontinued in 1996.

The petition identified eight stoneflies and requested that they be added to the List, including the following: Virginia stone (Acroneuria kosztarabi), Sevier snowfly (Allocapnia brooksi), Smokies snowfly (Allocapnia fumosa), Karst snowfly (Allocapnia cunninghami), Tennessee forestfly (Amphinemura mockfordi), Louisiana needlefly (Leuctra szczytkoi), Smokies needlefly (Megaleuctra williamsae), and lobed roachfly (Tallaperla lobata). The Virginia stone and Karst snowfly are assigned a NatureServe global ranking of G1, critically imperiled. The Sevier snowfly, Smokies snowfly, Tennessee forestfly, Louisiana needlefly, Smokies needlefly, and lobed roachfly are assigned NatureServe global rankings of G2.

Lastly, the petition identified 76 vascular plants and requested that they be added to the List of Endangered and Threatened Plants, of which 75 are included in this finding, including the following: Aeschynomene pratensis (meadow joint-vetch), Alnus maritima (seaside alder), Amorpha georgiana var. georgiana (Georgia leadplant or Georgia indigo bush), Arnoglossum diversifolium (variable-leaved Indian-plantain), Balduina atropurpurea (purple balduina or purple disk honeycombhead), Baptisia megacarpa (Apalachicola wild indigo), Bartonia texana (Texas screwstem), Boltonia montana (Doll's daisy), Calamovilfa arcuata (rivergrass), Carex brysonii (Bryson's sedge), Carex impressinervia (impressed-nerved sedge), Coreopsis integrifolia (ciliate-leaf tickseed), Croton elliottii (Elliott's croton), Elytraria caroliniensis var. angustifolia (narrowleaf Carolina scalystem), Encyclia cochleata var. triandra (Clam-shell orchid), Epidendrum strobiliferum (Big Cypress epidendrum), Eriocaulon koernickianum (small-headed pipewort), Eriocaulon nigrobracteatum (black-bracked pipewort), Eupatorium paludicola (a thoroughwort), Eurybia saxicastellii (Rockcastle wood-aster), Fimbristylis perpusilla (Harper's fimbristylis), Forestiera godfreyi (Godfry's privet), Hartwrightia floridan (Hartwrightia), Helianthus occidentalis ssp. plantagineus (Shinner's sunflower), Hexastylis speciosa (Harper's heartleaf), Hymenocallis henryae (Henry's spider-lily), Hypericum edisonianum (Edison's ascyrum), Hypericum lissophloeus (smooth-barked St. John's-wort), Illicium parviflorum (yellow anisetree), Isoetes hyemalis (winter or evergreen quillwort), Isoetes microvela (thin-wall quillwort), Lilium iridollae (panhandle lily), Lindera subcoriacea (bog spicebush), Linum westii (West's flax), Lobelia boykinii (Boykin's lobelia), Ludwigia brevipes (Long Beach seedbox), Ludwigia spathulata (spathulate seedbox), Ludwigia ravenii (Raven's seedbox), Lythrum curtissii (Curtis's loosestrife), Lythrum flagellare (lowland loosestrife), Macbridea caroliniana (Carolina birds-in-a-nest), Marshallia grandiflora (Large-flowered Barbara's-buttons), Minuartia godfreyi (Godfrey's stitchwort), Najas filifolia (narrowleaf naiad), Nufar lutea ssp. sagittifolia (Cape Fear spatterdock or yellow pond lily), Nufar lutea ssp. ulvacea (West Florida cow-lily), Nyssa ursina (Bear tupelo or dwarf blackgum), Oncidium undulatum (Cape Sable orchid), Physostegia correllii (Correll's false dragonhead), Potamogeton floridanus (Florida pondweed), Potamogeton tennesseensis (Tennessee pondweed), Ptilimnium ahlesii (Carolina bishopweed), Rhexia parviflora (small-flower meadow-beauty), Rhexia salicifolia (panhandle meadow-beauty), Rhynchospora crinipes (hairy-peduncled beakbush),

Rhynchospora thornei (Thorne's beakbush), Rudbeckia auriculata (eared coneflower), Rudbeckia heliopsidis (sun-facing coneflower), Salix floridana (Florida willow), Sarracenia purpurea var. montana (mountain purple pitcherplant), Sarracenia rubra ssp. gulfensis (Gulf sweet pitcherplant), Sarracenia rubra ssp. wherryi (Wherry's sweet pitcherplant), Schoenoplectus hallii (Hall's bulrush), Scuttelaria ocmulgee (Ocmulgee skullcap), Sideroxylon thornei (swamp buckhorn or Georgia bully), Solidago arenicola (southern racemose goldenrod), Sporobolus teretifolius (wire-leaved dropseed), Stellaria fontinalis (water stitchwort), Symphyotrichum puniceum var. scabricaule (rough-stemmed aster), Thalictrum debile (southern meadowrue), Trillium texanum (Texas trillium), Tsuga caroliniana (Carolina hemlock), Vicia ocalensis (Ocala vetch), Waldsteinia lobata (lobed barren-strawberry), and Xyris longisepala (Kral's yellow-eyed grass). One of the species petitioned, Solidago plumosa (Yadkin River goldenrod), is already a current Federal candidate species and is, therefore, not considered in this finding.

On December 11, 2010, the Service received a second petition from Wild South to list Tsuga caroliniana (Carolina hemlock) as endangered under the Act and to designate critical habitat. On December 20, 2010, we provided a response to the petitioners acknowledging receipt of the petition and identifying it as a supplementary petition as Tsuga caroliniana was also included in the CBD petition to list 404 southeastern U.S. species. Wild South provided additional information on the species' life history, status and threats.

Of the 75 vascular plants identified above, 46 held previous Federal candidate status, prior to 1996 and the discontinuance of the category 2 and 3C classifications. These include the following: Alnus maritima (seaside alder), Amorpha georgiana var. georgiana (Georgia leadplant or Georgia indigo bush), Balduina atropurpurea (purple balduina or purple disk honeycombhead), Baptisia megacarpa (Apalachicola wild indigo), Bartonia texana (Texas screwstem), Calamovilfa arcuata (rivergrass), Carex impressinervia (impressed-nerved sedge), Croton elliottii (Elliott's croton), Elytraria caroliniensis var. angustifolia (narrowleaf Carolina scalystem), Eriocaulon koernickianum (small-headed pipewort), Fimbristylis perpusilla (Harper's fimbristylis), Hartwrightia floridan (Hartwrightia), Hexastylis speciosa (Harper's heartleaf), Hymenocallis henryae (Henry's spider-lily), Hypericum edisonianum (Edison's ascyrum), Hypericum lissophloeus (smooth-barked St. John's-wort), Illicium parviflorum (yellow anisetree), Lilium iridollae (panhandle lily), Lindera subcoriacea (bog spicebush), Linum westii (West's flax), Lobelia boykinii (Boykin's lobelia), Lythrum curtissii (Curtis's loosestrife), Lythrum flagellare (lowland loosestrife), Macbridea caroliniana (Carolina birds-in-a-nest), Marshallia grandiflora (Large-flowered Barbara's-buttons), Minuartia godfreyi (Godfrey's stitchwort), Najas filifolia (narrowleaf naiad), Nufar lutea ssp. ulvacea (West Florida cow-lily), Nyssa ursina (Bear tupelo or dwarf blackgum), Physostegia correllii (Correll's false dragonhead), Potamogetan floridanus (Florida pondweed), Rhexia parviflora (small-flower meadow-beauty), Rhexia salicifolia (panhandle meadow-beauty), Rhynchospora crinipes (hairy-peduncled beakbush), Rhynchospora thornei (Thorne's beakbush), Rudbeckia auriculata (eared coneflower), Rudbeckia heliopsidis (sun-facing coneflower), Salix floridana (Florida willow), Sarracenia rubra ssp. wherryi (Wherry's sweet pitcherplant), Scuttelaria ocmulgee (Ocmulgee skullcap), Sporobolus teretifolius (wire-leaved dropseed), Stellaria fontinalis (water stitchwort), Thalictrum debile (southern meadowrue), Trillium texanum (Texas trillium), Vicia ocalensis (Ocala vetch), Waldsteinia lobata (lobed barren-strawberry), and Xyris longisepala (Kral's yellow-eyed grass). The NatureServe global ranking of these 75 species ranges from subspecies T1, to T2, to T3 status and species G1, to G2, to G3, and G4.

Evaluation of Information for This Finding

Section 4 of the Act (16 U.S.C. 1533) and its implementing regulations at 50 CFR 424 set forth the procedures for adding a species to, or removing a species from, the Lists of Endangered and Threatened Wildlife and Plants (Lists). A species may be determined to be endangered or threatened due to one or more of the five factors described in section 4(a)(1) of the Act:

(A) The present or threatened destruction, modification, or curtailment of its habitat or range;

(B) Overutilization for commercial, recreational, scientific, or educational purposes;

(C) Disease or predation;
(D) The inadequacy of existing regulatory mechanisms; or
(E) Other natural or manmade factors affecting its continued existence.
Listing actions may be warranted based on any of the above factors, singly or in combination.
In considering what factors might constitute threats, we must look beyond the mere exposure of the species to the factor to determine whether the species responds to the factor in a way that causes actual impacts to the species. If there is exposure to a factor, but no response, or only a positive response, that factor is not a threat. If there is exposure and the species responds negatively, the factor may be a threat and we then attempt to determine how significant a threat it is. If the threat is significant, it may drive or contribute to the risk of extinction of the species such that the species may warrant listing as endangered or threatened as those terms are defined by the Act. This does not necessarily require empirical proof of a threat. The combination of exposure and some corroborating evidence of how the species is likely impacted could suffice. The mere identification of factors that could impact a species negatively may not be sufficient to compel a finding that listing may be warranted. The information shall contain evidence sufficient to suggest that these factors may be operative threats that act on the species to the point that the species may meet the definition of endangered or threatened under the Act.
In making this 90-day finding, we evaluated whether information regarding threats to the 374 species, as presented in the petition and other information available in our files, is substantial, thereby indicating that listing any of the species in the petitioned action may be warranted. Our evaluation of this information is presented below. Our review of the species varied significantly depending on the amount of information presented in the petition and the amount of information available in our files. Because so little information was available in our files for many of these rare, locally endemic species, the information below summarizes only the information in the petition, unless noted otherwise.
Factor A. The Present or Threatened Destruction, Modification, or Curtailment of the Species' Habitat or Range
The petition states that all species, except for one (Oncidium undulatum, Cape Sable orchid) identified in the petition are threatened by the present or threatened destruction, modification, or curtailment of their habitat or range. According to the petition, aquatic and riparian habitats in the Southeast have been extensively degraded by direct alterations of waterways such as impoundment, diversion, dredging and channelization, and draining of wetlands, and by land-use activities such as development, agriculture, logging, and mining (Benz and Collins 1997; Shute et al. 1997). More than one-third of the petitioned species have experienced drastic range reductions, and up to a 90 percent range loss for many of the petitioned mussels and snails (Pyne and Durham 1993; Neves et al. 1997; NatureServe 2008). According to the petition, because many of the aquatic species in the Southeast are very narrow endemics or have experienced a dramatic range reduction, remaining populations are now susceptible to extinction from even relatively minor habitat losses (Herrig and Shute 2002). The petition asserts that habitat loss and degradation are driving the decline of reptiles, mollusks, and other aquatic taxa. Buhlman and Gibbons (1997) found that 36 percent of analyzed imperiled aquatic reptiles are threatened because of the "continuing, cumulative abuse sustained by river systems," and that at least 22 southeastern reptile taxa have declined due to degradation of rivers and streams. Habitat degradation and fragmentation is also asserted to be the primary cause of imperilment for southeastern mollusks (Neves et al. 1997; Lysne et al. 2008); mammals (Harvey and Clark 1997); fish (Warren et al. 1997); and plants (Stein et al. 2000).
Physical Alteration of Aquatic Habitats
Impoundment
According to the petition, nearly half of the petitioned species are threatened by impoundment, including 83 percent of the fishes and 67 percent of the mollusks. Dams modify habitat and aquatic communities both upstream and downstream of the impoundment (Winston et al. 1991; Mulholland and Lenat 1992; Soballe et al.

1992). Upstream of dams, habitat is flooded and in-channel conditions change from flowing to still water, with increased depth, decreased levels of dissolved oxygen, and increased sedimentation. Sedimentation alters substrate conditions by filling in interstitial spaces between rocks, which provide habitat for many species (Neves et al. 1997). Downstream of dams, flow regime fluctuates (with resulting fluctuations in water temperature and dissolved oxygen levels), the substrate is scoured, and downstream tributaries are eroded (Schuster 1997; Buckner et al. 2002). Negative "tailwater" effects on habitat extend many kilometers downstream (Neves et al. 1997). Dams fragment habitat of aquatic species by blocking corridors for migration and dispersal, resulting in population isolation and heightened susceptibility to extinction (Neves et al. 1997). Dams also preclude aquatic organisms from escaping polluted waters and accidental spills (Buckner et al. 2002).

As of the early 1990s, there were 144 major reservoirs in the Southeast, including 26 in Tennessee, 19 each in Alabama and North Carolina, and 17 in Kentucky (Soballe et al. 1992). There are 36 dams on the mainstem and major tributaries of the Tennessee River (Neves et al. 1997), resulting in the impoundment of more than 20 percent of the Tennessee River and its major tributaries (Shute et al. 1997). The Tennessee and Cumberland River drainages have approximately 70 major dams and reservoirs (Buckner et al. 2002). Waterways in Alabama have also been extensively impounded, with 16 major lock and dam structures on six rivers, 21 hydroelectric power dams, and over 20 public water supply impoundments (Buckner et al. 2002). The Coosa and Tallapoosa Rivers in Georgia and Alabama have been ranked among the most imperiled rivers in the nation due to damming (Buckner et al. 2002).

The petition asserts that, in addition to rivers, damming of streams and springs is also extensive throughout the Southeast (Etnier 1997; Morse et al. 1997; Shute et al. 1997). Noss et al. (1995) reports that practically every stream in the Mississippi Alluvial Plain has been channelized, levied, or hydrologically altered. Small streams on private lands are regularly dammed to create ponds for cattle, for irrigation, for recreation, and for fishing, with significant ecological effects due to the sheer abundance of these structures (Morse et al. 1997).

In Florida and other Southeast States, impoundment of large coastal tributaries has severely curtailed fish spawning runs (Gilbert 1992). Impoundment blocks migratory routes of fish and covers spawning habitat with silt (Etnier 1997). According to the petitioners, dams and the resultant substrate changes have imperiled disproportionately high numbers of benthic fishes (Warren et al. 1997).

Changes in the fish community jeopardize the survival of mussels because mussels are dependent on host fish to successfully reproduce, with some species of mussels being dependent on specific species of fish (Bogan 1993, 1996). If the fish species upon which a mussel is dependent to host its larvae goes extinct, then the mussel becomes "functionally extinct," even when there are surviving long-lived individuals (Bogan 1993). Impoundments can also separate mussel populations from host fish populations, resulting in the eventual extinction of the mussel species (Bogan 1993, 1996). The loss of mussels can in turn negatively affect fish, because some species of fish use empty mussel shells as nest sites (Bennett et al. 2008).

The petition claims that impoundments are also one of the primary reasons for the decline in crustaceans in the Southeast (Schuster 1997), in aquatic insects (Herrig and Shute 2002), and in forest-associated bird species, particularly for species with narrow niches and low tolerance to disturbance (Dickson 2007).

Dredging and Channelization

According to the petition, dredging and channelization are extensively employed throughout the Southeast for flood control, navigation, sand and gravel mining, and conversion of wetlands into croplands (Neves et al. 1997; Herrig and Shute 2002). Many rivers are continually dredged to maintain shipping channels (Abell et al. 2002). Dredging and channelization modify and destroy habitat for aquatic species by destabilizing the substrate, increasing erosion and siltation, removing woody debris, decreasing habitat heterogeneity, and stirring up contaminants that settle onto the substrate (Hart and Fuller 1974; Williams et al. 1993; Buckner et al. 2002; Bennett et al. 2008). Channelization can also lead to headcutting, sedimentation, and actual removal of mussels

from their beds during dredging operations (Hart and Fuller 1974; Williams et al. 1993).
The petition also claims that dredging and channelization also threaten imperiled fish, reptiles, crustaceans, and other species. Dredging removes woody debris, which provides cover and nest locations for fish such as the frecklebelly madtom (Bennett et al. 2008). Flood control projects and channel maintenance operations in Mississippi threaten aquatic species in the Yazoo Basin (Jackson et al. 1993), including the petitioned Yazoo crayfish. Dredging and channelization are also known to be the primary reason for imperilment of southeastern crustaceans (Schuster 1997), and to contribute to the decline of southeastern turtles (Buhlmann and Gibbons 1997). Many of the imperiled turtle species, including the highly imperiled map turtles, are threatened by the removal of woody debris, on which they depend for basking.
Water Development and Diversion and Decreased Water Availability
According to the petition, in the Southeast, demands for freshwater for electricity production, irrigation, agriculture, and industrial and residential development are increasing (Herrig and Shute 2002; Hutson et al. 2005; Lysne et al. 2008). Limited water supply is already a source of conflict in Tennessee, Alabama, and Georgia in particular, where rapidly growing metropolitan areas such as Atlanta, Birmingham, and Nashville have drastically increased the demand for water for residential and industrial uses (Buckner et al. 2002). The construction of numerous large Confined Animal Feeding Operations throughout the Southeast has led to an increased demand for inter-basin water transfers (Buckner et al. 2002). Increasing drought due to global climate change is expected to exacerbate the threat of limited water availability to aquatic and riparian species in southeastern States (Karl et al. 2009). Water demands to support gas-fired steam plants for electricity generation have increased in the Southeast. These plants require millions of gallons of water per day, and return only roughly one-fifth of that water back to the waterways, and even this water tends to be thermally polluted and may be inadequate to meet the dissolved oxygen needs of aquatic species (Buckner et al. 2002).
The petition also asserts that surface diversion of streams threatens southeastern aquatic species (Etnier 1997; Abell et al. 2000; Buckner et al. 2002; Herrig and Shute 2002), and that an increasing threat to southeastern species is the growing practice of damming small headwater streams to supply water for municipalities (Buckner et al. 2002). Water withdrawals reduce base flows, decreasing habitat availability for aquatic species, and the reduced water volume also increases the concentration of pollutants, posing another threat to species (Abell et al. 2000; Herrig and Shute 2002).
According to the petition, in addition to rivers and streams, many southeastern springs have been drastically altered to supply water for human uses (Etnier 1997). Spring development and diversion can alter flow regime and water quality parameters, lead to substrate disturbance and erosion, and alter the substance and composition of vegetative cover with resultant effects on freshwater fauna (Shepard 1993; Frest and Johannes 1995; Frest 2002). An additional threat to southeastern species is groundwater overdraft (pumpage of groundwater in excess of safe yields), which threatens spring flow and species that are dependent on consistent spring flow conditions (Strayer 2006). The petitioners also assert that the dewatering of groundwater systems in the Southeast threatens rare species of isopods, amphipods, fish, crayfish, and amphibians that are dependent on stable spring and cave environments (Herrig and Shute 2002).
Loss of Wetlands
According to the petition, through the mid-1980s, wetlands were lost in the Southeast as a rate of over 385,000 acres per year (Hefner and Brown 1984). In Florida alone, more than 9 million acres of wetlands had been lost by that time (Cerulean 1991). In Arkansas 6 million acres of Mississippi Delta wetlands had been converted to agricultural use by the mid-1980s (Smith et al. 1984). In the Lower Mississippi Valley Region, more than one-third of existing wetlands were destroyed from 1950 to 1970 (Mitsch and Gosselink 1986), with over 185,000 acres of wetlands continuing to be lost annually through the mid-1980s in this region (Tiner 1984). In Tennessee, up to 90 percent of upland wetlands on the Highland Rim have been destroyed, as have more than 90 percent of Appalachian bogs in the Blue Ridge Province (Pyne and Durham 1993). The destruction of

pocosins (evergreen shrub bogs) has been extensive throughout the Southeast, with greater than 90 percent loss in Virginia, nearly 70 percent loss in North Carolina, and nearly 70 percent loss on the Southeastern Coastal Plain (Noss et al. 1995).

The petition asserts that loss, degradation, and fragmentation of wetland habitat have negatively affected numerous southeastern freshwater species, and natural wetland habitats continue to be lost, placing more species at risk (Dodd 1990; Benz and Collins 1997; Semlitsch and Bodie 1998; Herrig and Shute 2002). Vegetated permanent wetlands are among the most jeopardized habitats in the Southeast, with the result that fish families that are dependent on these habitats are disproportionately imperiled, such as the pygmy sunfishes (Etnier and Starnes 1991; Cubbage and Flather 1993; Dickson and Warren 1994; Warren et al. 1994). According to petitioners, wetland destruction has also destroyed habitat for many bird species (Dickson 1997); aquatic reptile species that depend on standing water habitats (Herrig and Shute 2002),; and amphibians (LaClaire 1997), such as the Gulf Hammock dwarf siren (Amphibia Web 2009). Because many reptile and amphibian populations exist as metapopulations that rely on habitat connectivity to maintain genetic structure and provide recolonization opportunities in the event of localized extirpations, habitat fragmentation and isolation threaten their regional persistence by cutting off opportunities for migration and dispersal and by magnifying the likelihood of inbreeding depression and reproductive failure due to random environmental perturbation (Buhlmann and Gibbons 1997; Semlitsch and Bodie 1998).

Land Use Activities That Decrease Watershed Integrity

The petition asserts that southeastern aquatic species are threatened not only by direct physical alteration of waterways, but also by activities in the watershed that directly or indirectly degrade aquatic habitats such as residential, commercial, and industrial development; agriculture; logging; mining; alteration of natural fire regime; and recreation. Land use activities can alter water chemistry, flow, temperature, and nutrient and sediment transport, and can interfere with normal watershed functioning (Folkerts 1997).

Residential and Industrial Development and Human Population Growth

According to the petition, development threatens two-thirds of the petitioned species. The primary threat to the petitioned dragonfly, the purple skimmer, is lakeshore development. The Waccamaw fatmucket, a petitioned mussel, is threatened primarily by increasing development in its watershed. Also, according to the petition, the Carolina pygmy sunfish, Chauga crayfish, and many other petitioned species are also threatened primarily by development.

The human population nearly doubled in the Southeast between 1970 and 2000 (Folkerts 1997). Southeastern states continued to experience significant human population growth from 2000 to 2007, with the population of Georgia increasing by 17 percent, Florida by 14 percent, North Carolina by 13 percent, South Carolina by 10 percent, Virginia by 9 percent, and Tennessee by 8 percent (U.S. Census Bureau 2009). Metropolitan areas in the Southeast are among the fastest growing in the nation (Dodd 1997).

Population growth threatens biodiversity through an increased demand for food, water, and other resources. The strong geographic focus of development around freshwaters concentrates human ecological impacts on freshwater ecosystems more than on any other part of the landscape (Strayer 2006). Throughout the Southeast, increased development is creating water supply problems, stressing available water resources, and polluting aquatic habitats (Seager et al. 2009). Global climate change is expected to lead to fluctuating water supplies in the Southeast, and in conjunction with increasing human demand for freshwater, to place many aquatic at heightened risk of extinction (Karl et al. 2009).

The petition asserts that urbanization and residential, commercial, and industrial development threaten aquatic species in both direct and indirect ways. Habitat is directly lost and fragmented through land conversion and through water withdrawal and diversion (Benz and Collins 1997). Predation increases as populations of pets and synanthropic species ecologically associated with humans increase (Marzluff et al. 2001). Point-source pollution from industry and runoff from parking lots, roofs, roads, and lawns degrade water quality and have

lethal and sub-lethal effects on aquatic species. Urban runoff is associated with declines in macroinvertebrate diversity and with decreased mussel growth rates, and urban land use classes are associated with impairment of fish and macroinvertebrate communities (Soucek et al. 2003; Carlisle et al. 2008). Amphibians and reptiles are particularly threatened by development. Siltation and leachate from road runoff can be lethal to larval amphibians and other aquatic organisms (Dodd 1997). The construction of roads increases mortality and leads to population isolation and the disruption of the metacommunity structure on which the long-term population persistence of many herptile species depends (Buhlman and Gibbons 1997). Noise and light from roads and developments can interfere with behavior patterns and disrupt breeding and feeding activities, particularly for amphibians (Dodd 1997). Amphibian species' richness is lower in urbanized areas, as many species cannot persist in urbanized sites (Delis 1993; Herrig and Shute 2002).

According to the petition, habitat loss and degradation due to development is generally permanent and poses an increasing threat to southeastern aquatic species. Folkerts (1997) reports that particularly in the Southeast, development threatens aquatic species more than in other areas due to lax enforcement of environmental laws in the region.

Recreation

According to the petition, the increased human population is increasing the demand for recreational developments and activities. Housing developments, strip malls, and resorts are being constructed in very rural areas, and small towns are now burgeoning in previously undeveloped areas in the Southeast including, the Knoxville-Chattanooga suburban corridor, on the Cumberland Plateau, in the Cahaba River headwaters outside Birmingham, and in the Mobile-Tensaw Delta (Buckner et al. 2002). Many rapidly developing small communities are constructing dams on headwater streams, often in areas that were recently remote and inaccessible, with resultant impacts on aquatic species (Buckner et al. 2002). The development of housing and recreational facilities on lakeshores and in riparian areas results in the degradation of water quality and aquatic habitat (Tennessen 1997). For example, Morse et al. (1997) report the loss of rare stonefly species in a stream in North Carolina following the development of summer homes.

The petition asserts that recreational developments and activities threaten aquatic species by fostering air and water pollution, litter, and potentially high densities of recreationists (Houston 1971; White and Bratton 1980). Recreation can cause trampling of organisms and vegetation (Little 1975). Local habitat changes caused by trampling include simplification of vegetation and soil compaction, which can result in overall loss of habitat diversity (Speht 1973; Liddle 1975). Off-road vehicle use can lead to severe degradation of aquatic and riparian habitats through trampling of organisms, destruction of vegetation, erosion, and degraded water quality (Wuerthner 2007). According to the petitioners, off-road vehicle use threatens imperiled mussels (Hanlon and Levine 2004) and reptiles (Herrig and Shute 2002). Southeastern aquatic species are also alleged by the petitioners to be threatened by other forms of motorized recreation, such as motorized boats and jet skis, which cause oil and gas contamination and bank erosion (Buckner et al. 2002). Garber and Burger (1995) also document the extirpation of a turtle population in a protected area due to occasional poaching.

Decreased water quality, trampling, or other recreational impacts purportedly threaten 22 percent of the petitioned species including the Bigcheek cave crayfish, Blue Spring hydrobe snail, and small-flower meadow-beauty.

Logging

The petition asserts that southeastern aquatic and riparian species are threatened by the loss of forests and the negative effects of these losses on water quality and aquatic habitats that result from logging activities and canopy removal. The Southeast now supplies nearly 70 percent of the nation's pulp and paper products (Buckner et al. 2002). According to Folkerts (1997), the rate of deforestation in the Southeast at that time exceeded that of any tropical area of comparable size. The Tennessee, Cumberland, and Mobile basins have experienced a drastic increase in large clearcutting operations and chip mills, with 1.2 million acres of forest

being cut annually to supply 150 regional chip mills, two-thirds of which have been built since the 1980s (Buckner et al. 2002). In the area surrounding Great Smoky Mountain National Park, the rate of logging doubled from 1980 to 1990 (Folkerts 1997). Of the 70 million acres of longleaf pine forest which once covered over 40 percent of the Southeastern Coastal Plain, only 1 to 2 percent remains, and the remnant acreage is fragmented and "poorly-managed" (Noss et al. 1995; Dodd 1997). Clearcutting on the Coastal Plain has affected "virtually every aquatic habitat in the area" (Folkerts 1997).

According to the petition, logging has many direct and indirect negative effects on aquatic biota across taxa. Erosion from poor forestry practices degrades water quality (Williams et al. 1993). Increased sedimentation from logging can suffocate aquatic snails and their eggs, preclude their ability to feed, and extirpate populations (Frest and Johannes 1993). Increased sedimentation is also harmful to freshwater mussels (Neves et al. 1997). Clearcutting and conversion of deciduous forests to pine plantations increases sedimentation and reduces the input of large woody debris and leaf litter into streams, which are necessary to provide microhabitat and food for aquatic organisms (Morse et al. 1997; Herrig and Shute 2002). Clearcutting can lead to the disappearance of caddisflies and mayflies, with ramifications at higher levels of the food web (Morse et al. 1997). Amphibian diversity and abundance is reduced by clearcutting and the conversion of deciduous forests to pine plantations (Dodd 1997; Herrig and Shute 2002). Aquatic-breeding amphibians, which depend on ephemeral ponds or which are dependent on forested habitats to complete their life cycle or both, are particularly threatened by logging activities (Dodd 1997). Herbicides used after timber harvests also negatively affect amphibians and other aquatic organisms (Dodd 1997; Herrig and Shute 2002).

According to the petition, 51 percent of the petitioned species are threatened by logging. Logging is the primary threat to the newly discovered patch-nosed salamander, and to many of the petitioned crayfishes, including the Irons Fork burrowing crayfish, Kisatchie painted crayfish, and pristine crayfish. The petitioners assert that logging also threatens the petitioned dragonflies, including Westfall's clubtail and the Ozark emerald.

Agriculture and Aquaculture

According to the petition, southeastern aquatic species are also threatened by the loss and degradation of habitat due to poor agricultural practices. Intensive agriculture began in the Southeast in the 1930s, and agriculture continues to extensively impact southeastern aquatic ecosystems (Neves et al. 1997). The petitioners assert that agriculture in the Southeast has a tremendous impact on aquatic habitats both due to the extent of farmland and to farming practices (Buckner et al. 2002; Herrig and Shute 2002). In the Tennessee, Cumberland, and Mobile River basins, for example, farms cover nearly half the landscape. Throughout the Southeast, fields are commonly plowed to the edges of waterways, causing sedimentation and bank collapse and facilitating the runoff of fertilizers and pesticides (Buckner et al. 2002). Both traditional farming practices and confined animal feeding operations contribute to water quality degradation and the imperilment of indigenous biota in the Southeast through erosion, sedimentation, and chemical and nutrient pollution from point and non-point sources (Patrick 1992; Morse et al. 1997; Neves et al. 1997; Herrig and Shute 2002).

According to the petition, 50 percent of the petitioned species are threatened by conversion of their habitat to agricultural use or by agricultural runoff, including the striated darter, Logan's agarodes caddisfly, Sevier snowfly, and Tennessee clubtail. Agricultural land uses have been associated with impairment of fish and macroinvertebrate communities (Herrig and Shute 2002), communities of freshwater mollusks (Williams et al. 1993; Neves et al. 1997), and threats to imperiled amphibians (Herrig and Shute 2002).

Many of the petitioned species are allegedly threatened from confined animal feeding operations (CAFOs), including the Carolina madtom, corpulent hornsnail, and the Neuse River waterdog. Confined animal feeding operations and feedlots have caused extensive degradation of southeastern aquatic ecosystems (Neves et al. 1997; Buckner et al. 2002; Mallin and Cahoon 2003). The number of CAFOs in the Southeast has increased drastically since 1990, as livestock production has undergone extensive industrialization (Buckner et al. 2002; Mallin and Cahoon 2003). Alabama and Arkansas are now the nation's leading poultry producers, with Florida,

Georgia, and Kentucky also among the top 10 States for poultry production (U.S. Census Bureau 2009). Poultry CAFOs are also abundant in North Carolina, Mississippi, and Virginia (Mallin and Cahoon 2003). There are extensive swine CAFOs in the North Carolina Coastal Plain, and North Carolina is now the nation's second largest pork producer (Mallin and Cahoon 2003; U.S. Census Bureau 2009). Confined animal feeding operations threaten aquatic species both because of the vast amounts of fresh water necessary to support their operation and due to pollution (Buckner et al. 2002). Confined animal feeding operations house thousands of animals and produce a large amount of waste, which enters the environment either by being directly discharged into streams or constructed ditches, stored in open lagoons, or applied to fields in wet or dry form (Buckner et al. 2002; Mallin and Cahoon 2003; Orlando et al. 2004). Confined animal feeding operation wastes contain nutrients, pharmaceuticals, and hormones, and result in eutrophication (a choking of waters by excessive algae growth which has been stimulated by fertilizers or sewage) of waterways, toxic blooms of algae and dinoflagellates, and endocrine disruption in downstream wildlife (Mallin and Cahoon 2002; Orlando et al. 2004).
Both livestock holding lots and landscape grazing degrade habitats in the Southeast, according to the petitioners (Buckner et al. 2002; Herrig and Shute 2002). Several southeastern States produce large amounts of cattle and horses feeding them via both grazing and holding lots (Buckner et al. 2002; U.S. Census Bureau 2009). Livestock are generally allowed to wade directly into streams, trampling habitat and resulting in erosion and nutrient contamination (Buckner et al. 2002). The effects of livestock grazing on stream and riparian ecosystems are well documented and include negative effects on water quality and quantity, channel morphology, hydrology, soils, instream and streambank vegetation, and aquatic and riparian wildlife (Belsky et al. 1999). According to Frest (2002), snails and their habitats are harmed through direct trampling, soil compaction, erosion, water siltation and pollution, and drying up of springs and seeps. The petitioners claim that 14 percent of the petitioned species are threatened by grazing, including the Virginia stone (stonefly), Barrens darter, Cherokee clubtail (dragonfly), and many plants, including the eared coneflower.
The petition alleges that aquaculture poses an additional threat to aquatic species in the Southeast. According to Tucker and Hargreaves (2003), catfish farming is the largest aquaculture enterprise in the United States, with 95 percent of production occurring in Alabama, Arkansas, Louisiana, and Mississippi. Similarly, crayfish farming in Louisiana is the nation's second largest aquaculture enterprise, with over 49,000 hectares of crayfish ponds (Holdich 1993). According to the petitioners, aquaculture threatens aquatic habitats through habitat conversion; the withdrawal, diversion, or impoundment of natural waterways to support operations; and the release of effluent to waterbodies (Naylor et al. 2001). Water quality degradation threatens southeastern aquatic insect populations (Herrig and Shute 2002). Impoundments and diversions alter water chemistry and flow, and can be detrimental to native mollusks and fishes (Morse et al. 1997; Neves et al. 1997). The construction of shrimp farms in wetlands and estuaries also destroys and degrades habitat for native aquatic species (Hopkins et al. 1995).

Mining and Oil and Gas Development

According to the petition, mining for coal, gravel, limestone, phosphate, iron, and other raw materials poses a dire threat to many aquatic species in the Southeast (Dodd 1997; Buckner 2002), and 29 percent of the petitioned species are threatened by mining and oil and gas development. Extensive strip mining for coal occurs in West Virginia, Kentucky, Virginia, Tennessee, and Alabama (Dodd 1997). As of 2004, more than 1.1 million acres of land in Appalachia were undergoing active mining operations (Loveland et al. 2003), and the EPA projects that from 1992 to 2013, 761,000 acres of Appalachian forest will be lost to surface coal mining (Pomponio 2009). Up to 23 percent of the land area of some counties in Kentucky and West Virginia has been permitted for surface coal mining (U.S. Government Accountability Office 2009). Mining increases the potential for extreme flooding events, and reclamation does not restore pre-mining hydrologic characteristics or ecological functions (Townsend et al. 2009).
Mining often occurs directly through streams or ponds, and mine wastes are pushed directly into streams and

rivers (Dodd 1997; EPA 2005). From 1992 to 2002, more than 1,200 miles of Appalachian streams were buried or degraded by mountaintop removal coal mining (EPA 2005). This figure does not incorporate the thousands of miles of downstream reaches that have been substantially degraded by sedimentation and chemical pollution from coal mining (Palmer and Bernhardt 2009; Pomponio 2009; Palmer et al. 2010). According to the petitioners, in the Clinch and Powell watersheds of southwestern Virginia, where the highest concentration of imperiled species in the continental United States occurs (Stein et al. 2000), there were 287 active coal-mining point source discharges as of 2002 (Diamond et al. 2002), which are degrading habitat for imperiled species (Ahlstedt et al. 2005). The petitioners allege that 30 of the petitioned species are specifically threatened by mountaintop removal.

Coal mining negatively impacts aquatic species through direct habitat destruction, decreased water availability, variations in flow and thermal gradients, and chronic and acute pollution of surface and ground water (FWS 1996; Neves et al. 1997; Houp 1993; Pond et al. 2008; Palmer and Bernhardt 2009; Pomponio 2009; Wood 2009; Palmer et al. 2010). Pollution from mining adversely impacts invertebrates and vertebrates, and leads to less diverse and more pollution-tolerant species (Naimo 1995; Cherry et al. 2001; EPA 2005; Lemly 2009; Pomponio 2009). The petitioners allege that surface coal mining and associated road building increase human access to imperiled species, which can lead to poaching and contribute to the spread of invasive species (FWS 1996). Surface coal mining also causes long-term changes in land use and local ecology, and threatens the long-term viability of populations due to habitat fragmentation (FWS 1996).

The petition alleges that coal mining negatively impacts diatoms (a major group of algae) and macroinvertebrates (Serveiss 2001; Locke et al. 2006; Carlisle et al. 2008; Pond et al. 2008), amphibian diversity and abundance (EPA 2005; Wood 2009; Palmer and Bernhardt 2009), and the index of fish biotic integrity (Diamond and Serveiss 2001). The petition states that coal mining is also reported to cause reproductive failure in riparian birds (Lemly 1985; Ohlendorf 1989).

According to the petition, other forms of mining and oil and gas development are also causing severe degradation of aquatic habitats: In-stream gravel mining and rock removal fragment and destroy habitat for aquatic insects, crayfish, mussels, and fish (Buckner et al. 2002); and sand and gravel mining have been associated with both on- and off-site mussel extirpation (Hartfield 1993), and with decreased downstream mussel growth rates (Yokley 1976). The petitioners allege that many species are threatened by sand and gravel mining, including the cobblestone tiger beetle, bluestripe darter, hellbender (salamander), and many mussels and snails. Historic phosphate and iron mines resulted in precipitous declines in mussel populations (Ortmann 1924). Mining of industrial minerals such as kaolin, mica, and feldspar also results in loss and degradation of habitat for aquatic species (Tennessee Valley Authority 1971; EPA 1977; Duda and Penrose 1980). The petition alleges that kaolin mining threatens the petitioned mussel, the Alabama spike, and the petitioned fish, the robust redhorse, and that oil and gas development threatens many of the petitioned mussels.

Factor B. Overutilization for Commercial, Recreational, Scientific, or Educational Purposes

The petition stated that all 15 amphibians petitioned (13 of which are subjects of this finding) were threatened by overutilization for commercial, recreational, scientific, or educational purposes; in addition this factor threatens 1 beetle (Cobblestone tiger beetle), 2 birds (Florida sandhill crane and black rail), 1 butterfly (rare skipper), 1 crayfish (Big Blue Springs Cave crayfish), 2 dragonflies (Septima's clubtail and Appalachian snaketail), 5 fish (northern cavefish, Carolina pygmy sunfish, robust redhorse, orangefin madtom, and bluehead shiner), 6 mussels (brook floater, brother spike, Suwannee moccasinshell, Tennessee clubshell, warrior pigtoe, and pyramid pigtoe), 11 reptiles (Kirtland's snake, western chicken turtle, Florida Keys mole skink, Barbour's map turtle, Escambia map turtle, Pascagoula map turtle, black-knobbed map turtle, Alabama map turtle, striped mud turtle--lower Florida Keys, Florida red-bellied turtle--Florida panhandle, and northern red-bellied cooter), and 7 vascular plants (Baptisia megacarpa, Epidendrum strobiliferum, Hymenocallis henryae, Illicium parviflorum, Lilium iridollae, Oncidium undulatum, and Sarracenia purpurea var. montana).

The petition alleges overutilization is the primary threat for the hellbender salamander, which is commonly killed by fishermen. Collection for the pet trade threatens a few of the petitioned fishes, crayfishes, and amphibians. Historical overuse greatly threatened many of the petitioned mussels, fishes, and the Florida sandhill crane. Throughout the Southeast, reptiles are exploited for use as pets or food, or are killed for recreational purposes, which may all cause significant population declines. The petitioners allege that many southeastern turtle species, such as the Florida red-bellied turtle, Pascagoula map turtle, Barbour's map turtle, and black-knobbed map turtle, are threatened by over-collection because they are commonly harvested for food, the pet trade, or recreation. Several southeastern turtle species are being driven to extinction by unregulated commercial harvest. The petition alleges that the States of Arkansas, Kentucky, Georgia, Louisiana, and Tennessee allow unlimited harvest of freshwater turtles. The international trade in turtles for use as food, as pets, or in traditional medicine is extensive and largely unregulated (Buhlman and Gibbons 1997; Sarma 1999). Records indicate that the trade in live turtles from the United States to China is thousands of tons per year. The Tennessee Wildlife Resources Agency reports that more than 25,000 turtles were reported as harvested in Tennessee from 2006 to 2007. Overutilization of imperiled turtle species is especially problematic because the reproductive success of long-lived reptile species is dependent on high adult survivorship, and population declines occur when adults are harvested (Brooks et al. 1991; Heppell 1998; Pough et al. 1998; Congdon et al. 1993, 1994).

Over-collection and recreational killing are also a threat to some southeastern snake and lizard species (Gibbons et al. 2000; Herrig and Shute 2002). The Kirtland's snake, and the Florida Keys mole skink are all threatened by over collection (NatureServe 2008).

The petition alleges that southeastern mussels are also threatened by overutilization, although to a lesser extent than in the past (Neves et al. 1997). The harvest of southeastern mussels for commercial purposes is well documented (Anthony and Downing 2001; Williams et al. 2008). Mussels are collected for their pearls, meat, and shells, and many populations of mussels have been depleted by harvest in the last 200 years (Strayer 2006). Although mussel fisheries targeted abundant species, the historical bycatch of rare species was likely substantial (Strayer 2006). Mussel collections declined by mid-century, but a resurgence in the commercial harvest has occurred since the 1960s to supply nucleus seeds for the cultured pearl trade (Ward 1985; Williams et al. 1993). In 1991 and 1992, 570 tons of shells were harvested from the Wheeler Reservoir on the Tennessee River (Williams et al. 2008). Most harvested mussels are common species, but bycatch remains a threat to native mussels.

Imperiled native mussels are threatened not only by the amount of harvest, but also by the method used to collect shells, which when conducted non-selectively, can result in substantial bycatch of non-target species and juveniles (Williams et al. 1993). Although unwanted mussels are thrown back, Sickel (1989) found that mortality of undersized mussels that are thrown back may be as high as 50 percent. Very rare species of mussels are also threatened by over-collection from shell collectors and biologists for biological collections. Overutilization for biological collections may have contributed significantly to the decline of the Suwannee moccasinshell (NatureServe 2008).

Other southeastern taxa are also threatened by overexploitation, including fish, amphibians, crayfish, butterflies, and plants. Amphibians are threatened by over-collection for use as food, for the pet trade, and for the biological and medicinal supply markets (Dodd 1997; Amphibia Web 2009). Southeastern fish and crayfishes are vulnerable to overutilization. Crayfishes are threatened by collection for use as bait or food (Herrig and Shute 2002). The Carolina pygmy sunfish (Elassoma boelhkei) is threatened by over-collection for the pet trade (NatureServe 2008). Collection of invertebrates for bait or the pet trade can deplete populations (Strayer 2006). Collection also threatens the rare skipper (Problema bulenta) (NatureServe 2008). White et al. (2002) documented the removal of an entire population of Panhandle lily (Lilium iridollae) from the Conecuh National Forest by horticultural collectors.

The petition alleges that the impacts of overutilization compound the threats facing imperiled southeastern

species whose populations have already been reduced due to habitat loss or other factors. Overutilization may drive species that are already struggling to survive to extinction.

Factor C. Disease or Predation

The petition stated that disease or predation threatened 11 amphibians addressed in this finding (streamside salamander, one-toed amphiuma, hellbender, Cumberland dusky salamander, seepage salamander, Chamberlain's dwarf salamander, Oklahoma salamander, Tennessee cave salamander, West Virginia Spring salamander, Georgia blind salamander, and Neuse River waterdog), 3 birds (MacGillivray's seaside sparrow, Florida sandhill crane, and black rail), 8 fish (Carolina pygmy sunfish, candy darter, paleback darter, Shawnee darter, Barrens topminnow, robust redhorse, Carolina madtom, and bluehead shiner), 1 mammal (Sherman's short-tailed shrew), 6 mussels (Tennessee heelsplitter, Cumberland moccasinshell, Tennessee clubshell, Tennessee pigtoe, purple lilliput, and Savannah lilliput), 6 reptiles (Kirtland's snake, Barbour's map turtle, Escambia map turtle, Pascagoula map turtle, Florida red-bellied turtle, and northern red-bellied cooter), and 6 vascular plants (Lilium iridollae (Panhandle lily), Najas filifolia (narrowleaf naiad), Rudbeckia auriculata (eared coneflower), Schoenoplectus hallii (Hall's bulrush), Sideroxylon thornei (swamp buckhorn or Georgia bully), Tsuga caroliniana (Carolina hemlock)).

Disease

According to the petition, the spread of disease has contributed to the decline of aquatic species globally and in the southeastern United States (Daszak et al. 1999; Corser 2000; Gibbons et al. 2000; Cunningham et al. 2003). Amphibians, in particular, have been decimated by the spread of disease (Kiesecker et al. 2004). Numerous diseases are contributing to amphibian declines, including infections of fungi (Batrachochytrium dendrobatidis "chytrid"; Saprolegnia), ranavirises, iridovirises, mesomycetozoea, protozoa, helminthes, and undescribed diseases (Dodd 1997; Daszak et al. 1999; Briggs et al. 2005; Davis et al. 2007; Peterson et al. 2007). Chytrid fungus affects not only frogs but has also now been reported in both aquatic and terrestrial salamanders (Davidson et al. 2003; Cummer et al. 2005; Padgett-Flohr and Longcore 2007). The decline of map turtles, musk turtles, snapping turtles, and pond turtles is partially attributable to disease (Dodd 1988; Buhlmann and Gibbons 1997). Southeastern freshwater fishes are also threatened by diseases, which are being spread by aquaculture operations and in shipments between fish hatcheries (Kautsky et al. 2000; Naylor et al. 2001; Strayer 2006; Green and Dodd 2007).

The petition alleges that other threats exacerbate the vulnerability of southeastern aquatic fauna to disease and population decline. The hellbender, which is threatened by both habitat loss and overuse, is also threatened by disease. Reptile declines have also been attributed to disease (Diemer Berish et al. 2000; Gibbons et al. 2000). In freshwater fishes, stress-related diseases are prevalent in polluted rivers, where chronic, sub-lethal pollution has increased the susceptibility of organisms to infection (Moyle and Leidy 1992).

Predation

According to the petition, predation threatens several of the petitioned species, including reptiles, amphibians, birds, plants, fishes, crayfishes, and mollusks. Heavy predation of turtle nests by raccoons can be a primary factor limiting recruitment of imperiled turtle populations (Browne and Hecnar 2007). At least two of the petitioned bird species are threatened by predation. MacGillivray's seaside sparrow is threatened by predation from rice rats (Post and Greenlaw 1994). The black rail is threatened from predation from various species during high tides, when the rails are forced away from cover (Evans and Page 1986). Two of the petitioned plant species are threatened by predation. Hall's bulrush is threatened by predation from mute swans and Canada geese (McKenzie et al. 2007). The Panhandle lily is threatened by predation from cattle grazing and potentially by insect herbivory (Barrows 1989). Southeastern fishes, amphibians, and crayfishes are threatened by predation from native and nonnative fishes and crayfishes (NatureServe 2008). The streamside salamander is threatened by predation from fish, flatworms, and water snakes (Petranka 1983; AmphibiaWeb 2009). Predation can contribute heavily to the decline of imperiled mussels because of their restricted distributions and small

population sizes (NatureServe 2008, Rock pocketbook species account). Imperiled southeastern mussels are threatened by predation from fishes, muskrats, raccoons, otter, mink, turtles, and some birds (Neves and Odom 1989; Parmalee 1967; Snyder and Snyder 1969). A number of fish species, including catfishes (Ictalurus ssp. and Amieurus ssp.) and freshwater drum (Aplodinotus grunniens) consume large numbers of unionid mussels at certain life stages (NatureServe 2008). As populations of imperiled mussels continue to decline, predation becomes an increasing threat. For example, the only viable population of the Savannah lilliput in North Carolina is threatened by predation from raccoons (Hanlon and Levine 2004). According to the petition, the petitioned fish, Barrens topminnow, is threatened by predation from introduced mosquitofish.

Disease and predation, alone and in conjunction with other factors, pose serious threats to the survival of many of the petitioned species and are magnified by other environmental stressors such as habitat loss, pollution, invasive species, and climate change (Gibbons et al. 2000; Pounds et al. 2006).

Factor D. The Inadequacy of Existing Regulatory Mechanisms

The petition states that inadequate regulatory mechanisms threaten all the petitioned species, with the following five exceptions: Linda's roadside-skipper, least crayfish, Broad River spiny crayfish, Chowanoke crayfish, and Tallapoosa orb.

Inadequacy of Existing Federal Regulatory Mechanisms

According to the petition, the Federal Clean Water Act (CWA) (33 U.S.C. 1251 et seq.) provides a basic level of water quality protection for imperiled southeastern species, but is inadequate to ensure their continued survival. Pollution from point and non-point sources is causing ongoing degradation of water quality, current water quality standards are not effectively protecting sensitive species or sensitive developmental stages of species, and loss of stream and wetland habitat continues. The Environmental Protection Agency (EPA) and individual States regulate point sources of pollution under the National Pollution Discharge Elimination System (NPDES), under which point sources are licensed and maximum pollutant discharge concentrations are set. The NPDES system is not adequate to protect the petitioned species from the negative effects of pollution because permits may be issued with few restrictions, cumulative effects of all the point sources within a watershed are not taken into consideration when permits are issued, and State governments often lack the resources or political will to monitor and enforce permits (Buckner et al. 2002).

The petition claims that existing regulations are also inadequate to protect aquatic species from non-point sources of pollution such as agricultural, residential, and urban runoff. Agricultural runoff accounts for over 70 percent of impaired U.S. river kilometers, yet is largely exempt from permitting requirements (Neves et al. 1997). Existing regulatory mechanisms are also inadequate to protect southeastern aquatic species from accidental spills from retention ponds, which are used to store wastes from agriculture, coal-fired power plants, coal mining, and other activities (Herrig and Shute 2002), and to prevent the continued loss of stream and wetland habitat from fills. In Appalachia, from 1992 to 2002, the EPA permitted the filling of more than 1,200 miles of headwater streams for surface coal mining activities (EPA 2005). The permitted filling of streams for surface coal mining is causing permanent downstream pollution and loss of biodiversity (Neves et al. 1997; Pond et al. 2008; Pomponio 2009; Wood 2009; Palmer et al. 2010).

The permitted filling of wetlands is also ongoing. While section 404 of the CWA sets as a goal no net loss of wetlands, this is not a required outcome of permit decisions (Connolly et al. 2005). In fiscal year 2003, the U.S. Army Corps of Engineers issued 4,035 permits for the destruction of natural wetlands, while denying only 299 permits (Connolly et al. 2005). Lost wetlands are required to be replaced by mitigation wetlands, but mitigation wetlands often differ in structure, function, and community composition from the natural wetlands that are destroyed (Holland et al. 1995). Mitigation requirements are also not strictly enforced. Mitigation is rarely effective in preserving biodiversity (Cabbage et al. 1993; Water Environment Federation 1993). Many species of amphibians, reptiles, and insects require both wetland and upland habitat to complete their life cycles, and wetland protection criteria do not protect the upland habitats these species need to survive (Dodd 1997).

The petition alleges that the Surface Mining Control and Reclamation Act of 1977 (SMCRA) (30 U.S.C. 1201 et seq.) does not adequately protect aquatic species due to increased demands for coal, lax enforcement of environmental laws, and deference to economic development over species' protection. Sedimentation from active mines is a primary contributor to the decline of mollusks due to water quality degradation, shell erosion, and reproductive failure (Anderson 1989; Houp 1993; Neves et al. 1993). Reclamation required under SMCRA is not rigorously enforced (Ward 2009), and even when reclamation is conducted, it has not resulted in the restoration of pre-mining hydrologic characteristics or ecological functions (Townsend et al. 2009).

The petition alleges that management of National Wildlife Refuges, National Recreation Areas, National Forests, and Wild and Scenic Rivers fails to adequately protect the petitioned species for a variety of reasons, including lack of fiscal resources, threats from climate change, invasive species, recreation, poaching, and conflicting resource mandates (such as timber production and recreation).

Inadequacy of Existing State Regulatory Mechanisms

According to the petition, some of the petitioned species are listed as endangered or threatened by State fish, wildlife, and game departments, but State endangered and threatened species designations generally do not provide species with meaningful regulatory protections or with any habitat protection. Many of the species petitioned are classified as Species of Conservation Priority or Species of Greatest Conservation Need under State Wildlife Action Plans or Wildlife Conservation Strategies. These documents provide a framework for conservation, but are not regulatory documents and do not contain mandatory or enforceable provisions to protect species or their habitats. Further, the implementation of conservation strategies is dependent on the cooperation of resource managers and stakeholders, making their implementation and effectiveness uncertain. State conservation priorities and initiatives are also sharply limited by funding, with charismatic and game species generally receiving the majority of resources, and the focus generally being on vertebrates, which makes these priorities and initiatives inadequate to protect imperiled invertebrate species. Additionally, some States have regulations to protect some wildlife from direct take, but these regulations are not comprehensive, are generally poorly enforced, and are not adequate to protect wildlife from other threats (FWS 1997).

Other Regulatory Mechanisms and Protections

According to the petition, the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) conveys some degree of protection to a few of the petitioned species listed under it, but it is inadequate to ensure their continued survival. For example, highly sought-after species such as rare map turtles are threatened by the international pet trade despite being protected under CITES (NatureServe 2008). Likewise, habitat preserves alone are insufficient to protect imperiled species. While habitat protection is an essential component of species' preservation, threats from a host of other factors, including climate change, poaching, pollution, and genetic isolation due to lack of habitat connectivity, influence habitat conditions and the success of the preservation efforts.

Land Ownership Patterns

The majority of land in the Southeast is privately owned. Private land use is either not regulated or only loosely regulated throughout much of the region (Buckner et al. 2002). According to the petition, most southeastern forests are in private ownership, and forestry best management practices to control erosion and protect aquatic resources are not mandated or voluntarily followed in the majority of southeastern forests. In addition, extensive clearcutting and poor logging practices threaten aquatic resources due to sedimentation, landslides, and degraded water quality (Buckner et al. 2002).

Factor E. Other Natural or Manmade Factors Affecting the Species' Continued Existence

The petition states that other natural or manmade factors, including pollution, global climate change, drought, invasive species, and synergies between multiple threats, threatened 13 of 15 amphibians, 1 amphipod (tidewater amphipod), 1 beetle (Avernus cave beetle), 3 birds (MacGillivray's seaside sparrow, Florida sandhill crane, and black rail), 4 butterflies (Linda's roadside-skipper, Duke's skipper, Palatka skipper, and rare skipper),

2 caddisflies (Morse's little plain brown sedge and setose cream and brown mottled microcaddisfly), 43 of 83 crayfish, 3 dragonflies (Cherokee clubtail, Septima's clubtail, Appalachian snaketail), 43 of 47 fish, 3 mammals (Pine Island oryzomys or marsh rice rat, Sanibel Island oryzomys or marsh rice rat, insular cotton rat), 1 moth (Louisiana eyed silkmoth), 35 of 48 mussels, 3 non-vascular plants (Fissidens appalachensis (Appalachian fissidens moss), Fissidens hallii (Hall's pocket moss), and Phaeophyscia leana (Lea's bog lichen)), 9 reptiles (Kirtland's snake, western chicken turtle, Florida Keys mole skink, Escambia map turtle, Pascagoula map turtle, black-knobbed map turtle, Alabama map turtle, striped mud turtle, northern red-bellied cooter), 27 of 44 snails, 1 stonefly (Smokies needlefly), and 31 of 76 vascular plants.

Pollution

According to the petition, pollution threatens two-thirds of the petitioned species, including 81 percent of the wildlife. Southeastern waterways are degraded by point and non-point source pollution from a variety of sources including agriculture, forestry, urban and suburban development, coal mining, and coal combustion wastes. Non-point source pollution, or runoff, is difficult to document, but its impact on aquatic species is both pervasive and persistent (Schuster 1997). Non-point source pollution is the most common factor adversely impacting the nation's fish communities, with more than 80 percent of fish negatively affected (Judy et al. 1982). Both non-point and point source pollution are pushing southeastern aquatic species towards extinction by carrying sediments, contaminants, nutrients, and other pollutants into waterways.

Sedimentation, Contamination, and Nutrient Loading

The petition alleges sedimentation is one of the primary causes of habitat degradation in southeastern waterways (Neves et al. 1997). Sedimentation and siltation result from a variety of activities including agriculture, forestry, development, and mining, with silt reaching the waterways during both ground-disturbing activities and storm events (FWS 2000). Suspended sediments threaten the entire aquatic community, from fish to invertebrates to birds.

In the Southeast, sedimentation is responsible for nearly 40 percent of fish imperilment problems (Etnier 1997). It both directly and indirectly adversely affects fish. Suspended sediments cut and clog gills and interfere with respiration. Sedimentation blocks light penetration, which interferes with feeding for species like minnows and darters, which feed by sight (Etnier and Starnes 1993). For species that feed by flipping over rocks and consuming the disturbed insects, sedimentation increases the embeddedness of rocks, making them more difficult to move and decreasing habitat suitability for aquatic invertebrate prey (Etnier and Starnes 1993). Sedimentation also interferes with feeding behavior for nocturnal feeders like catfish and imperiled madtoms, which catch aquatic insects by relying on the sensitivity of their barbells and on chemoreceptors, both of which are negatively affected by sedimentation (Todd 1973; Buckner et al. 2002). Benthic species require specific substrate conditions for spawning, feeding, and cover, all of which are degraded by sedimentation (Etnier and Starnes 1993; Warren et al. 1997). When sedimentation fills in the crevices between and beneath rocks, it decreases the availability of cover for resting and predator evasion (Herrig and Shute 2002). Madtoms, darters, suckers, and some minnows deposit their eggs on or near the substrate, and sedimentation interferes with their reproduction both by decreasing habitat suitability and by directly smothering eggs. Benthic fishes are also negatively affected by toxins stored in sediments (Reice and Wohlenberg 1993). Ultimately, excessive sedimentation can eliminate fish species from an area by rendering their habitat unsuitable (FWS 2000). Similarly, excessive sedimentation has strong, persistent, negative effects on freshwater invertebrates (Strayer 2006). Siltation is one of the primary factors implicated in the decline of freshwater mollusks (Williams et al. 1993). Suspended sediments have both direct and indirect negative effects on mollusks. Sedimentation clogs the gills of mollusks and can cause suffocation (FWS 2000). Sedimentation reduces feeding efficiency both by interfering with respiration of filter feeders and by coating algae, which snails scrape from rocks (FWS 2000). Decreased visibility due to sedimentation can interfere with mussel reproduction by making it difficult for host fishes to detect glochidia (Neves et al. 1997). Sedimentation also reduces substrate suitability (Herrig and Shute

2002).
The petition also alleges that aquatic insects are threatened by excessive sediment levels. Stoneflies (Plecoptera) and mayflies (Ephemeroptera) are intolerant of siltation and disappear from impacted streams (Morse et al. 1997). Increased siltation impacts the ability of dragonflies and damselflies to survive (Morse et al. 1997). Caddisflies, which require spaces among rocks for shelter and stable surfaces for grazing, are also negatively impacted by siltation (Morse et al. 1997). Sedimentation and other pollutants from mountaintop-removal coal mining operations are extirpating aquatic macroinvertebrate communities. In some streams that drain mountaintop-removal operations, entire orders of Plecoptera and Ephemeroptera have been extirpated (Wood 2009). Sedimentation is also negatively impacting rare ground-water inhabiting species of isopods and amphipods (Herrig and Shute 2002).
According to the petition, in addition to sediments, contaminants such as heavy metals, pesticides, and persistent organic pollutants threaten aquatic species. In a nationwide assessment of streambed sediment contaminants, the EPA found that 43 percent of sediments are probably associated with harmful effects on aquatic life or human health, and that 6 to 10 percent of streambed sediment is sufficiently contaminated to cause significant lethality to benthic organisms (EPA 2004b). Southeastern rivers are laden with a variety of toxic chemicals, with the lower Mississippi River receiving contaminants from half the continent (Folkerts 1997). Contaminants have both lethal and sub-lethal negative effects on aquatic species and may interfere with immunity, growth, and reproduction (Colborn et al. 1993; Gibbons et al. 2000). Selenium contamination from surface coal mining is causing teratogenic (developmental malformations) deformities in larval fish (Palmer et al. 2010). The negative effects of many contaminants will persist for centuries (Folkerts 1997).
Aquatic species are threatened both by chronic low-level contaminant pollution and acute exposure from accidental spills. For example, in 2009, a wastewater spill from a coal mine on the West Virginia-Pennsylvania border killed all the fish, salamanders, and mussels in 35 miles of 38-mile-long Dunkard Creek (Hopey 2009). Endemic species are particularly at high risk from accidental spills. Because many aquatic species exist only in small, isolated populations, a single spill event could drive a species to extinction.
The petition alleges that contaminants threaten all taxa of aquatic species. Declines in many fish species are attributed to chronic, sub-lethal pollution, which causes reduced growth, reduced reproductive success, and increased risk of death from stress-related diseases (Moyle and Leidy 1992). Cave fishes and other species that are directly dependent on groundwater levels are disproportionately threatened by contaminants that become concentrated if there is a reduction in the volume of springflow (Herrig and Shute 2002). Chemoreception in blind cave fishes can be disrupted by contaminants from surface aquifer recharge areas (Herrig and Shute 2002). Chronic low-level exposure to contaminants may be preventing the recovery of imperiled species of mollusks (FWS 1997). Juvenile mussels are sensitive to heavy metals and other pollutants (Naimo 1995; Neves et al. 1997). Amphibians are particularly sensitive to contaminants as all life stages are sensitive to toxins (AmphibiaWeb 2009). Many substances can be toxic to amphibians including heavy metals, pesticides, phenols, fertilizers, road salt, mining waste, and chemicals in runoff (Dodd 1997). Changes in pH can adversely affect amphibian eggs and larvae, and can inhibit growth and feeding in adults (Dodd 1997). Amphibians are threatened by accidental and intentional pesticide treatments.
Contaminants negatively impact aquatic species at the level of individuals, populations, and species. Fish, turtles, and other aquatic animals assimilate pesticides, heavy metals, and other persistent pollutants into their tissues (Buhlman and Gibbons 1997; de Solla and Fernie 2004). Animals at higher levels of the food chain can accumulate considerable levels of toxins. Significant concentrations of numerous contaminants have been detected in southeastern freshwater turtles including pesticides such as: aldrin, chlordane, dichlorodiphenyltrichloroethane (DDT), dieldrin, endrin, mirex, nonachlor, and toxaphene; and metals such as: Aluminum, barium, cadmium, chromium, cobalt, copper, iron, lead, mercury, molybdenum, nickel, strontium, and zinc (Meyers-Schoene and Walton 1994). Contaminant exposure can disrupt normal endocrine functioning,

threatening reproduction and survival (Colborn et al. 1993). Turtles exposed to polychlorinated biphenyls (PCBs) have exhibited sex reversal and abnormal gonadal development, and alligators exposed to various contaminants have shown altered testosterone levels and gonadal abnormalities (Guillette et al. 1994, 1995). Water snakes in wetlands that have been contaminated with coal ash exhibit altered metabolic activity (Hopkins et al. 1999). Endocrine disruption caused by contaminants can lead to demographic shifts in aquatic reptile populations (Gibbons et al. 2000). Bioaccumulation of contaminants has contributed to the decline of map turtles, musk turtles, snapping turtles, and pond turtles (Buhlmann and Gibbons 1997).

The petition alleges that nutrient loading also threatens southeastern aquatic species. Excessive nitrates and phosphates entering waterways from point and non-point sources can lead to algal blooms, eutrophication, and depleted dissolved oxygen, which can be lethal to aquatic organisms (Mallin and Cahoon 2003). Some algal blooms are toxic and can cause direct mortality. The toxic dinoflagellates (Pfiesteria piscicida and P. shumwayae) have bloomed downstream of CAFOs in the Neuse, New, and Pamlico River estuaries in North Carolina (Mallin and Cahoon 2003). Even at sub-lethal levels, nutrient loading threatens aquatic species via many mechanisms. For example, excessive phosphate levels, especially in combination with the herbicide atrazine, have been shown to increase nematode infections in amphibians, leading to amphibian deformities (Johnson and Sutherland 2003; Rohr et al. 2008).

Sources of Nutrients, Contaminants, Sediments, and Other Pollutants

The petition claims that agriculture, forestry, urban and industrial development, coal mining and processing, and coal combustion all contribute to nutrient loading, contaminants, sediments, and other pollutants that make their way into southeastern waterways. In the Southeast, agricultural fields are commonly plowed to the edge of rivers and streams, which results in erosion and stream bank collapse and deposits tons of soil into waterways annually. Agricultural runoff carries sediment, pesticides, fertilizers, animal wastes, pathogens, salts, and petroleum particles into waterways.

The petition claims that atrazine is the most commonly detected pesticide in U.S. waters and is pervasively found in surface waters of the southern States, with the chemical being detected in every watershed sampled (EPA 2007; Wu et al. 2009). According to the petition, concentrations of atrazine in various southeastern waterways exceed levels harmful to non-vascular plants and aquatic biota (U.S. EPA 2007; Wu et al. 2009). The toxic and endocrine-disrupting effects of atrazine are well established (Wu et al. 2009) and include detrimental reproductive effects.

According to the petition, animal holding lots and CAFOs produce animal wastes that may be discharged directly into streams applied to agricultural fields, or stored in lagoons (Buckner et al. 2002). These wastes contain enormous amounts of nitrogen and phosphorus, and these nutrients enter the environment and contribute to the eutrophication of waterbodies via runoff, via volatilization of ammonia, or by percolating into groundwater (Mallin and Cahoon 2003). Extreme weather events, lax management, and lagoon ruptures have led to acute pollution events from CAFOs, which have resulted in fish kills and algal blooms (Mallin and Cahoon 2003). Decaying carcasses from these operations also produce a significant source of nutrient pollution. In addition to nutrient loading, CAFOs release pharmaceuticals (growth promoters and antibiotics) and hormones (estrogens and androgens) into aquatic habitats (Orlando et al. 2004). These have led to endocrine disruption in female turtles (Irwin et al. 2001), and disruption of the reproductive biology of fathead minnows (Pimephales promelas) (Orlando et al. 2004).

The petition asserts that wastewater from aquacultural facilities also contributes significant amounts of sediments, nutrients, pharmaceuticals, and pathogens to southeastern aquatic habitats (Tacon and Forster 2003). Catfish farms, trout farms, and shrimp and crayfish ponds all release nutrients to aquatic habitats when they are drained or flushed during large rain events (Tucker and Hargreaves 2003; Morse et al. 1997; Holdich 1993).

According to the petition, pollution from forestry and silviculture affects the Mobile Basin. Logging and effluent

from pulp mills contribute sediments and herbicides to waterways, degrading habitat for aquatic organisms. Erosion from deforestation and poor forestry practices increases silt loading and makes stream bottoms unstable, both of which threaten mollusks and other aquatic organisms (Williams et al. 1993). Herbicides used to kill hardwoods and herbaceous vegetation may be harmful to amphibians and other species (Dodd 1997), and some herbicides are toxic to algae and interfere with aquatic ecology (Austin et al. 1991).

Urban and industrial development is also cited in the petition as contributing to pollution of southeastern aquatic habitats. Point source pollution from manufacturing sites, power plants, and sewage treatment plants is a major cause of aquatic habitat degradation (Morse et al. 1997). Non-point source pollution in the form of runoff from urban and industrial areas contributes sediment, contaminants, nutrients, and other pollutants that can be harmful to aquatic organisms and their habitats, including petroleum particles, highway salts, silt, fertilizers, pesticides, surfactants, and pet wastes (Neves et al. 1997; Buckner et al. 2002).

The petition states that coal mining and processing are a major source of pollution in West Virginia, Kentucky, Tennessee, Virginia, Alabama, and Georgia. Contaminants from coal mining and processing include sediments, metals, hydraulic fluids, frothing agents, modifying reagents, pH regulators, dispersing agents, flocculants, and media separators (Ahlstedt et al. 2005). Sediments, heavy metals, and other pollutants from mining are one of the causal factors in mussel declines (Houp 1993; Neves et al. 1997; Locke et al. 2006). Heavy metals, including aluminum, cadmium, copper, iron, manganese, mercury, selenium, sulfate, and zinc, are released into the environment and act as metabolic poisons in freshwater species (Earle and Callaghan 1998), and cause weight loss, altered enzyme activity and filtration rates, and behavioral modifications (Naimo 1995). The effects of metals on mussel feeding, growth, and reproduction can result in significant consequences for mussel populations, and Naimo (1995) concludes that the chronic, low-level exposure to toxic metals is partially responsible for the widespread decline in species diversity and population density of freshwater mussels. Selenium is particularly prevalent in coal effluents and is associated with deformities and reproductive failure in aquatic species (Lemly 2009; Pomponio 2009).

The petition also asserts that pollution, including sediments, metals, acids, and other substances, in drainage from abandoned mined lands negatively impacts aquatic species in a variety of ways from acute toxicity to physical impacts from solid precipitants (Cherry et al. 2001; Soucek et al. 2003). Surface waters receiving mine discharge commonly have extremely low pH levels, below 3.0, with toxic impacts extending several miles downstream (Soucek et al. 2003).

Coal combustion produces nitric and sulfuric acids, mercury, and coal ash, that all negatively impact aquatic species (Fleischer et al. 1993). Nitric and sulfuric acids released from coal-fired power plants cause acidification of water bodies. Streams and lakes in Great Smoky Mountains National Park and elsewhere have been degraded by acid precipitation (Morse et al. 1997). Phytoplankton is negatively affected by acidification, which has ramifications throughout the food web (Dodd 1997). Acid precipitation harms caddisflies and stoneflies (Morse et al. 1997). The petition claims that several of the petitioned insects, including the Smokies snowfly and Smokies needlefly, are threatened by acid deposition. Acidity in aquatic habitats can also result in direct amphibian mortality, and plays a major role in limiting amphibian distribution (Dodd 1997).

Coal combustion also releases mercury into the environment. Atmospheric deposition of mercury is responsible for the contamination of most waterways. In a U.S. Geological Survey study that examined mercury in fish, sediments, and water drawn from 291 rivers and streams, detectable mercury contamination was found in every single fish sampled (Scudder et al. 2009). The highest concentrations among all sampled sites occurred in fish from blackwater coastal-plain streams draining forested lands or wetlands in Louisiana, Georgia, Florida, and North and South Carolina, and from basins in the west with gold or mercury mines or both. Mercury levels in fish at over 70 percent of the sites exceeded the levels of concern for the protection of fish eating-mammals.

The combustion of coal produces over 129 million tons of solid waste, or coal ash, annually (Eilperin 2009). Coal ash contains concentrated levels of chlorine, zinc, copper, arsenic, lead, selenium, mercury, and other

toxic contaminants, and improper storage of coal combustion waste has resulted in pollution of ground and surface waters (EPA 2007b). There are 44 coal ash ponds in Kentucky alone. Hopkins et al. (1999) reported behavioral, developmental, and metabolic abnormalities in amphibians and reptiles in wetlands that have been contaminated with coal combustion waste in South Carolina.

Global Climate Change and Drought

According to the petition, global climate change threatens all of the petitioned species. Climate models project both continued warming in all seasons across the Southeast, and an increase in the rate of warming (Karl et al. 2009). The warming in air and water temperatures will create stress for fish and wildlife. Increasing water temperatures and declining dissolved oxygen levels in streams, lakes, and shallow aquatic habitats will lead to fish kills and loss of aquatic species diversity (Folkerts 1997; Karl et al. 2009). Climate change will alter the distribution of native plants and animals and will lead to the local loss of imperiled species and the displacement of native species by invasives (Karl et al. 2009).

Climate change will increase both the incidence and severity of droughts and major storm events in the Southeast (Karl et al. 2009). The percentage of the Southeast region experiencing moderate to severe drought has already increased over the past 3 decades (Karl et al. 2009). The threat to aquatic ecosystems posed by drought is magnified both by climate change and by human population growth. Decreased water availability coupled with human population growth will further stress natural systems. Drought, and increased evaporation and evapotranspiration due to warmer temperatures, will lead to decreased groundwater recharge and potential saltwater intrusion in shallow aquifers in many parts of the Southeast, further exacerbating threats to aquatic organisms (Karl et al. 2009).

Intense drought and increasing temperatures resulting from climate change will cause the drying of water bodies and the local or global extinction of riparian and aquatic species (Karl et al. 2009). Declines of mollusks as a direct result of drought have already been documented (Golladay et al. 2004; Haag and Warren 2008). Populations of amphibians dependent on consistent rainfall patterns for breeding, such as those that breed in temporary ponds, could be extirpated by drought (Dodd 1997). Amphibian declines are already linked to climate change globally (Pounds et al. 2006) and in the southeastern United States (Daszak et al. 2005).

The warming climate will likely cause ecological zones to shift upward in latitude and altitude, and species' persistence will depend upon, among other factors, their ability to disperse to suitable habitat (Peters and Darling 1985). Human modifications to waterways, such as dams, and changes to the landscape, including extensive development, will make dispersal of species to more suitable habitat difficult to impossible (Strayer 2006; Buhlman and Gibbons 1997; FWS 2009). Many species of freshwater invertebrates are likely to go extinct due to climate change (Strayer 2006). Freshwater mussels and snails are capable of moving only short distances and are unlikely to be able to adjust their ranges in response to climatic shifts (FWS 2009). The petitioners allege that deteriorating habitat conditions and obstacles to dispersal place all of the petitioned species at risk of extinction due to global climate change.

According to the petition, several of the coastal petitioned species are threatened by sea level rise and increased storm intensity resulting from global climate change, including the Florida Keys mole skink, MacGillivray's seaside sparrow, and Louisiana eyed silkmoth.

Invasive Species

The petition alleges that invasive species are a major threat to native aquatic plants and animals in the Southeast, and a known threat for 96 of the petitioned species. Invasive species negatively affect native species through competition, predation, and disease introduction. Introduced Asian carp, which are used to control trematodes in catfish ponds, have become established in rivers throughout the Mississippi Basin, where they consume native mollusks and compete for resources with native fishes (Naylor et al. 2001). There are at least 30 species of invasive fish in the Tennessee and Cumberland River basins, including carp, alewife, rainbow and brown trout, striped bass, yellow perch, nonnative forms of muskellunge, and walleye (Etnier 1997). Nonnative

mosquitofish (Gambusia holbrooki) have been widely introduced for vector control and now compete with native species for resources (Buckner et al. 2002). Game fish, such as trout and bass, have been widely introduced and prey on native fish, invertebrates, and amphibians (Herrig and Shute 2002; Kats and Ferrer 2003; Strayer 2006). Native fish fauna in southern Florida have been displaced by tropical species, and more than 60 indigenous southeastern fish species have been introduced to drainages where they are not native (Warren Jr. et al. 1997).

According to the petition, freshwater mollusks are threatened both by invasive fish and invasive mollusks. The introduction of nonnative fishes such as the round goby has indirect negative effects on native mussels due to negative impacts on their host fishes (NatureServe 2009). The invasion of nonindigenous mollusks is one of the primary reasons for the decline of freshwater mussels (Williams et al. 1993). Invasive mussels can reach densities of thousands per square meter, outcompeting and literally covering native species (Williams et al. 1993).

The zebra mussel has been detected in Alabama, Arkansas, Kentucky, Louisiana, Mississippi, Tennessee, Virginia, and West Virginia (NatureServe 2009). Zebra mussels infest most major Mississippi River tributaries, including the Ohio, Tennessee, Cumberland, and Arkansas Rivers (NatureServe 2009), and are expected to spread to all the navigable rivers in the Southeast, as well as tributary reservoirs and smaller streams (Jenkinson and Todd 1997). Zebra mussels and other invasive mollusks compete with native mussels for food and space, attach to native mussels and weaken or kill them, and alter the suitability of the substrate for native species (Herrig and Shute 2002). Where zebra mussels establish large populations, they are likely to destroy native mussels and snail populations (Jenkinson and Todd 1997).

The petition alleges that native southeastern mollusks are also threatened by the invasion of the Asian clam. Asian clams spread rapidly throughout every major drainage in the South following their introduction in the 1960s. Asian clams compete with native mussels for space and food.

The petition asserts that other southeastern taxa, in addition to fish and mollusks, are also threatened by the spread of invasive species. Native crayfish are threatened by invasive mussels, which can attach to their exoskeletons, and by invasive species of crayfish and fish, which compete with and prey on native crayfish (Schuster 1997). Nonnative crayfish are commonly introduced via "bait buckets." Several species of nonnative snails have also invaded the Southeast (Neves et al. 1993). Native amphibians are threatened by invasive fish and invasive amphibians, which can act as predators, competitors, and disease vectors (Dodd 1997). Additionally, the petition asserts that exotic cattle egrets, armadillos, and wild hogs can "exact a substantial toll" on amphibians (Dodd 1997). Fire ants also threaten amphibians, as they have been known to kill metamorphosing individuals (Freed and Neitman 1988).

According to the petition, many invasive plant species are wreaking havoc on aquatic habitats in the Southeast. Species such as Myriophyllum spicatum (Eurasian watermilfoil), Alternanthera philoxeroides (alligatorweed), Hydrilla verticillata (hydrilla), and Eichhornia crassipies (water hyacinth) are thriving in aquatic and wetland habitats and negatively impacting native species (Folkerts 1997; Buckner et al. 2002). Invasive plants displace native plants, alter substrate availability for aquatic invertebrates, and interfere with the food web (Folkerts 1997). Invasive plants threaten several of the petitioned plants, including Baptisia megacarpa (Apalachicola wild indigo), Ptilimnium ahlesii (Carolina bishopweed), and Hexastylis speciosa (Harper's heartleaf).

Outbreaks of invasive and native forest-destroying insects have weakened and killed trees in riparian areas and reduced nutrient inputs to aquatic systems (Morse et al. 1997). The petitioned Tsuga caroliniana (Carolina hemlock) is threatened by hemlock woolly adelgid (Adelges tsugae). Streamside habitat degradation due to exotic pests also threatens aquatic insect populations in the Southeast due to altered microhabitat conditions (Herrig and Shute 2002).

Inherent Vulnerability of Small, Isolated Populations

According to the petition, 224 of the petitioned species now exist in primarily small, isolated populations, which

heightens their risk of extinction. Small, isolated populations are vulnerable to extirpation due to limited gene flow, reduced genetic diversity, and inbreeding depression (Lynch 1996). Population isolation also increases the risk of extinction from stochastic genetic and environmental events, including drought, flooding, and toxic spills (FWS 2009). Habitat modification and cumulative habitat degradation from non-point source pollution are also major threats for species that exist in isolated populations. Due to blocked avenues of dispersal or limited dispersal ability, isolated populations gradually disappear as habitat conditions deteriorate (FWS 2000).

Synergies and Multiple Causes

The petition alleges that the risk of extinction for the petitioned species is heightened by synergies between threats as most species face multiple threats and these threats interact and magnify each other. Across taxa, interactions among threats place southeastern aquatic biota at increased risk of extinction. Reptiles are threatened by habitat loss and degradation, invasive species, pollution, disease and parasitism, unsustainable use, global climate change, and synergies between these factors (Gibbons et al. 2000). Freshwater snails are threatened by the combined effects of habitat loss, pollution, drought, and invasive species (Lydeard et al. 2004). Likewise, amphibians are imperiled by multiple, interacting threats. Stress from the effects of increased UV-b radiation, pollution, and climate change has made amphibians more vulnerable to the spread of disease (Gendron et al. 2003; Pounds et al. 2006). The interaction between climate change and compromised immunity due to various stressors threatens both amphibian populations and entire species (Green and Dodd 2003). Similarly, threats to freshwater fish are "many, cumulative and interactive," and fish extirpation is nearly always attributable to multiple human impacts (Warren et al. 1997). Any factor that causes the decline of the host fishes on which mussels depend for reproduction also threatens the mussels, which themselves face multiple threats including impoundment, pollution, and invasive species (Neves et al. 1997). The petition claims that because of the multifaceted ecological relationships among species, the extirpation of a species can have effects that cascade throughout the community, highlighting the need to protect entire communities simultaneously.

Evaluation of the Information Provided in the Petition and Available in Service Files

We reviewed and evaluated 374 of 404 species in the petition, as well as the additional information contained in the second petition for the Carolina hemlock and the supplemental information provided for the Panama City crayfish. Due to the large number of species reviewed, we were only able to conduct cursory reviews of the information in our files and the literature cited in the petition. For many of the narrowly endemic species included in the 374 species, we had no additional information in our files and relied solely on the information provided in the petition and provided through NatureServe.

Finding

On the basis of our evaluation under section 4(b)(3)(A) of the Act, we determine that the petition presents substantial scientific or commercial information that listing 374 species (listed in Table 2) as endangered or threatened under the Act may be warranted. This finding is based on information provided under Factors A, B, C, D, and E. Because we have found that the petition presents substantial information indicating that listing may be warranted, we are initiating status reviews to determine whether listing these species under the Act is warranted.

In addition, we find that the petition presents substantial scientific or commercial information indicating that listing 18 species that are current candidate species or the subjects of proposed rules to list may be warranted. The 18 species (listed with details in the Petition History section) are sicklefin redhorse, laurel dace, spectaclecase, narrow pigtoe, round ebonyshell, southern sandshell, sheepnose, fuzzy pigtoe, southern kidneyshell, rabbitsfoot, tapered pigtoe, Choctaw bean, rayed bean, black mudalia, Coleman cave beetle, Black Warrior waterdog, Yadkin River goldenrod, and the snuffbox. As a warranted determination for listing has already been made for these species, we will not be initiating status reviews for these species at this time. Further information on the assessments for these 18 species can be found at http://ecos.fws.gov/tess_public/.

The "substantial information" standard for a 90-day finding differs from the Act's "best scientific and commercial data" standard that applies to a status review to determine whether a petitioned action is warranted. A 90-day

finding does not constitute a status review under the Act. In a 12-month finding, we will determine whether a petitioned action is warranted after we have completed a thorough status review of the species, which is conducted following a substantial 90-day finding. Because the Act's standards for 90-day and 12-month findings are different, as described above, a substantial 90-day finding does not mean that the 12-month finding will result in a warranted finding.

We previously determined that emergency listing of any of the 404 petitioned species is not warranted. However, if at any time we determine that emergency listing of any of the species is warranted, we will initiate an emergency listing at that time.

The petitioners requested that critical habitat be designated concurrent with listing under the Act. If we determine in our 12-month finding, following the status review of the species, that listing is warranted, we will address the designation of critical habitat in the subsequent proposed rule.

360 Audiologist is a hearing hero for artists, fans

Author: Barnes, Michael

Publication info: Austin American Statesman [Austin, Tex] 13 Sep 2011: D.1.
ProQuest document link

Abstract: "Without any protection at all and noise levels exceeding 100 decibels for longer than one hour, then they are susceptible to permanent hearing loss," Estes says. Estes became fascinated with the relatively young field of audiology on a sports field, where her boyfriend - now her husband of 14 years - played high school baseball.

Full text: Michael Barnes AMERICAN-STATESMAN; Soriya Estes founded the HEAR program, which will hand out 5,000 pairs of earplugs at this weekend's music festival.

When Soriya Estes visits the Austin City Limits Music Festival this week, the audiologist will worry about ears. "Without any protection at all and noise levels exceeding 100 decibels for longer than one hour, then they are

susceptible to permanent hearing loss," Estes says. "Anywhere close to the chair line, you are already close to 100 decibels. And (guests) aren't there for just an hour. They are there all day. For three days."

The owner of Estes Audiology and founder of the HEAR program that helps professional musicians has come up with a partial solution for music lovers during the fest. Her practice will pass out 5,000 pairs of foam plugs in reusable cases that snap onto any bag. The free earplugs will be available at the HAAM - Heath Alliance for Austin Musicians - table in the ACL Cares area.

"It's just really important to have that hearing protected," she says. "Even if you don't have the hearing loss at that time, studies show that, when age factor kicks in, it's going to go quicker."

Estes, 36, is one of that rare breed who has always known what she would do. Born in Perry, Okla., she grew up in nearby Tonkawa, alongside members of the tribe that formerly populated Central Texas. ("I've never lived more than 20 miles off Interstate 35 all my life.") Her mother, DeAnna Smith, worked as a hospital administrator and now manages Estes' practice with offices in Georgetown, Kyle and New Braunfels. Her father, Iranian-born Majid Hamidi, owned restaurants and has since retired to Henderson, Nev. (Her first name, pronounced Sor-EYE-ya, is borrowed from Persian royalty.)

"Growing up, I never felt that different," she says of her Iranian ancestry. "The very first time I ever had a concern was after the Oklahoma City bombings. I was in college at Oklahoma State. Before they knew who did it, my father called and said 'Don't go to class today.' I thought: 'Wow. My name could ignite prejudice.'"

The same anxiety followed 9/11, says Estes, who grew up Christian.

Estes became fascinated with the relatively young field of audiology on a sports field, where her boyfriend - now her husband of 14 years - played high school baseball.

"There was a pitcher in the playoffs who was in a zone: Killing it, killing it, killing it during a championship game," she recalls. "I looked over at his coach, who was signing to him. You didn't see deaf students incorporated in the mainstream back then, not in a small town. It was one of those quirky little moments."

She sat down with the deaf player's family and started researching audiology. From that point, she never deviated, studying first at Oklahoma State University, then the University of Texas and - long-distance - finishing her doctorate at Pennsylvania's Salus University.

She and her husband, Brian Estes, who serves as business development director for a precast concrete company, settled in Austin, where they are raising two young daughters. After teaming with an ear, nose and throat specialist to build a practice in New Braunfels, she worked for Phonak Hearing Systems, a global hearing-aid manufacturer. Estes Audiology was born in 2005. (A fourth office is planned for Austin.)

So what causes hearing loss?

"Noise," she says. "That's one of the leading causes in people under 65. The mistake is thinking: 'Hearing loss means I'm old.' It affects all ages, mainly because of noise."

A recent study shows that the incidence of hearing loss in teens is on a sharp rise.

"I thought: Holy cow! We are trying to educate hunters and musicians. We are forgetting teens," she says. "Go to the mall and you see all the teens with iPods in the hands and in their ears. We are not doing a good enough job of looking at that."

Very high numbers of active-duty soldiers are coming home with noise-induced hearing loss, too.

Variable hearing loss can be experienced by anyone who attends a concert or a dance club. (Just ask your social columnist. If he can hear you.) This is called a "temporary threshold shift."

"You have these tiny, thin, upright hair cells," Estes says. "Repeated beatings tend to make them not stand up straight all the time."

Less glamorously, allergens can inflame the middle ear for temporary loss. That condition is treated with allergy medications.

Musicians and music lovers tend to suffer from permanent damage at different pitches inside the snail-like inner ear spiral.

"The hairs here look like keys on a keyboard," Estes says. "Every center is a pitch. High-frequency keys on the outside go first. Low-frequency hairs - protected, hidden, warm, fuzzy - they go last."
The music clan tends to ignore such hearing loss, hoping it will go away.
"During early hearing loss, people tend to 'squint' for a little bit," Estes says. "Ray Wylie Hubbard would say: 'I find my ears are squinting. I have to squint to hear people.'"
So how did the HEAR program start four years ago? Estes: "I was getting ready for work one day. Tim Taylor, local attorney and HAAM board member, was promoting HAAM benefit day on the radio. I thought: 'There's the Seton part of HAAM (general medical) and the SIMS part (mental health care and addiction recovery). Where's their hearing health care? Wait a minute. We are talking about musicians. This doesn't make sense.'"
She contacted Taylor, who talked to HAAM executive director Carolyn Schwarz, who in turn surveyed her members. The vast majority requested hearing health care.
"Screen, educate and protect are the three missions," Estes say of the HEAR sessions. Eighty musicians may sign up at one time. Estes closes down her practices and they meet at a central location. Musicians learn about their hearing levels and types of exposure. Then the audiologists take silicon castings of each ear, sending them to labs to make custom ear plugs with filters that allow all frequencies to be evenly attenuated, so sound quality is not compromised when volume is reduced.
Musicians pay $25 for a pair that would usually cost $150.
Estes: "It is so rewarding when we can actually tell most of the musicians they have normal hearing or they are doing the right thing by beginning to protect their ears."

Concert sound, anywhere

Author: Gugliotta, Guy

Publication info: International Herald Tribune [Paris] 07 Sep 2011: 13.
ProQuest document link

Abstract (Abstract): Acousticians have been designing concert halls for more than a century, but Dr. [Chris Kyriakakis] does something different. He shapes the sound of music to conform to the space in which it is played. The goal is what Dr. Kyriakakis calls the "ground truth" -- to replicate the original in every respect. "We remove the room," he said, "so the ground truth can be delivered."
"Hearing aids are not the same as glasses," said Dr. [Andrew J. Oxenham], at the University of Minnesota. "It's never been just about hearing sound, it's also about understanding sound and separating it from background noise. We can help with microprocessors. Without them it would have been impossible."
"The technology is really being strained," said Dr. [William M. Hartmann], at Michigan State. Because of psychoacoustics, "we know so much more, and therefore we can do so much more," but "there is so much more to do."

Full text: Psychoacoustics is the key to replicating the ear's experience of live music.
There is, perhaps, no more uplifting musical experience than hearing the "Hallelujah" chorus from Handel's

"Messiah" performed in a perfect space. Many critics regard Symphony Hall in Boston -- 70 feet wide, 120 feet long and 65 feet high -- as just that space.

On the other side of the United States however, a visitor led into the pitch-blackness of Chris Kyriakakis's audio lab at the University of Southern California to hear a recording of the performance would have no way to know how big the room (which in metric measurements is 21.3 meters by 36.5 meters by 19.8 meters) was.

At first it sounded like elegant music played in the parlor on good equipment. Nothing special.

But as engineers added different combinations of speakers, the room seemed to expand and the music swelled in richness and depth, until finally it was as if the visitor were sitting with the audience in Boston.

Then the music stopped and the lights came on. It turned out that the Immersive Audio Lab at U.S.C.'s Viterbi School of Engineering is dark, a bit dingy, and only 30 feet wide, 45 feet long and 14 feet high.

Acousticians have been designing concert halls for more than a century, but Dr. Kyriakakis does something different. He shapes the sound of music to conform to the space in which it is played. The goal is what Dr. Kyriakakis calls the "ground truth" -- to replicate the original in every respect. "We remove the room," he said, "so the ground truth can be delivered."

Dr. Kyriakakis, an electrical engineer at U.S.C. and the founder and chief technical officer of Audyssey Laboratories, a Los Angeles-based audio firm, could not achieve his results without modern sound filters and digital microprocessors.

But the basis of his technique is rooted in the science of psychoacoustics, the study of sound perception by the human auditory system. "It's about the human ear and the human brain, and understanding how the human ear perceives sound," Dr. Kyriakakis said.

Psychoacoustics has become an invaluable tool in designing hearing aids and cochlear implants, and in the study of hearing generally. "Psychoacoustics is fundamental," said Andrew J. Oxenham, a psychologist and hearing expert at the University of Minnesota. "You need to know how the normally functioning auditory system works -- how sound relates to human perception."

The field's origins date back more than a century, to the first efforts to quantify the psychological properties of sound. What tones could humans hear, and how loudly -- or softly -- did they need to be heard?

Pitch could be measured in hertz and loudness in decibels, but other phenomena were not so easily quantified. Human hearing can discern the movement of sound with a surprising degree of accuracy. It can distinguish timbre -- the difference between a clarinet and a saxophone. It can remember patterns of speech -- to immediately identify a friend in a phone call years after last hearing the voice. And a parent's ear can effortlessly sift the faint sound of an infant's cry from the blare of a televised football game.

Finally there were the imponderables, things humans do with their hearing simply because they can. "Everyone knows the sound of a bowling ball as it rolls down the alley," said William M. Hartmann, a Michigan State University physicist who is former president of the Acoustical Society of America. "What is it about that sound that we can identify?"

For much of the 20th century, engineers devoted themselves to developing acoustical hardware like amplifiers, speakers and recording systems. After World War II, scientists learned how to use mathematical formulas to "subtract" unwanted noise from sound signals. Then they learned how to make sound signals without any unwanted noise.

Next came stereo. By recording two tracks, engineers could localize sound for the listener. "Simple enough," said Alan Kraemer, chief technological officer for the audio company SRS Labs, based in Santa Ana, California. "If something's louder on one side, you'll hear it on that side."

But stereo had no real psychoacoustics. It created an artificial sense of space with a second track, but did so by dealing with only one variable -- loudness -- and enhanced human perception simply by suggesting that listeners separate their speakers.

The digital age changed all this, allowing engineers to manipulate sound in ways that had never been tried

before. They could create sounds that had never existed, eliminate sounds they did not want and use constant changes in filter combinations to deliver sound to listeners with a fidelity that had never before been possible.
Digital technology has led to innovations that have been critical in improving sound reproduction, in tailoring hearing aids to the needs of individual patients and in treating hearing impairment and developing cochlear implants -- tiny electronic devices linking sound directly to the auditory nerve of a deaf person.
"Hearing aids are not the same as glasses," said Dr. Oxenham, at the University of Minnesota. "It's never been just about hearing sound, it's also about understanding sound and separating it from background noise. We can help with microprocessors. Without them it would have been impossible."
Despite recent advances, however, psychoacoustics has shown engineers that they still have a long way to go. No machine can yet duplicate the ability of the human ear to understand a conversation in a crowded restaurant. People with cochlear implants have "a terrible time" with background noise, Dr. Oxenham said. They also have trouble with pitch perception and distinguishing the sounds of different instruments. "Hearing loops," which are transmitters that broadcast sound signals directly to a receiver in a hearing aid, are catching on in concert halls, places of worship and even subway booths.
"The technology is really being strained," said Dr. Hartmann, at Michigan State. Because of psychoacoustics, "we know so much more, and therefore we can do so much more," but "there is so much more to do."
One factor that slows the pace of innovation, Dr. Hartmann suggested, is that the human auditory system is "highly nonlinear." It is difficult to isolate or change a single variable -- like loudness -- without affecting several others in unanticipated ways. "Things don't follow an intuitive pattern," he said.
For the unsophisticated listener, top-of-the-line sound equipment by itself seems good enough, but it is not nearly the same as the psychoacoustically adjusted version. A video of the Eagles singing "Hotel California" sounded nice to a visitor until Audyssey's hardware director, Andrew Turner, pointed out that there was no bass when the volume was low. He flicked a switch and the bass returned, enriching the music with startling impact.
"At the concert itself, where there was a big room with a lot of high-volume sound, you could hear the low tones," he said. "But here in the studio, your brain is filtering them out as irrelevant at low volume. So you have to restore them.
"It's pure psychoacoustics."

LOS ANGELES -- There is, perhaps, no more uplifting musical experience than hearing the "Hallelujah" chorus from Handel's "Messiah" performed in a perfect space. Many critics regard Symphony Hall in Boston -- 70 feet wide, 120 feet long and 65 feet high -- as just that space.

Some 3,000 miles away, however, a visitor led into the pitch-blackness of Chris Kyriakakis's audio lab at the University of Southern California to hear a recording of the performance would have no way to know how big the room was.

At first it sounded like elegant music played in the parlor on good equipment. Nothing special. But as engineers added combinations of speakers, the room seemed to expand and the music swelled in richness and depth, until finally it was as if the visitor were sitting with the audience in Boston.

Then the music stopped and the lights came on. It turned out that the Immersive Audio Lab at U.S.C.'s Viterbi School of Engineering is dark, a bit dingy, and only 30 feet wide, 45 feet long and 14 feet high.

Acousticians have been designing concert halls for more than a century, but Dr. Kyriakakis does something different. He shapes the sound of music to conform to the space in which it is played. The goal is what Dr. Kyriakakis calls the "ground truth" -- to replicate the original in every respect. "We remove the room," he said, "so the ground truth can be delivered."

Dr. Kyriakakis, an electrical engineer at U.S.C. and the founder and chief technical officer of Audyssey Laboratories, a Los Angeles-based audio firm, could not achieve his results without modern sound filters and digital microprocessors.

But the basis of his technique is rooted in the science of psychoacoustics, the study of sound perception by the human auditory system. "It's about the human ear and the human brain, and understanding how the human ear perceives sound," Dr. Kyriakakis said.

Psychoacoustics has become an invaluable tool in designing hearing aids and cochlear implants, and in the study of hearing generally. "Psychoacoustics is fundamental," said Andrew J. Oxenham, a psychologist and hearing expert at the University of Minnesota. "You need to know how the normally functioning auditory system works -- how sound relates to human perception."

The field's origins date back more than a century, to the first efforts to quantify the psychological properties of sound. What tones could humans hear, and how loudly or softly did they need to be heard?

Pitch could be measured in hertz and loudness in decibels, but other phenomena were not so easily quantified. Human hearing can discern the movement of sound with a surprising degree of accuracy. It can distinguish timbre, the difference between a clarinet and a saxophone. It can remember patterns of speech, to immediately identify a friend in a phone call years after last hearing the voice. And a parent can effortlessly sift the sound of an infant's cry from the blare of a televised football game.

Finally there were the imponderables, things we do with our hearing simply because we can. "Everyone knows the sound of a bowling ball as it rolls down the alley," said William M. Hartmann, a Michigan State University physicist and former president of the Acoustical Society of America. "What is it about that sound that we can identify?"

For much of the 20th century, engineers devoted themselves to developing acoustical hardware like amplifiers, speakers and recording systems. After World War II, scientists learned how to use mathematical formulas to "subtract" unwanted noise from sound signals. Then they learned how to make sound signals without any unwanted noise.

Next came stereo. By recording two tracks, engineers could localize sound for the listener. "Simple enough," said Alan Kraemer, chief technological officer for SRS Labs, an audio company in Santa Ana, Calif. "If something's louder on one side, you'll hear it on that side."

But stereo had no real psychoacoustics. It created an artificial sense of space with a second track, but did so by dealing with only one variable -- loudness -- and enhanced human perception simply by suggesting that

listeners separate their speakers.

The digital age changed all this, allowing engineers to manipulate sound in ways that had never been tried before. They could create sounds that had never existed, eliminate sounds they did not want and use constant changes in filter combinations to deliver sound to listeners with a fidelity that had never before been possible.

Digital technology has led to innovations that have been critical in improving sound reproduction, in tailoring hearing aids for individual patients and in treating hearing impairment and developing cochlear implants -- tiny electronic devices linking sound directly to the auditory nerve of a deaf person.

"Hearing aids are not the same as glasses," said Dr. Oxenham, at the University of Minnesota. "It's never been just about hearing sound; it's also about understanding sound and separating it from background noise. We can help with microprocessors. Without them it would have been impossible."

Despite recent advances, however, psychoacoustics has shown engineers that they still have a long way to go. No machine can yet duplicate the ability of the human ear to understand a conversation in a crowded restaurant. People with cochlear implants have "a terrible time" with background noise, Dr. Oxenham said. They also have trouble with pitch perception and distinguishing the sounds of different instruments. "Hearing loops," which are transmitters that broadcast sound signals directly to a receiver in a hearing aid, are catching on in concert halls, places of worship and even subway booths.

"The technology is really being strained," said Dr. Hartmann, at Michigan State. Because of psychoacoustics, "we know so much more, and therefore we can do so much more," but "there is so much more to do."

One factor that slows the pace of innovation, Dr. Hartmann suggested, is that the human auditory system is "highly nonlinear." It is difficult to isolate or change a single variable -- like loudness -- without affecting several others in unanticipated ways. "Things don't follow an intuitive pattern," he said.

It was this anomaly, in part, that led Dr. Kyriakakis in the 1990s to venture into psychoacoustics. He, his U.S.C. film school associate Tomlinson Holman, and their students were trying to improve the listening qualities of a room by measuring sound with strategically placed microphones.

"Often our changes were worse than doing nothing at all," Dr. Kyriakakis recalled. "The mic liked the sound, but the human ear wasn't liking it at all. We needed to find out what we had to do. We had to learn about psychoacoustics."

The trick was to establish a baseline for what sounded best, and there was no guidebook. So Dr. Kyriakakis and his students went to Boston Symphony Hall in 1998 to conduct a series of sound tests and to record the "Messiah."

At that time, acousticians had long known that a shoebox-shaped concert hall like Boston's offered the best sound, but what was important for Dr. Kyriakakis was to know why the human ear and the human brain that processed the signal felt that way.

Back in Los Angeles, his team began a series of simple experiments. Listeners were invited into the labs to hear the Boston tests and music and to rate the sound, using a scale of 1 to 5. Researchers shifted the sound to different combinations of speakers around the room.

Statistics showed that speakers directly ahead, combined with speakers 55 degrees to either side of the listener, provided the most attractive soundstage. The "wide" speakers mimicked the reflection from the side walls of the concert hall by causing the sound to arrive at the listener's ears milliseconds after the sound from the front. Sound from other angles did not have as great an effect.

Next, the team asked listeners what combination of speakers gave the best impression of "depth of stage." Here again, statistics showed a clear preference for speakers in front of listeners and high above them. This sound -- also slightly delayed -- gave the ear and the human brain a sense of where the different instruments were on a bandstand.

With these results as his template, Dr. Kyriakakis founded Audyssey. His idea was to make dens and living rooms sound like concert halls and movie theaters. Microprocessors made it possible to filter sound to minimize

distortion and add the delays that make the music sound nearly perfect to the human ear from anywhere in the room.

Audyssey's first product, MultEQ, started with a five-speaker configuration, but for a full concert-hall-like effect, it now offers what Dr. Kyriakakis calls an "11.2" system: three speakers in front of the listener; two elevated speakers; two wides; two speakers slightly behind the listener, and two speakers directly in back. Audio-video receivers with Audyssey's latest MultEQ technology cost $1,000 to $2,000.

For the unsophisticated listener, top-of-the-line sound equipment by itself seems good enough, but it is not like the psychoacoustically adjusted version. A video of the Eagles singing "Hotel California" sounded nice to a visitor until Audyssey's hardware director, Andrew Turner, pointed out that there was no bass when the volume was low. He flicked a switch and the bass returned, enriching the music with startling effect.

"At the concert itself, where there was a big room with a lot of high-volume sound, you could hear the low tones," he said. "But here in the studio, your brain is filtering them out as irrelevant at low volume. So you have to restore them.

"It's pure psychoacoustics."

Correction: September 7, 2011, Wednesday

This article has been revised to reflect the following correction: A picture in some editions on Tuesday with an article about advances in psychoacoustics was published in error. It showed the Boston Symphony Orchestra performing at Carnegie Hall in Manhattan -- not at Symphony Hall in Boston, which is regarded by many critics as an acoustically perfect space.

Marian Anderson and "Sonic Blackness" in American Opera

Author: Eidsheim, Nina Sun

Publication info: American Quarterly, suppl. Special Issue: Sound Clash: Listening to American Studies 63.3 (Sep 2011): 641-671,857.

ProQuest document link

Abstract: [...] my question is the following: given that all American classical singers are trained in a musical culture that, equally for all of them, is bound to a secondary (European) culture, and given classical music's minimal indulgence of individual style, what singles out African American classical singers as nonetheless inhabiting a particularly "black" voice? [...] no ear is innocent.

Full text: The Saints were supposed to be Spaniards [wrote Time Magazine about Four Saints in Three Acts,] but Virgil Thomson had chosen Harlem Negroes because of their diction. White singers, he feared, would act foolish and self-conscious chanting such lines as "Let Lucy Lily Lily Lucy Lucy let Lucy Lucy Lily Lily Lily Lily Lily let Lily Lucy Lucy let Lily. Let Lucy Lily."

-"Music: Saints in Cellophane," Time Magazine

A great diva with a long career behind her was singing Tosca at the Met in 1961. Her dresser asked her whether she had yet heard Leontyne Price, who had just made her unmatched debut as Leonora in Il Trovatore. "Ah, yes," purred [the diva]. "Price. A lovely voice. But the poor thing is singing the wrong repertory!" The dresser registered surprise. "What repertory," he asked, "should Price be singing?" The great diva smiled a knowing smile. "Bess," she purred. "Just Bess."

-Martin Bernheimer, "Yes, but Are We Really Colour Deaf?," Opera

On a cloudy January 7 in 1955, the golden-red auditorium glowed with expectation. On the dark, gaping stage beyond the proscenium, Marian Anderson took her position as the gypsy sorceress Ulrica in Giuseppe Verdi's Un Ballo in Maschera.

The curtain rose . . . and I was there on the stage, mixing the witch's brew, [Anderson recalls]. I trembled, and when the audience applauded and applauded before I could sing a note I felt myself tightening into a knot. . . . and things happened to my voice that should not have happened. . . . my emotions were too strong.1

The emotional power of this moment is not surprising. At the time of Anderson's debut, the Metropolitan Opera, the largest and most prestigious opera house in the United States, had been exclusively white for its entire seventytwo- year history. Most people felt in 1955 that despite her brief tenure (only eight performances over two seasons) Anderson's hiring was a decisive moment on the path toward desegregating classical music; it was celebrated as a new chapter in American racial relations and policies. As the New York Times noted, it would "open doors" for "other Negro singers."2 In fact, Anderson's triumphant debut was one of many concrete manifestations of incremental improvements for which the civil rights movement had fought long and hard. Many of the conditions that Anderson had to overcome to reach this pivotal moment gradually improved for later generations of African American singers. However, while the second half of the twentieth century saw American opera houses decisively integrated, the black performer is yet consistently viewed as peculiar. While descriptions of her visual appearance have been toned down through the decades, the timbre of her voice has routinely (if often admiringly) been characterized as "black."

Racialized Voice

Several opera scholars discuss the visual appearances of African American singers in terms of casting. Rosalyn Story investigates the ambiguous feelings expressed by many African American singers toward George Gershwin's black-cast-only opera Porgy and Bess (1935) and its racial typecasting. Lisa Barg describes how the first casting of Virgil Thomson's Four Saints in Three Acts (1934) relied on preconceptions that tended to exoticize African American performers.3 And Jason Oby's important bouquet of interviews reveals that it is easier for African Americans to succeed as baritones or basses, because the roles written for these vocal types are typically villains. There is also considerable resistance to casting African American tenors as romantic leads, which could entail their playing opposite white love interests.4 However, while much research exists on racialized language perception and casting, there is no thorough investigation of the oddly discerning listening practice that so readily identifies certain classical voices as "black," that specifically locates blackness in timbre- the characteristic sound of the voice.5

The identification of a person who has mastered Western classical vocal production and repertoire as black requires a very different conceptual process than does the identification of a popular-music singer as a member of a racial category.6 In popular genres, vernacular languages and pronunciation styles are used to tag performers with social distinctions.7 In other words, contextual or linguistic information is available in popular music genres and can be used to position the singer. The resultant identification is not primarily about race per

se; it involves, for instance, geographic and social location, which often coincide with racial divisions. In contrast, not only does classical repertoire feature narrowly defined conventions of pronunciation, timbre, and stylistic range determined by a work's historical period, geography, and composer, but the notated compositions also dictate fixed pitches and durations for syllables and pauses, which therefore must be produced in the same way by each singer.8 Unlike popular music genres in which individual style is encouraged, taking liberties with pronunciation is not rewarded in the classical vocal world.

It is not an exaggeration to say that the classical singer is defined by adherence to these established aesthetic, technical, and stylistic conventions, and that it is through the characteristic vocal timbre resulting from adherence to the aforementioned conventions that a voice is recognized as a "classical voice."9 Without these vocal qualities the singer is simply not considered a classical singer by the opera community. Hence my question is the following: given that all American classical singers are trained in a musical culture that, equally for all of them, is bound to a secondary (European) culture, and given classical music's minimal indulgence of individual style, what singles out African American classical singers as nonetheless inhabiting a particularly "black" voice? We must take this distinction to be based on an assumption that the black body is intrinsically different from the white body and that even when emitting a timbre recognized as classical, the resonance of a singer's black body is evident. In interactions with recording media the black voice has indeed been viewed as distinct. "Negroes [record] better than white singers, because their voices have a certain sharpness or harshness about them that a white man has not," the trade paper Phonogram reported in 1891.10 This fundamental physiological difference-"there is a peculiar vibrating quality in the negro voice, due, perhaps, to a peculiar arrangement of the vocal chords [sic], which is not found in the white race"-was clearly expressed in a 1903 Washington Post article.11 However, my research on vocal morphology concludes that there are no more similarities within a so-called racial group than there are differences between groups.12 Therefore the distinction must lie beyond the sound itself.

Linguistic research forcefully demonstrates that nonsonic information plays a crucial role in how we perceive voices and determine racial identities in general. Asked to rate the comprehensibility and intelligence of a lecture recorded by a native speaker of American English, paired with a photo of either an Asian-looking or a Caucasian-looking lecturer, listeners gave lower ratings to the recording paired with the Asian-looking lecturer. Since the same recording accompanied both photos, researchers concluded that the listeners expected the Asian-looking lecturer to speak in accented, simplified English, and therefore heard her speech that way.13 Additionally, the participants in this study listened with the assumption not only that the voice discloses the speaker's racial category but also that the Asian lecturer was less intelligent. Considering how the study was designed, it becomes clear that the participants listened with their eyes and judged intelligence with their prejudices.

Examples from outside the laboratory, illustrating people's propensity for this type of judgment, are not hard to come by. American equal-rights activists have shown that landlords make decisions based on potential renters' vocal accents, tending to decide against tenants whose accents reflect "undesirable" populations-that is, black and Latino, according to the study.14 The American legal system also assumes that every voice is tied to an unambiguously raced or unmarked body. In 1999 the Kentucky Supreme Court ruled that since witnesses' recognitions of female voices are admissible as evidence, "we perceive no reason why a witness could not likewise identify a voice as being that of a particular race or nationality, so long as the witness is personally familiar with the general characteristics, accents or speech patterns of the race or nationality in question."15 In this decision voice is established as unambiguously representative of a stable body.16 In summary, both visual information and accent are relied on to determine people's racial category.

Blackness and Vocal Timbre

It is presumably such a stable, inescapable body that the critic Geerd Heinsen hears. About Cynthia Clarey's voice in Les Contes d'Hoffmann, he writes that its "tone quality [is] too Negroid for the French vocal line," adding

hastily that his judgment was merely "a matter of taste."17 In The Singing Voice Robert Rushmore writes, "I think today that if he did not know, a perceptive listener would instantly recognize the voice of Leontyne Price as belonging to a black."18 Did Heinsen's and Rushmore's "perceptive listeners" base this distinction on listening only, or was their hearing influenced by nonsonic aspects?

A popular narrative attests that African American singers arrive at a distinctly "black" version of the classical timbre by first working with spirituals. Two celebrated African American opera singers, Simon Estes and Barbara Hendrix, do indeed cite their experience with spirituals as influential on their growth as classical singers. Specifically, Hendrix attributes her ability to express suffering in Mozart arias to her embodied understanding of spirituals. In contrast, the first African American Metropolitan Opera coach, Sylvia Lee, hired in 1950, said about the African American soprano Martina Arroyo's attempts at spirituals that she had never heard such white spirituals in her life.19 Lee subsequently coached Arroyo in that repertoire in the same way she coached diction and phrasing in German lieder. Thus while some singers acknowledge spiritual singing as an important stage in their artistic development, others were not brought up with the spiritual and were in fact "illiterate" in the idiom, having to learn it like any other vocal style as part of a professional repertoire. Nonetheless, the claim that the distinguishable African American operatic vocal timbre is conditioned by spiritual-singing is relentless. Based on the studies mentioned earlier, one may suspect that this narrative's persistence stems from unspoken beliefs about a uniform black culture, that the black body is distinct from the white body and thus possesses a different vocal timbre.20

In the twenty-first century, many of us believe such racist attitudes outmoded. Yet in 2007 the African-American soprano Hope Briggs was fired by the San Francisco Opera at the eleventh hour from the role of Donna Anna in Don Giovanni, sparking a storm of protest letters and articles claiming that her dismissal was a reaction to her race.21 General Director David Gockley's official announcement was that Briggs's voice "was not ultimately suited for this role in this production."22 Yet both the San Francisco Chronicle and the New York Times published reports from unnamed sources within the opera house that stated that Briggs had sounded fine at the final dress rehearsal.23 These articles raised serious questions as to the relevance of Briggs's race to Gockley's decision, highlighting the generally precarious position of African American opera singers.

As Arroyo demonstrates, the African American vocal apparatus possesses no physical features that would account for the perception of its "black" vocal timbre.24 Nor do socialization and acculturation quite make sense as explanations for lingering dialects or accents, vis-à-vis vocal virtuosi who routinely sing in languages of which they are not native speakers. Moreover, listeners have been known to misjudge singers' or actresses' races-Marilyn Horne as black, Arroyo as white.25 In these cases timbral blackness is not the resonance of a particular type of body; instead it resonates in the listener's ear.

By locating blackness in timbre, audiences and critics alike were able to name racial difference while they acknowledged, seemingly without conflict, impeccable vocal runs and otherwise flawless delivery. In her discussion of the use of hip-hop in film soundtracks, Mendi Obadike discovers that sound may summon the presence of blackness even without the attendance of black bodies-a phenomenon that she terms "acousmatic blackness." This concept may help us theorize how black vocal timbre is constructed and perceived in the voices of African Americans in general, and in those of African American opera singers, who otherwise adhere to the strict sonic and stylistic formulae of classical music, in particular.26 As Obadike argues that hip-hop music may summon the presence of blackness without an accompanying black body, in the case of African American opera singers I suggest that acousmatic blackness-the perceived presence of the black body in a voice that otherwise meets all of the standards of a professional classical voice-is called into presence in an otherwise idiomatic classical voice. Today, when the identification of race in strongly visual terms and discrimination on visual bases are both taboo and unlawful, blackness is subsumed into sound and vocal timbre, the disparagement of which can readily be clothed as a personal sonic (not necessarily conscious racist) preference. Ironically, as Jennifer Stoever notes, because critical race studies focus on the visual realm, they

risk overlooking the potential for racism in other sensory realms.27 The traces of racialized timbre that my investigation uncovers in the seemingly integrated and progressive environment of the musical arts indicate the power that whiteness still wields.

In what follows I move backward in time from Anderson's debut. I first call to mind earlier performance contexts that laid the foundations for the association of black voices with certain repertoire. African American singers performed classical music in the same spaces and on the same programs as minstrel repertoire, burlesque shows, and spirituals; thus perceptions of classical performances by African Americans became inextricably linked to these genres. Second, I engage Jon Cruz's work on how abolitionists listened to slave song, examining his notion of ethnosympathy to understand how provisional subjectivity was granted to slaves and what this meant to how they and subsequent African Americans were heard. Third, I revisit two American operas from the early twentieth century, Four Saints in Three Acts and Porgy and Bess, which formally reenacted prevalent white views of African American identity and performance skills. Having unpacked the cultural baggage at play in the years leading up to the pregnant moment recalled at the opening of this article, I return to Anderson's story. And finally, in light of the surge of African American operatic divas who entered the scene during the 1960s and 1970s, I look closely at the frayed edges and visible seams of the integrated stage. Taking Anderson as a focal point for reflection on how listeners approach the black voice, this essay descends into the deep veins of racial history that run through American culture and examines the listening ears they have produced. By investigating the evocation of blackness within the very narrow timbral ideal of classical vocal music, I hope to uncover the complex and historically bound process of listening to voices. Thus this article aims to foreground the practice of listening to opera in the United States as exemplary of listening as a socially and culturally bound undertaking, rather than as immanent and neutral.28 Listening in to how we listen to voices may reveal deep-seated feelings about body and race that persist in today's United States.

Early African American Classical Singers

In the nineteenth century Elizabeth Taylor Greenfield (1820s-1876), a freed slave, and Matilda Sissieretta Jones (1869-1933) were among the first African American singers to perform classical repertoire for large interracial audiences, winning national and international acclaim.29 Their performance practices and receptions by audiences-where listeners based their opinions on related artists' work and on the work of white artists in blackface-colored later reception of African American classical singers.30 Greenfield was largely an autodidact, as no voice teacher during her era would have staked his reputation on a black singer. A generation later, improved race relations enabled Jones to train. But beyond this, her experiences and Greenfield's bore similarities, many based in hardship resulting from the racial climate and white audiences' limited perceptual frameworks. Both singers had to either perform in segregated venues, with black audience members relegated to separate balconies, or sing for all-white gatherings. According to Story, for audiences of the day, the sight of a white usher accompanying Greenfield to the stage was so jarring that, judging by their reactions, the viewers might have been watching a "carnival freak show."31 The New York Herald (1854) described one escort who "seemed afraid to touch her with even the tips of his white kids, and kept [the performer] at a respectable distance, as if she were a sort of biped hippopotamus. The audience laughed at the attitude of the gentleman usher and still applauded with all their might," treating the performance as a "super minstrel show."32

The public's piqued awareness of Greenfield's and Jones' physical appearances are clear from their sobriquets. Greenfield performed under the name of the Black Swan, most likely a reference to her Scandinavian vocal contemporary Jenny Lind, endearingly called the Swedish Nightingale, while Jones was dubbed Black Patti, a play on the moniker of Adelina Patti, a contemporary Italian diva. Both nicknames imply that the American women were their namesakes' lesser counterparts.

Music critics also applied derogatory racial epithets to Greenfield's and Jones' physical appearances, overlooking their musical abilities, including instrumental proficiency.33 The Cincinnati Enquirer called Greenfield the "African Crow," the Detroit Daily Advertiser a "woolly headed, flat nose[d] negro woman, and no

one would suppose there was any more enchantment . . . in her than a side of leather."34 Certainly some critics were aware of their racist biases. An Ohio journalist wrote: "We know the natural prejudice [sic] that we all have against [Greenfield's] color . . . and it is very difficult to divest one's self entirely of them and criticize fairly and justly in such a case."35 In the same spirit, another critic reported that "upon the suggestion of another . . . we listened to her without looking toward her during the entire performance of 'The Last Rose of Summer' and were at once satisfactorily convinced that her voice is capable of producing sounds right sweet."36 Elsewhere, Greenfield's voice was lauded for its "naturalness," as though it were somehow primal, primitive, untouched by cultivation.37 Knowingly or otherwise, these journalists acknowledged that historical-cultural lenses influenced how they heard Greenfield's voice. Despite such self-awareness on behalf of a few reporters, when Jones was presented to the public a generation later, the singer's physique continued to fascinate white audiences. Jones's attributes were logged with the most embarrassing details. "Her teeth," a journalist reports, "would be the envy of her fairer sisters and the despair of dentistry. Her rather thin lips are fond of exposing heir [sic] even row of teeth."38

The dissonance felt by many members of the public when confronted with the unfamiliar sight and sound of a black person singing classical music was too much to overcome. The solution for which many reached, it seems, was to categorize these performances as minstrel shows rather than artistic experiences-attempting to deny that African American voices were suitable for classical music qua classical music. Although audiences shamefully deprecated Greenfield's and Jones's visual appearances, critics could not help but be in awe of their voices. Nevertheless, much like participants in the above-mentioned linguistic experiment, in which listeners' perceptions of a recorded voice were deeply affected by visual cues, audiences' limited exposure to the sounds of black classical singers, via performance genres and repertoire predicated on stereotypical and deprecating depictions, caused them to project their expectations of blackness onto those performers' operatic vocal timbres.

Greenfield's voice rivaled that of her contemporary, the world-renowned Lind, reaching to a high E above high C. Unlike Lind, Greenfield also reached a low G in the bass clef. In 1852 the Toronto Globe not only rhapsodized about "the amazing power of [Greenfield's] voice, the flexibility and the ease of execution," but also reported that the "higher passages were given with clearness and fullness, indicating a soprano of great power."39 Although Jones was intermittently criticized for her lack of training, she was also reputed to have "great range," "power," "sweetness and smoothness" of tone, "distinct enunciation," with compliments for the "ease and naturalness with which she handled the voice."40 Both Greenfield and Jones performed in a wide range of genres. Although Greenfield was noted for her performances of George Handel, Vincenzo Bellini, and Gaetano Donizetti, audiences frequently requested such repertoire as Steven Foster's "Old Folks at Home." Jones also offered a collection of favorites from the operatic repertoire-arias from Robert le Diable, L'Africaine, Rigoletto, La Traviata, and more-mixed with popular ballads such as "Home Sweet Home" and "Swanee River." She also sang a "stammering" song, "Wait 'til the Clouds Roll By," and an early "coon song," the Paul Allen 1883 hit "A New Coon in Town."41 Even though minstrel vocal style was timbrally close to bel canto style and for the most part given voice by white performers, Greenfield's and Jones's repertoire lists conform to white audiences' expectations of black voices.42

In the nineteenth century the classical repertoire seemed an anomalous choice for black singers. Audiences' expectations posed perennial challenges to Greenfield's and Jones's obvious desire to be taken seriously as artists while also having to consider the reality of earning a living. An overbalance of classical music seemed improperly "serious" for, and probably unmarketable to, the burlesque venues in which African American artists were typically able to perform. Moreover, although during Jones's lifetime the African American baritone Theodore Drury headed a black opera company (with which she did not perform), there were hardly any opportunities open to black singers in the world of "art" music.43 As Graziano points out, few companies were willing to pay black artists enough to make a living.44 Lacking "serious" performance outlets, African American

singers were primarily relegated to minstrel songs, popular songs, and spirituals.

In Jones's case, difficulties in finding enough opportunities and willing coworkers to sustain an operatic career forced her to reevaluate the direction of her line of work. In 1896 she rejoined the minstrel circuit after a hiatus as the lead singer of Black Patti's Troubadours.45 The Troubadours offered a rousing and popular "Operatic Kaleidoscope" that included scenes from such operas as Carmen, Faust, Il Trovatore, La Bohéme, and Rigoletto while conforming to the minstrel-show format.46 But although she appreciated the Troubadours as an outlet for her operatic skill, Jones always preferred concert venues. "There are so many things in vaudeville performance to distract the attention of the audience," she said, "that they are not in a proper frame of mind to enjoy straight singing."47 In her own way Greenfield, too, was reconfined to the minstrel show, as she became the inspiration for the minstrel "wench" character Lucy Neal-implying that audiences made little distinction between a blackface performer in an Italian burlesque opera and an African American singer performing classical repertoire.48 Even with superb reviews and calls for listening beyond racial difference, neither Greenfield nor Jones was able to shed the acousmatic blackness that their audiences heard over and above their otherwise celebrated renditions.

In summary, nineteenth- and early twentieth-century audiences dealt with the shocking phenomenon of black classical singers by, mentally or in practice, rerelegating the singers to stereotypical black roles. Even when they were included in classical performances, these singers' vocal abilities and timbres were impossible for white audiences to assess independently of visual and other contextual information. Visual blackness was projected onto timbre, resulting in the perception of sonic blackness. To gain a greater understanding of the historically racialized operatic voice in the United States, I now turn to an even earlier node in the history of the black body and its voice, where a different form of acousmatic blackness may be found.

"Ethnosympathetic" Ears

In 1845 Frederick Douglass, emancipated slave, author of the first well-known ex-slave autobiography, and one of the foremost leaders of the abolitionist movement, asked his readers to pause and listen to the songs of the slaves. In their "songs of sorrow" a listener would hear "tales of woe," for "every tone was a testimony against slavery."49 Douglass's audience did listen, and by the end of the Civil War voices and melodies once considered noise were heard as song and were used by abolitionists as symbolic weapons against slavery. The sociologist Jon Cruz describes this as a "new mode of hearing," possible only under the assumption that slaves possessed an inner life.50 Cruz terms this mode of reception ethnosympathy: a humanitarian pursuit of classifiable subjects. In this perceptual mode, the spiritual was recognized as a clear cultural expression, the form preferred for blacks by "white moral and cultural entrepreneurs." The ability of whites to hear the cries to God embedded in spirituals indicated a mature cultural interpretation of a vocal culture that, until then, had been impenetrable.51

Such unprecedented interest in slaves' songs constituted a break from the previous perceptual framework that classified black song as alien noise. The combination of white efforts to convert slaves to Christianity (under the assumption that blacks, like whites, were created and loved by God) and whites' growing appreciation of slaves' religious songs gradually "granted [slaves] a new subjectivity" within white discourse.52 It also functioned as a vehicle for sympathetic whites, particularly abolitionists, to further imagine slaves as culturally expressive subjects. "Cultural authenticity," Cruz writes, "was the key to subject authenticity."53 In other words, evidence that slaves were not only capable of worship but also of cultural exchange, was taken as proof that they possessed agency and emotion-that they were human subjects, not mechanisms or animals. Hearing enslaved voices with ethnosympathetic ears allowed listeners to discover an "underlying authenticity of subjects through their cultural practices," a perception arguably carried over into conceptions about African Americans singing classical music.54 Possibly ethnosympathy underlies the prevailing preference, among audiences, for spirituals paired with classical repertoire, as well as discourse that attributed the emotional capital present in interpretations of classical music to a natural aptitude for spirituals.

The changing perception of the slave voice, from noisy and incomprehensible to lamenting and expressive, can be observed in later dynamics as blackness of skin and hair are displaced to the aural sphere and often referred to by placeholder terms indicating exceptional emotional expressivity. When the Fisk Jubilee Singers introduced spirituals to the concert circuit in the 1870s, the performers' vocal presentations were praised as "plaintive and touching," "thrilling with their weight of sorrow," and having "an indescribable pathos."55 An anonymous reviewer described the voices as being "so full of character and so full of color, and so little originality is met with these days that their strangeness is agreeable."56 As Julia Chybowski observes, this language echoes that of the abolitionists, especially that of Harriet Beecher Stowe, who sponsored many of Greenfield's British appearances. Greenfield's reception in America and Britain would influence that of the Fisk Jubilee Singers.57 For her British listeners, Greenfield embodied American slave culture. Audiences were "charmed by her perceived musical humanity" and "[Anglo-European] musical achievement."58 A review of Jones echoes both abolitionist accounts of slaves' voices and reviewers' sketches of the Fisk Jubilee singers:

In every note Mrs. Jones sang in her concerts here that one quality was unfailingly present. In the arias, in the ballads comic or sentimental, it was noticeable, and it soon became evident that it was the most individualizing element in the voice, and that no amount of schooling or training could create it. Not that one would desire to have it eradicated. It is the heritage the singer has received from her race, and it alone tells not only of the sorrows of a single life but the cruelly sad story of a whole people. . . . the tones of the negro voice are totally devoid of the humorous quality. The song that is sung may be comic but the voice itself never ceases to be plaintive. This is true of Mrs. Jones, and is it not equally true of every negro singer in every place and under every condition?

In the Washington Post's 1903 consideration of the "Negro voice," we find sentiments and language resonating with earlier descriptions of slaves; African Americans, such as Greenfield and Jones, who tried their luck as concert singers; and later the Fisk Jubilee Singers. The voice is heard as "absolutely unique and indescribable," with a "remarkable quality" that would be "lessened by cultivation." This unique quality arises from a "music almost as old as the world, for it has been chanted in the wilds of Africa to the accompaniment of rude drum and punctured reed ever since human beings could articulate. It still retains much of its original savagery, and when sung with the peculiar timbre which is the especial attribute of the negro's voice it produces an effect which sets the nerves tingling."60

Just as the perceptual filter of ethnosympathy changed the way abolitionists heard slaves' voices, we can see that the modern assumption of acousmatic blackness, applied to African Americans singing classical repertoire, offers African Americans a place in this normative cultural space while maintaining their difference. Might the persistent association of black classical singers' voices with the sound of the spiritual be an updated form of ethnosympathy?

To summarize the discussion so far, operatic acousmatic blackness arose from several historical and cultural turns. White audiences first perceived the black body in performance as enslaved and subhuman through distorted, derogatory images brought to life by, among other cultural-social forces, minstrel performances. Because of how such imagery colored whites' perceptions of the first African American classical performers, it was difficult if not impossible for them to advance their careers without reinforcing the stereotypes, as Jones's return to the minstrel stage attests. Even when black voices won the ethnosympathy of white listeners, their acceptance as subjects was contingent on blacks' distinctiveness from other members of society.

Along with its complex history, acousmatic blackness has significantly influenced the trajectory of subsequent African American singers' careers, including Anderson's, as well as characterizations and vocal writing in original American opera. I suggest that this particular trajectory, which also played a role in how Anderson developed vocally, has proved difficult for subsequent African American singers to escape. It is to that story, and to an exploration of how American opera deals with the idea of blackness and produces acousmatic blackness, that I now turn, considering the racialization of the voice in performance and uncovering the

relationships between performance, body, and race in American opera in the twentieth and early twenty-first centuries.

Racial Sentiments in All-Black Casting

Characterization and vocal writing in early American opera were not far removed from African American performers' burdensome roles in burlesque, vaudeville, and minstrel shows. Premiered in 1934 with an all-black cast, Thomson's opera Four Saints in Three Acts is described by Barg as rehearsing "romantic racialist discourse on black sound."61 There are a few explanations of Thomson's choice in circulation. Carl Van Vechten quoted the composer on tone quality: "[Negro singers] alone possess the dignity and the poise, the lack of self-consciousness that proper interpretation of the opera demands. They have the rich, resonant voices essential to the singing of my music and the clear enunciation required to deliver Gertrude [Stein]'s text."62 In an interview, he shared that they had a "more direct and unself-conscious approach to religious fantasy."63 Thomson also related that the idea for an all-black cast came to him in 1932-33, after he attended a Harlem performance featuring Jimmy Daniels as host and entertainer.

I turned to Russell, realizing the impeccable enunciation of Jimmy's speech-in-song, and said, "I think I'll have my opera sung by Negroes." The idea seemed to be a brilliant one; Russell, less impressed, suggested I sleep on it. But next morning I was sure, remembering how proudly the Negroes enunciate and how the whites just hate to move their lips.64

Here it seems Thomson was attracted to what he viewed as the "racial qualities" of Daniels's voice. Yet another story relays how he conceived the idea for an all-black cast while attending DuBose and Dorothy Heyward's play Porgy in Princeton.65 Whichever inspirational moment came first, these tales convey Thomson's fascination with the black voice and body, his recognition of and pleasure in the "grain" of the black voice.66 But he expressed his approval in patronizingly loud praise that, to Barg, masks a "deeper racial logic, one with considerable historical precedence in cultural commentary about black singing." 67

The material from which this racial "logic" was bred is also evident in the public discourse surrounding Four Saints. After opining that the conceptual strength of Thomson's opera consisted in its resistance to traditional "reason and logic," one critic observed that it "is doubtful if white singers could have given the core, with its strange alternation of comedy and exaltations, the flavor it requires."68 Another review found that "the players from Harlem . . . speak their lines without spoofing them, and lend a poignant dignity to even some of the most absurd moments of the text."69 W. J. Henderson agreed that the "spell" of the production was "to be found in the natural talent of Negroes for playing seriously like a lot of children." The cast, he wrote, "knelt and rolled their eyes toward stage heaven, genuflected, saint before saint with the deepest gravity, and sang their nonsense syllables with as much faith and devotion as they might have sung, 'It's me, Lord, standin' in the need of prayer.'" And, he added, "[Ma]ybe it was meant to be a burlesque on 'grand opera.' If so, it is a gorgeous success."70

One contemporary humorist parodied the opera by writing a parody of a spiritual: "Nobody knows the opera I seen; nobody knows but Gertrude."71 Additionally, commentators ran with the idea that Gertrude Stein's libretto played with racialized speech. Stein's nonsensical use of the name Lucy does indeed carry references to two minstrel songs, one of which features a Lucy, the ur-wench of minstrelsy.

Let Lucy Lily Lily Lucy Lucy let Lucy Lucy Lily Lily

Lily Lily Lily let Lily Lucy Lucy let Lily. Let Lucy Lily.72

At least two of the most popular songs in minstrel repertoire referred to this stock character. "Miss Lucy Long" was a love song with a twist of humor, while "Miss Lucy Neal" was a sentimental "plantation song" with a tragic ending. And if indeed Greenfield was the inspiration for the character of Lucy Neal, an early African American singing classical repertoire but perceived as burlesquing opera is also invoked here. Over and over, in the conception and production of Four Saints in Three Acts and in the discourse surrounding the opera, we observe free uses of preconceived modules of blackness as imagined in voice and body, minstrelsy, and the spiritual, as

well as the parodying of black language and pronunciation.

Premiering one year after Four Saints, Porgy and Bess stipulated a similar cast. George Gershwin's folk opera in three acts (with a libretto by DuBose Heyward and lyrics by Heyward and Ira Gershwin) has been a mixed blessing for African American singers ever since. "Thank God, I never had to sing Bess," the Metropolitan Opera soloist and long-time executive director of the Harlem School of the Arts Betty Allen said. She continued, "I never had to sing Aida. I was really against the typical casting that had nothing to do with your voice, or your type, but just to do with your dark skin. What's that?"73 Allen's sigh not only indicates relief at avoiding what some African American singers call the "Porgy and Bess curse" but also points to the larger issue of racialized casting in opera.74 In 1985, when the Metropolitan Opera mounted a fiftieth-anniversary production of Porgy and Bess, the employment rate of African American singers rose to 25 percent, compared with only 2 percent in the 1970-71 opera season. In 1989, when Porgy and Bess was not produced, the employment rate dropped to 14 percent.75 These statistics imply that there is only a decent amount of work for African American opera singers when Porgy and Bess is mounted. Regarding the depiction of African Americans in Porgy, Edward Said declared, "It is so condescending. These are not real characters. These are folklore characters, harmless in some ways, distant. . . . A natural sense of rhythm; they eat watermelon-all the clichés that go back to Al Jolson."76

Overall, while operas such as Four Saints in Three Acts and Porgy and Bess help launch careers and secure work for African American singers, they are also double-edged swords, working against efforts to integrate American opera in earnest. These operas reproduce stereotypical ideas about African American culture, music, and voice, and oblige African American performers to be molded into "natural" portraits of the stereotypes, which the performers themselves thereby unwillingly reinforce. Since American opera (and not only minstrel, vaudeville, burlesque, or spiritual concert performances) presented African American singers in what may arguably be described as compromising roles, the question becomes whether African Americans could be cast and perceived beyond such stereotypes in opera and classical performance.

Anderson: The Door Opens

Anderson (1897-1993), the granddaughter of a freed slave, was born into a Philadelphia working-class family. Biographies of her early life tell of a young girl feverishly absorbing music with the help of communities that recognized and supported her talent and dedication.77 Her church community, the Union Baptist Church in Philadelphia, embraced and supported her vocal talent, inviting her to sing solos during services. But racism and financial difficulties obstructed her efforts to obtain musical training. Even when the congregation offered to pay for her tuition at a local music school, she was turned away: the school "[didn't] take colored."78 It proved impossible for Anderson to study with a white teacher, who would have had more performing experience and professional connections to offer. Years went by with help from various black teachers and choir directors, but it was not until 1919 that she found her first long-term instructor, one who possessed the competence she deserved. He was the Russian Jewish Philadelphian Giuseppe Boghetti (born Joe Bogash), graduate of the Royal Conservatory in Milan, a mentor with whom Anderson maintained contact throughout her life. With Boghetti she expanded her vocal technique and repertoire, and developed the desire to perform opera.79 During the initial phase of her career (1915-27) Anderson toured the American South. But, growing steadily impatient with the restrictions imposed on black traveling musicians by Jim Crow laws, and with an increasing desire to delve deeply into the German lieder repertoire, she set out in 1927 for London, and a year later had her London debut.80 Despite her recent training with some of the foremost European vocal pedagogues, critics in London were far from impressed. Although her "warm and rich tone" is mentioned by one reporter, others noticed a certain "naive appeal in her readings that compensated for occasional lack of subtlety."81 One wrote that "her voice has the peculiar timbre common to colored vocalists"; another opined more harshly that "the 'scoop' is evidently a racial fault, for it fell into place as the natural thing in some Negro spirituals."82 These journalists questioned her delivery of classical repertoire while noting that what they heard as vocal flaws in that

genre seemed to suit her realization of spirituals.

Like American reviewers, London critics typically insisted on a connection between African American timbres and spirituals, questioning any black singer's choice to attempt anything but the latter. Before Anderson, the African American tenor Roland Hayes experienced considerable resistance to his performance of lieder. And years after Anderson's debut the Paris critic Mercer Cook dryly wrote, regarding a skimpily attended American performance of Four Saints in Three Acts, that had it offered a program of spirituals "the theater would have been packed for months."83

Vincent Sheean's reception of Anderson's performance of spirituals in Salzburg is not unusual and echoes the London critics' sentiments:

In the last group she sang a spiritual, "They crucified my Lord, and he never said a mumblin' word." Hardly anybody in the audience understood English well enough to follow what she was saying, and yet the immense sorrow-something more than the sorrow of a single person-that weighted her tones and lay over her dusky, angular face was enough. At the end of this spiritual there was no applause at all-a silence instinctive, natural and intense, so that you were afraid to breathe. What Anderson had done was something outside the limits of classical or romantic music: she frightened us with the conception, in musical terms of course, but outside the normal limits, of a mighty suffering.84

Recalling the "collective sorrow" that reviewers heard in Jones's voice, Sheean evokes the same sentiment for which abolitionists reached as, for the first time, they grasped the humanity and subjectivity of slaves. But even Sheean's favorable review insists on the spiritual as the root of African American expressivity. Anderson's attitude toward repertoire was very open and exploratory. Her repertoire encompassed all of the major arias suitable for her fach, including some for soprano.85 She went on to develop programs of Finnish, French, German, Italian, Norwegian, Spanish, and Swedish art and folk songs, always ensuring that she would sing something by a national composer on her concerts throughout Europe. When she was invited to sing a recital at the White House she was asked to sing a set of spirituals only-yet, characteristically, she insisted on including a few pieces by Franz Schubert.86

Although she was arguably one of the most gifted singers of the twentieth century-of whom Arturo Toscanini said, "What I heard today one is privileged to hear only in a hundred years"-in the public's mind Anderson's artistic career was often overshadowed by her assigned role as a "tattered social symbol."87 While her appearance at the 1939 Lincoln Memorial on Easter morning, where she sang for over seventy-five thousand people including President and Eleanor Roosevelt, became an iconic moment for the civil rights movement, her symbolic role in the movement ran counter to her own intention to be a classical musician. It is likely that acousmatic blackness, fostered by persistent connections between Anderson's abilities and spirituals, served to propagate her symbolic image, as did her Metropolitan Opera debut as a gypsy sorceress.

Racialized Casting

After Anderson's door-opening performance at the Metropolitan Opera, a relatively large number of African Americans won operatic roles. Dorothy Maynor, Leontyne Price, Arroyo, Grace Bumpry, and Shirley Verrett triumphantly sang on both American and European stages. But however much they were recognized as divas, attitudes toward color always haunted them. For example, critics credited Price's voice with "an unmistakably individual fragrance-husky, musky, smoky, misty (on a bad day foggy!)-and palpitating pagan sexiness. It is not the voice of a good girl."88 And, like Anderson, Price ultimately lamented, "Whenever there was any copy about me, what I was as an artist, what I had as ability, got shoveled under because all the attention was on racial connotations."89 While these artists were hired alongside whites, their color was a novelty that outshone their vocal ability.

We have seen that African Americans have been constrained and limited in terms of performance opportunities. It would seem that these obstacles had been overcome once the operatic glass ceiling was shattered, but while these singers were now offered opportunities beyond characters who parodied black speech and sound, a

curious pattern also emerged.

The term typecasting refers to an actor's strong association with a character he or she has played, with a certain type of character, or with the idea that his or her personal appearance and demeanor lend themselves to a particular kind of role. Rosalyn Story refers to the "maid/slave-girl/gypsy syndrome" as a form of racialized typecasting.90 As I have shown, the black body in opera has been so consistently associated with certain categories of roles that this association amounts to typecasting of African Americans in the role of the other: Japanese war bride slowly going insane, enslaved Ethiopian princess, gypsy seductress, a liminal figure: the cripple, and so on. For example, with her 1946 debut at the New York City Opera, Camilla Williams was the first female African American to receive a contract with a major American opera company. (While she preceded Anderson, Anderson's debut eclipsed hers in symbolic importance.) Williams was hired to sing the title role, a Japanese war bride, in Madame Butterfly. One year earlier, Robert (Todd) Duncan became the first African American member of the New York City Opera, signed as the hunchback actor Tonio in Ruggiero Leoncavallo's I Pagliacci. Price, who might be considered the first African American diva after debuting in the role of St. Cecilia in the premier of Virgil Thompson's Four Saints in Three Acts, went on to sing the role of Bess. However, her versions of Aida and Cleopatra (a role written for her by Samuel Barber) are the interpretations with which her audience came to identify her most strongly. In effect, each of these African American opera singers were "plugged into" the standard repertoire's liminal roles.

As African American singers were integrated into standard repertoire, their visual appearance underwent debate. The critic Bernard H. Haggins recounts a 1974 performance of Don Giovanni at the Met: "Price's superb singing as Donna Anna up to the concluding florid last [sic] passages of 'Non mi dir,' which she managed in a sort of vocal shorthand that implied the notes she didn't sing." Haggin continues: "Price presented with her Donna Anna the same obtrusive incongruity as previously with her Leonora in Il Trovatore and her Pamina in the Magic Flute but not with her Aida. When I look at what is happening on stage my imagination still cannot accommodate itself to a black in the role of a white."91 And as I have shown, one diva imagined Price, despite her celebrated voice, to be appropriate only for the role of Bess. While we know that realism in terms of age and body size is routinely violated in opera, a so-called realistic hue of skin casting was apparently a crucial point on which many audiences were unable to suspend disbelief.

Although he has sung at major opera houses across the world, one of the most celebrated African American baritones, Simon Estes, has encountered obstacles throughout his career because of the practice of racialized casting. At Bayreuth, Estes sung the title role of the Flying Dutchman (1978) with great success, as well as Amfortas in Parsifal (1982). However, when Sir Georg Solti and Sir Peter Hall assembled their new Ring (1983), Estes's audition for the role of Wotan was rejected. Stephen Fay writes that Hall "might indeed have been troubled by the idea of a black Wotan surrounded by a large family of white singers. . . . he did not object in principle to a black Wotan, as long as there were black singers among his daughters, but he felt that Estes' audition had relieved him of the need to make such a choice."92 Despite denials by Hall and Solti, who claimed that the decision was based purely on his vocal abilities, Estes publicly claimed that the unfavorable casting decision was racially based.93 The implication is that racial conflicts which, in late twentieth-century culture, were unable to be tackled head-on, could be freely discussed under the auspices of vocal aptitude (as was the case with Hope Briggs).

For a Glyndebourne Festival production of Don Giovanni, Director Sir Peter Hall ignored suggestions that he hire Leonora Mitchell for the role of the Spanish aristocrat Donna Anna. Her presence, he said, would "ruin the realism and social structure which were to form the very heart of the production." 94 Mitchell responded: "You'd think people wouldn't even consider all that any more. They just shouldn't be saying that somebody doesn't look the part when certain singers are 350 pounds fat. Now are they gonna play a nice young Donna Anna?" Cynthia Clarey was turned down for a role when a director claimed he wanted to do an "authentic" production of a particular opera. "If the director feels that way, fine," said Clarey. "I don't like it-it's a job that I could have had.

But if he really feels that way, I think I'd be a lot happier not doing it."95 Such subtler forms of discrimination are difficult to pinpoint. "Opera is such a subjective art," said Mitchell, that "they can always hide behind words like 'She's just not my type.'" In so many ways opera is the art of disbelief: the stories are mythical and fantastical; plots turn on the inability to recognize one's wife only because she wears somebody else's clothes; and narrative flow is suspended in time by arias that meditate on a singular feeling over improbably long stretches of time. Yet, when it comes to the question of integrated racial hiring, a production calling for demographic "authenticity" is often a key objective. Might directors be wary of the influence of a visually raced body on the way audiences will hear the voices in the production?

In more recent opera journals and reviews, there seem to be fewer public conflicts of this nature; but there are also considerably fewer black major opera stars today than there were in the golden age, beginning with Price and continuing through the 1980s.96 The latest highly exposed and publicly debated incident of which this author is aware is Briggs's 2007 dismissal from the San Francisco opera.

Conclusion: Listening to Opera in the United States

In choosing Anderson, years beyond her vocal prime, to break the color barrier, the Metropolitan Opera presented a figure who symbolized quiet perseverance and patience. Listeners could therefore hear Anderson through the "new mode of hearing," ethnosympathy.97 Although Patricia Turner lauds the Metropolitan director Rudolf Bing for his astuteness in casting Anderson as Ulrica, a role that did not require a young, fresh-sounding voice, it was, to one reporter, a belated and "tardy tribute to [Anderson's] rank and achievement as an artist of international fame."98 Moreover, the role portrayed a gypsy, internationally imagined as other; and the year-1955-coincides with the decade in which amateur minstrel performers finally put down their cork.99 I wonder if this role led audiences to again connect the voice of Anderson with the sight and therefore with the sound of the other, thus confirming the otherness of blackness, as did Jones's and Greenfield's often-compromised performance opportunities. Would "the door," as the New York Times dubbed Anderson's Met debut, open only for those who could credibly be heard through the conceptual filter that registers blackness?

While race relations and human rights in the United States have certainly changed tremendously since the nineteenth century, each listening moment carries with it the resonance of the past. Opportunities for African American classical performers have improved incrementally, from the days of the minstrel and burlesque circuits through exotic and stereotypical characters in blackonly operas written by white composers, typecasting as others in integrated opera houses, and, finally, a larger range of operatic characters distinguished by "individual" and particularly expressive voices. Each period deposited a new perceptual layer, adding to the sediment from which American audiences' ears are molded. As a result, while the discourse surrounding the black voice has been reorchestrated, an underlying motive persists. Political correctness has shifted the color line into the micro-audible sphere-the phenomena that blackness in timbre cannot technically be heard with the naked ear, yet people think they can hear it100-suggesting that timbre is still acceptable to recognize as distinctly black, while skin color and speech are not.101 As I have shown, timbral assessment along these lines may be cloaked in language concerning taste and aesthetic preference, distinctions sanctioned and valued in the opera world.

What, then, is "sonic blackness"? It is not a single phenomenon, but might be a combination of interchangeable self-reproducing modes: a perceptual phantom projected by the listener; a vocal timbre that happens to match current expectations about blackness; or the shaping of vocal timbre to match current ideas about the sound of blackness.102 "Sonic blackness" is not the unmediated sound of essential otherness or the sound of a distinct phenotype. In an interesting parallel, Aleksandr Pushkin opens Eugene Onegin with women singing while picking strawberries: in fact, their mistress has ordered them to sing so that they cannot eat the strawberries.103 Each servant-woman's voice becomes the mechanism through which her mistress guards her property. Similarly, in the world of opera, an artificial belief that timbre evokes blackness consistently becomes a way to maintain otherness and thus maintain whiteness, with its accompanying privileges.

As Ronald Radano affirms, it is because we continue to believe in racial differences that we "enact those differences in sound."104 Acousmatic blackness is timbral blackness that occurs largely in the listening ear-indeed independent of the actual timbre-and seems to arise when a given timbre fulfills expectations or ideas about blackness. In contrast, whiteness as a timbral quality is not openly discussed in the operatic world. Rather, its presence is dormant- envisioned as the normative unmarked, only drawing forward when forced to confront the other. However, claims of black essence are necessarily supported by an assumption of white essence-a distinction that will not fade until "white society" fully and completely renounces racial categorization. "It's up to you," James Baldwin observes. "As long as you think you're 'white,' I am going to be forced to think I'm 'black.'"105

In Ruth Frankenberg's study of whiteness, an interviewee told her that as a "white girl," she had "nothing"-no culture, no people; being white was like being cultureless.106 Another woman remarked that in the sixties, when slogans such as "Proud to be Black" or "Proud to be Hispanic" appeared, it was "popular" to be proud of your ethnicity. Even feminists could say that they were proud to be women, but still most Americans had nothing to be proud of in this regard. The women in the study linked whiteness to capitalism, viewing nonwhite cultures as unsoiled and unspoiled, and unconsciously drawing on colonial discourse in which the West stands for progress and industrialization while others occupy themselves with tradition and culture.107 "When whiteness qua whiteness does come into focus," Richard Dyer writes, "it is often revealed as emptiness, absence, denial or even a kind of death."108

By maintaining the black body as distinct from the white body, the African American opera singer's voice seems to offer a promise of nonwhite vitality and the possibility of filling a void in white culture. In the words of Radano, "If Euro-Americans 'won the race' in economic terms, they also-many believe- paid the price with their souls."109 In this equation opera capitalizes both on the assumption that black bodies and voices are forms of otherness and on the hope that the introduction of difference into opera may help revitalize standard repertoire. The prevalent ability to detect acousmatic blackness, or racialized vocal timbre, demonstrates that listening does not connote passive reception of information and is not a neutral activity. Rather, in listening we participate in social processes both embedded in and producing cultural forms. Consequently, no ear is innocent. Each cochlea curls around its past, and this past resonates with the present. The ways in which Americans hear black voices are tethered to century-old beliefs about black bodies, and thus listening to opera in the United States is an archeological endeavor. Only by educating ourselves about the complex set of practices that constitute listening can we emerge from layers of perception molded by the values, ideologies, fears, and desires carried by our forebears and liberate our hearing from the cultural commodity of blackness.

4. Jason Oby, Equity in Operatic Casting as Perceived by African American Male Singers (Lewiston, N.Y.: Edwin Mellen Press, 1998). See also George Shirley, "The Black Performer," Opera News, January 30, 1971, 6-13.
5. Richard Powers's radiant novel In the Time of Our Singing (New York: Farrar, Straus and Giroux, 2003)

powerfully portrays the personal triumphs and tragedies of an American mixed-race family, as they intersect with those of the nation from 1955 to 1992. Whereas music and singing bind the entire family together through the upbringing of three children, the oldest son is an exceptionally gifted singer who trains at Juilliard and goes on to an international career with his brother as accompanist. The book sensitively portrays the hardships that might have been experienced by any interracial family in mid-twentieth century America, and it also vividly conveys the particular complexities experienced by the oldest son, who is perceived as black (although he is also half German Jewish), while undertaking training and pursuing a career as a classical singer.
While eldest son Jonah's brilliant New York debut is described by the book's narrator, his younger brother and accompanist Joseph, as transcendent-beyond time and race-the fictional New York Times reviewer could not but cap an otherwise congratulatory review by concluding that Jonah was "one of the finest Negro recitalists this country has ever produced." When Jonah finally receives an offer from the Metropolitan Opera, it is in the role of a nameless "Negro" in a contemporary production. Discouraged, he leaves for Europe, where he enjoys a successful career as a tenor. But it is when Jonah enters the world of early music, a movement then in its infancy, he is able to experience a (musical) era predating the racial discord experienced by his Jewish German father before he fled Europe and endured by his African American mother and their interracial family.
Additionally, the book is fascinating in that voice lessons, vocal anatomy, and musical form are described in the minutest and most accurate detail (as a person trained in the classical vocal tradition I recognized every intrigue and technical point).
6. While identification of race in relation to popular music genres is entangled in racial stereotypes, it is not completely arbitrary (the music industry has worked to create links between race and genre for marketing purposes). For a discussion of genre and race in contemporary musical life, see David Brackett, "Questions of Genre in Black Popular Music," Black Music Research Journal 25.1-2 (2005): 73-92.
7. Jonathan Greenberg provides an interesting discussion of three phonemes with strong racial (black) and geographic connotations, and Ethel Waters's manipulation of these phonemes and related racial expectations. Greenberg, "Singing Up Close: Voice, Language, and Race in American Popular Music, 1925-1935" (PhD diss., University of California, Los Angeles, 2008): 200-247.
8. Language acquisition is an integral part of voice training. In addition, singers learn the International Phonetic Alphabet (IPA) so they can read, transcribe, and reproduce the phonetic realization of any language.
9. In brief, timbre refers both to the overall sound that enables us to distinguish one instrument from another and to the different sounds within a single instrument. This composite sound is made up of different partials, or frequencies. In classical vocal production a concentration of partials around 3,000 Hz-known as the singer's formant-is favored. This creates the characteristic "ring" in the voice (the intense "core") and enables it to cut through and be heard over the massive sound of a symphony orchestra. Many vocal pedagogical texts feature in-depth discussions of the physics and vocal training that go into its production. Two classic texts include Johan Sundberg, The Science of the Singing Voice (DeKalb: Northern Illinois University Press, 1987); and William Vennard, Singing: The Mechanism and the Technic (New York: Carl Fischer, 1968).
10. Quoted in Tim Brooks and Richard K. Spottswood, Lost Sounds: Blacks and the Birth of the Recording Industry, 1890-1919 (Urbana: University of Illinois Press, 2004), 30.
11. Quoted in Jacob Smith, Vocal Tracks: Performance and Sound Media (Berkeley: University of California Press, 2008), 135.
12. Not only is it difficult to distinguish race physically or anatomically, but it is also just as difficult to distinguish a male voice from a female one based on a given vocal apparatus. This suggests that much of the difference between male and female voices is acquired. See Suzanne G. Cusick, "On Musical Performances of Gender and Sex," in Audible Traces: Gender, Identity, and Music, ed. E. Barkin and L. Hamessley, 25-48 (Los Angeles: Carciofoli Verlagshaus, 1999); and Nina Sun Eidsheim, "Voice as a Technology of Selfhood: Towards an Analysis of Racialized Timbre and Vocal Performance" (PhD diss., University of California, San Diego, 2008), 1-

27, 20-66.
13. D. L. Rubin, "Nonlanguage Factors Affecting Undergraduates' Judgments of Nonnative English- Speaking Teaching Assistants," Research in Higher Education 33.4 (1992): 511-31.
14. John Baugh, "Linguistic Profiling," in Black Linguistics: Language, Society, and Politics in Africa and the Americas, ed. S. Makoni (London: Routledge, 2003), 155-68.
15. Clifford v. Kentucky, 7 SW 3d 371. Supreme Court of Kentucky (1999). Arguably the police officer in this example relied mainly on accent, as opposed to timbre, which is the focus of this study. However, vowel variations are the basis for timbre and accents, and I use this example not to make a point about vocal timbre but to illustrate the belief that the voice is intimately tied to the essential, social identity of the speaker's or singer's body.
16. The countless examples that disprove this assumption include two contemporary actresses, Anna Deavere Smith and Sarah Jones, who have made their names based on their vocal acrobatics while traversing a stunning range of characters and accents in their one-woman shows. In Bridge and Tunnel (2004) Jones's voice moves seamlessly between the emotional range and wit of an elderly Jewish woman, a young hip-hop artist, and a proper British lady. Vocal parodying and disguise turn on the thrill and amazement of the ability to take a voice where the body cannot follow. More than what the character says, it is the transgression of passing between timbres that gives rise to the excitement. Many plots are based on the ability to pass vocally, from the world of opera-Mozart's Susanna in The Marriage of Figaro- to film, Eliza in Pygmalion (both are class transgressions).
17. Quoted in Martin Bernheimer, "Yes, but Are We Really Colour Deaf?," Opera 36 (July 1985): 758. Clarey's debut took place December 16, 1984.
18. Robert Rushmore, The Singing Voice, 2nd ed. (1971; New York: Dembner Books; distributed by W. W. Norton, 1984), 130-31. To the contrary, Verrett shared in an interview: "When I first heard Marilyn Horne sing she was auditioning for a conductor at the Hollywood Bowl at the same time I was there. I didn't know her, and I thought it was a black singer singing. When I found out it was a white person I said, 'Hmmm, there goes that.' But that doesn't happen very often, I do admit. It's very rare when I would mistake a white singer for a black singer, but I have mistaken black singers for white singers many times, especially the lighter voices. When you get down to the mezzo voices, the dramatic soprano voices, somehow the weight of the voice gives it away." Rosalyn Story, And So I Sing: African-American Divas of Opera and Concert (New York: Warner Books, 1990), 187.

28. Others have written about listening as a socially and historically bound process, including Veitl Erlmann, Reason and Resonance: A History of Modern Aurality (Brooklyn: Zone Books, 2010), about a shift in its relation to rationality; Jonathan Sterne, The Audible Past: Cultural Origins of Sound Reproduction (Durham, N.C.: Duke University Press, 2003), in relation to sound reproduction; and Stoever, "Contours of the Sonic Color-Line," on listening to race through textual sources.
29. Later in life, during her time in England, she was invited to study with Sir George Smart, the queen's organist and music director. Arthur R. LeBrew, The Black Swan, Elizabeth Taylor Greenfield Songstress (Detroit: La Brew, 1969), 18.
30. In his discussion of recording media's influence on the voice, Jacob Smith cites both class and technology as reasons why minstrel, folk, and traditional material were sung and recorded by operatic voices. For the former, Smith draws on Robert Toll's Blacking Up (New York: Oxford University Press, 1974), writing, "Minstrel troupes such as the Ethiopian Serenaders 'sought the respectability of "high" culture,'" and William Howland Kinney's Recorded Music in American Life (New York: Oxford University Press, 1999), who has argued that folk material was sung with an operatic approach because of the prominence of European classical music on the phonograph market. Related to this, we recall that black voices-because of the "sharpness or harshness that the white man's has not" (quoted in Smith, Vocal Tracks, 136)-were thought to be better suited for recording. This could not, however, have been believed in earnest, as most minstrel recording artists were white. According to Smith, only George Washington Johnson and Bert Williams were substantially recorded and widely distributed during this era.
31. Story, And So I Sing, 21.
32. New York Herald, April 1, 1854, quoted in Vera Brodsky Lawrence and George Templeton Strong, Strong on Music: The New York Music Scene in the Days of George Templeton Strong (New York: Oxford University Press, 1987), 413.
33. Greenfield also received letters from supporters with detailed advice "respecting [her] dress." One recommendation was to dress with "great modesty and with much simplicity" and goes into details: "Wear nothing in your hair, unless it be a cluster of white flowers in the back; never wear coloured flowers, nor flowing ribbons. Let your dress be a plain black silk, high at the back of the neck, and open in the front about half way to the waist: under this, war a square of lace, tarltan [sic], or muslin, doubled and laid in folds to cross over the breast." The letter continues another two long paragraphs and is signed "Your friend, E.S.M." Quoted in William S. Young, The Black Swan at home and abroad; or, A biographical sketch of Miss Elizabeth Taylor Greenfield, the American vocalist (Philadelphia: W. S. Young, 1855), 11.
34. Both quotations from Story, And So I Sing, 23.
35. Ibid., 25.
36. Ibid.
37. Julia Chybowski, "The 'Black Swan' in England," American Music Research Center Journal 14 (2006): 8-25. About British audiences, Chybowski writes: "Audiences went to Greenfield's performances looking and listening for what they expected based on Greenfield's former slave identity-an untrained musicality that accentuated the bodily aspects of the voices as the natural human instrument. Reviews of Greenfield's performance characterize her voice as 'wholly natural,' and as 'lacking the training and exquisite cultivation that belongs to the skillful Italian singer'" (15).
38. Both quotations from Chybowski, "'Black Swan' in England," 4.
39. Quoted in James M. Trotter, Music and Some Highly Musical People (Boston: Lee and Shepard; Charles T.

Dillingham, 1881), 78.
40. Quoted in John Graziano, "The Early Life and Career of the 'Black Patti': The Odyssey of an African American Singer in the Late Nineteenth Century," Journal of the American Musicological Society 53.3 (October 2000): 571. 100. Entering public discourse in 1903, W. E. B. Du Bois's concept of the "color-line" has engendered much discussion of race in visual terms. However, Jennifer Stoever-Ackerman notes that the visible color-line is imbricated with an aural dimension, which she terms the "sonic color-line." Jennifer Stoever-Ackerman, "Splicing the Sonic Color-Line: Tony Schwartz Remixes Postwar Nueva York." Social Text 28.1 (2010): 59-85.
101. Timbre seems to be unmediated. Its racialization is a testament to the persistent notion of inherently racially different bodies. The notion of race is so strong in music (and in its association with genre) that even vocal synthesis software is created and sold as having a black soul voice. See Nina Eidsheim, "Synthesizing Race: Towards an Analysis of the Performativity of Vocal Timbre," TRANS-Transcultural Music Review 13 (2009), http://www.sibetrans.com/trans13/art06.htm (accessed January 1, 2010).
102. An ethnographic study of classical voice teachers and their students reports that proper training will "free" and unleash young nonwhite singers' true, natural voices-resulting in vocal timbres that cannot but express their ethnic origins. This idea may have arisen from the example set by the casting choices made possible when the "door" opened for nonwhite opera singers, exemplifying Ruth Frankenberg's study of whiteness and a fear of what opera-which many have considered the pinnacle of Western art-might succumb to. See Eidsheim, "Voice as a Technology of Selfhood," 30-66, 239-72; and Nina Eidsheim, "Modern Vocal Pedagogy, Race, and the Aesthetic of Vocal Timbre," in Changing the Subject: Difference in Musical Scholarship, ed. Study on the Four-channel Skin-hearing Aid Based on Morse Codes

Author: Li, Jianwen; Hou, Yuanyuan; Li, Jianghong

Publication info: Computer and Information Science 4.5 (Sep 2011): 111-115.
ProQuest document link

Abstract: To enhance the identification capacity of the skin-hearing aid for voice signals, the four-channel skin-hearing aid based on Morse encoding method is proposed in this article, which can overcome many disadvantages such as low identification rate and bad anti-jamming capability existing in analog variable pressure skin-hearing aid. By processing voices, seeking the corresponding Morse code of voice signals, establishing the skin response voltage sequence by the Morse encoding, stimulating the skins by this voltage sequence, and making the skins to more clearly feel different signals of voice, the identification rate of skin hearing can be enhanced obviously. [PUBLICATION ABSTRACT]

Full text: Headnote
Abstract
To enhance the identification capacity of the skin-hearing aid for voice signals, the four-channel skin-hearing aid

based on Morse encoding method is proposed in this article, which can overcome many disadvantages such as low identification rate and bad anti-jamming capability existing in analog variable pressure skin-hearing aid. By processing voices, seeking the corresponding Morse code of voice signals, establishing the skin response voltage sequence by the Morse encoding, stimulating the skins by this voltage sequence, and making the skins to more clearly feel different signals of voice, the identification rate of skin hearing can be enhanced obviously.

Keywords: Morse codes, Voice model, Variable pressure skin-hearing aid

1. Introduction

Deaf-mutes' hearing and talking is one big problem in the world, and to solve this problem, people used various method and aid tools such as hearing-aid, electric cochlea, and speech-reading, which are helpful for deaf-mutes' hearing and talking, but there is no one method which can solve this problem perfectly. Though the variable pressure skin-hearing aid prevented by Professor Li Jianwen in Shaanxi University of Science &Technology (Li, 2004, P. 66-69) could achieve certain effect for the hearing, but it is still not ideal for the voice identification. To improve the voice identification effect in the skin hearing, several key approaches in the variable pressure skin-hearing aid are improved in this article.

Frist, the pronunciation of Chinese language is classified. Second, the voice base based on intelligent voice identification is established by the computer voice identification technology. Third, the exterior voice signals are converted into the digital signals and the corresponding relationship with the voice model base is established. Fourth, the corresponding relationship between the voice model and the Morse code is designed. Fifth, the four-channel Morse encoding method is designed. Sixth, the output signals such as point and line in Morse codes are confirmed. Seventh, the identified voice information output is exported as the analog current signals based on Morse encoding principle. Finally, the voice identification of deaf people's hearing based on the voice model is realized.

2. Principle of the Four-channel skin-hearing aid

The multi-channel skin-hearing aid based on Morse codes is mainly composed by the microphone, the filter, the ADC and DAC, the voice processor, the audio-frequency amplifier, the small-power transformer, and the planar electrode (seen in Figure 1).

Microphone: Acquire voice signals and convert the signals to analog current signals.

Filter: Identify the environmental voices, increase the voice signals, and eliminate the noise signals.

ADC/DAC: The digital signals are better than the analog signals in the identification degree, the anti-jamming capacity, and the establishment of voice model, so the analog signals should be converted to the digital signals for processing.

Process [arrow right] Voice base [arrow right] Morse codes: Provide the digital signals corresponding with inputs, based on Morse encoding.

Power transformer: Increase the voltage signals to the secure range in which people can feel (Li, 2006, P. 253-257).

Planar electrode: Stimulate the nerve of skin.

3. Design scheme

3.1 Establishment of the voice model of computer voice identification technology

At present, the voice identification technology has been a comprehensive technology including acoustics, linguistics, digital signal processing, and statistical pattern recognition (Wang, 2009, P. 28-30). The modern v system based on the voice identification technology has been applied in many scenes successfully, and the technologies adopted in different tasks are different. The theoretical research thought of the multi-channel skin-hearing aid based on Morse codes includes classifying the deaff languages, establishing a set of voice model base according with daily standards, and then providing the voltage sequence based on Morse codes by checking corresponding Morse codes and combining with the response of skin for the planar electrode voltage, and hearing voice by this sequence.

3.2 Corresponding relationship between voice base and Morse codes

Morse code is a kind of signal code with break (Li, 2011, P. 5-10), and it expresses different English characters, numbers, and punctuation marks through different sort orders. Generally speaking, any code which can express the written characters by the signals with variable length could be called as Morse code. Aiming at the deaff voice identification, the new Morse encoding method respectively encodes the initial consonants and the final sounds (seen in Figure 2 and Figure 3). This experiment selects four channels as the output of signals, which corresponds with the searching algorithm, and the programming result shows that the binary tree four-depth algorithm could quickly and exactly find the corresponding signals, and the amount of channel is closely related with the depth.

The sequence table of Morse encoding is seen in Table 1, and expect that both a(-E-E) and b(-EE-) are specified codes, other codes correspond with the binary tree searching algorithm.

3.3 Implementation method

The signals with different voltages produced by the analog signal producer are used to stimulate the skin, and when the voltage equals to 100V, the identification effect is good, and the test report for the deaf-mute is seen in Table 2.

4. Tests and conclusions

The deaf-mute male who is 50 years old is selected as the test object, and the electrode is wear at the front of the left arm, inside of the wrist. 100V simulation voltage is selected to achieve good perception effect, and to distinguish the long and the short obviously, large numbers of tests show that the best durative time to feel the short is 0.02s, and the best durative time to feel the long is 0.05s. With the help of the skin-hearing aid, the deaf could identify simple voice signals through about 2 hoursf training. Through about 50 times of test, for ten numbers from 0 to 9, except 4 and 7 could not be identified well, which correct recognition rate was only 60%, other numbers could be identified well, with the correct recognition rate above 86%. The voice identification is the process with continual studying and training, and through long-time training, the deaf could obtain good voice identification capability with the help of the skin-hearing aid. The test result shows that the four-channel skin-hearing aid based on Morse code proposed in this article has good voice identification effect.

Full text: I want to thank Dr. Mark Ross for his tireless efforts over the past 18 years writing about research and technology developments in technology for Hearing Loss Magazine. His words have been ones to live by professionally and personally since before I completed my bachelor's degree in communication disorders. I have been extremely fortunate to have him as a friend and mentor since we met at the HLAA Convention in Phoenix in 1997. I am honored and humbled to have been asked by HLAA and the RERC on Hearing Enhancement to write on research and technology following Marks very well-deserved retirement.
- Brad Ingrao, Au. D.
What Exactly is a Hearing Aid Anyway?
The first hearing aids, like those described in Mark Ross' article "From a Body Hearing Aid to Cochlear Implant" Hearing Loss Magazine, July/ August 201 1) were little more than miniature public address systems. The amplifiers were fairly simple and had a limited frequency (pitch) range. They contained basic tone controls, but often over- or under- amplified areas of hearing loss. In order to hear well, people with hearing loss needed to manually adjust the volume control to try to match the sounds environment. They made life markedly better for people with hearing loss, but were far from ideal.
Modern digital hearing aids are built around tiny computer chips called DSPs (Digital Sound Processors). These, in combination with improved microphones and speakers (sometimes called receivers) allow hearing aids to amplify a wider range of pitches with far less distortion than their predecessors. Using computer software, they can be very finely tuned to the individual's hearing loss and even include memories, analyzers and sub-miniature radio stations. They automatically measure the surroundings and adjust volume and, in some cases, microphone behavior, many times per second. All of this technology comes at a price, and anyone who has researched hearing aids knows that the range of prices is large and the choices numerous.
Why an Article on Hearing Aid Features and Price?
In the July/ August 201 1 issue of Hearing Loss Magazine, HLAA Executive Director Brenda Battat described an HLAA initiative to make hearing aids more affordable. An important part of the transparency she calls for in her editorial is a better understanding of the features available in hearing aids at different price points. When we spoke at the recent HLAA Convention in June, she asked me to address this, so here goes. By the way, the second part of Brenda's transparency concern is addressed in the Stephanie Sjoblad, Au. D. and Barbara Winslow Warren, Au. D. article "Unbundling: A Way to Make Hearing Aids More Affordable?" on page 1 8 of this issue of Hearing Loss Magazine.
This article will define the basic functions in hearing aids that address these common needs as well as providing a few of the more common brand names for these features. Following that, we will look at the current offerings by the top six manufacturers and give you an idea of what features you should expect in several price

categories.

Channels

The human inner ear, or cochlea, contains tens of thousands of tiny sensory hair cells that convert sound waves into nerve impulses that our brains perceive as sound. These are organized like a piano keyboard with each "key" being a critical band of hair cells. When we develop hearing loss, some of the keys become less effective and sound softer and less distinct in pitch. Hearing aids attempt to compensate for this by adding more volume. If the added volume is provided by pressing hard on the weak keys with trained and skilled fingers, the correction will be precise and the overall sounds will be mostly satisfactory. If, however, the volume is added by pounding on the keys with an open hand, the result is imprecise, noisy and generally unpleasant.

In hearing aids, the DSP's amplifier is divided into several specific areas of pitch (frequency), each of which can be adjusted independently. One would think that the more the better, which is true to a certain extent. More channels do assist with some automatic features like feedback reduction (see below for more on that), but clinical research doesn't really bear out the need for more than five or six channels. The location of these channels relative to your hearing loss is more important than the absolute number.

Compression

Since the mid-1980s, hearing aids have attempted to correct the distortion of loudness perception inherent in sensorineural hearing loss (recruitment) by adding more amplification (gain) for soft sounds and less for loud sounds. The most effective form of this is called Wide Dynamic Range Compression (WDRC). Nearly all hearing aids today have at least two WDRC compressors in each channel for speech level sounds and one to control the maximum loudness of the hearing aid. Depending on your hearing loss, having more of these compression controls might allow you to hear more sounds more comfortably and accurately. As with channels, some hearing aids use these compression circuits to assist with noise and feedback reduction.

Multiple Memories

Most of us dont live only in one sound environment. As "smart" as current hearing aids are, they can't predict everything. In addition, certain special situations, such as listening in a hearing loop, on the phone or with an FM system, require very specific hearing aid settings. Most hearing aids allow the audiologist or hearing aid provider to assign these settings to memories that can be accessed with ear level or remote controls.

"Wireless Connectivity"

The newest trend in hearing aids is to use a very short range wireless radio called Near Field Magnetic Induction (NFMI). This is not the same as the traditional magnetic inductance used by the telecoil. Hearing aids use NFMI to share information between hearing aids, or to send and receive information with a gateway device. The ear-to-ear NFMI can be used to make volume and program changes happen in both ears with a single sided adjustment or to assist with directional microphone or noise reduction settings. NFMI to and from gateway devices allow the hearing aids to interface with Bluetooth and 900 MHz telephone and audio devices.

Addressing Feedback

At their very basic core, hearing aids are miniature public address systems. Just like the PA at a county fair, if the microphone and speakers get too close, the amplified sound loops through the system again and again until you hear a high pitched squeal. In hearing aids, this occurs when the sounds delivered into the ear escape, usually through a vent, and then reenter the microphone.

In the old days, we fixed feedback by reducing the size of the vent, reducing the output of the hearing aid or by adding acoustic filters to the sound pathway (earmold, speaker tube, etc.) until the feedback stopped. Today, most manufacturers include a feedback test in their hearing aid fitting software to "search and destroy" feedback.

Currently, hearing aids with automatic feedback management use one of two approaches to manage feedback: Notch filtering systems measure the specific pitch where feedback occurs, then the DSP reduces the amplification at that frequency only. This leaves the overall amplification intact and just removes the very narrow

"notch" in pitch that is causing the feedback.

The other is ? phase reversal system. Much like noise cancelling headphones seen on airplanes, phase reversal systems detect feedback and then tell the hearing aid to produce a sound exactly opposite in phase, which cancels the feedback out. This takes a second or two, so there will still be some feedback, but they do a good job. The more channels in a hearing aid, the more precise these automatic feedback systems can be.

Hearing Better in Noise

In 20 years of practicing audiology, I have almost never encountered a person whose hearing aids were unable to help them hear well in a small, quiet room with carpet, drapes or no air conditioning. On the other hand, almost all of my hearing aid patients complain that no matter how much they spent on their hearing aids, they still struggle in noisy and reverberant rooms. People with hearing loss need speech to be much louder than other sounds in order to understand well. A high signal-to-noise ratio is the best way to deliver improved speech understanding in less than ideal settings.

While nearly all hearing aids have some kind of noise reduction the best evidence available shows that directional microphones provide the best signal-to-noise ratio for ear level devices. The ideal solution in noise is a remote microphone connected to the hearing aid (Hearing Assistive Technology), but that is a topic for another time.

Nearly all current behind-theear hearing aids and larger in-the-ear hearing aids include or can be made to include directional microphones. The most notable difference across different price points is how different hearing aids control the microphones in an attempt to deliver optimal signal-to-noise ratio, and therefore, better understanding in noise and reverberation.

Control vs. Convenience

One of the buzz words in hearing aids today is "automatic." Some people can do very well with a fully automatic hearing aid assuming they spend most of their time listening to one or two kinds of sound in the same setting. The more common reality is that people with hearing loss, especially well informed, proactive people like HLAA members, are out and about listening and living in many complex environments. They need to be able to tell their hearing aids how to behave rather than the other way around.

Let's Go Shopping!

Hearing aid pricing is a bit tricky to discuss in a national magazine since prices are somewhat indexed to the local cost of living. A recent review of available products from GN ReSound, Oticon, Phonak, Siemens, Starkey and Widex found at least one product in the following price points with these features:

Entry Level (Under $1,000 per hearing aid)

* Wide Dynamic Range Compression in at least four channels and two loudness levels
* Directional Microphone with basic automatic operation
* At least two memories (programs)
* Telecoil (Behind-the-Ear and larger In-The-Ear models)
* Notch filtering feedback management

Mid Range ($1,000 to $2,500 per hearing aid)

* Wide Dynamic Range Compression in at least four channels and two loudness levels
* Directional Microphone with basic automatic operation
* At least four memories (programs)
* Telecoil (Behind-the-Ear models)
* NFMI connectivity for volume, program control and Bluetooth gateway
* Dynamic feedback management
* Noise reduction

Advanced ($2,500 to $3,000 per hearing aid)

* Wide Dynamic Range Compression in at least six channels and two loudness levels

* Directional Microphone with two or three modes of operation
* At least four memories (programs)
* Telecoil (Behind-the-Ear models) with selectable orientation
* NFMI connectivity for volume, program control and Bluetooth gateway
* NFMI for directional microphone adjustment
* Dynamic feedback management
* Noise reduction

Premium (over $3,000 per hearing aid)

* Wide Dynamic Range Compression in at least eight channels and three loudness levels
* Directional Microphone with two or three modes of operation
* At least four memories (programs)
* Telecoil (Behind-the-Ear models) with selectable orientation
* NFMI connectivity for volume, program control and Bluetooth gateway
* NFMI for directional microphone adjustment and noise reduction
* Dynamic feedback management

So7 What's the Best Hearing Aid?

As Mark Ross has written many times, finding your ideal hearing aid solution isn't about the product, but rather the process. The hearing aid and its features are only as good as they are appropriate for your needs. Further, the person fitting them must have the skill to make the hearing aid work for you, and have a personality that is compatible with you and your needs. Being an informed and critical consumer allows you to always get the best bang for your buck.
