Chennai doctors design app that works as hearing aid [Chennai]

Publication info: The Times of India (Online) [New Delhi] 09 Dec 2013.

Full text: CHENNAI: There are apps to play with, there are apps to learn. And now comes an app that helps those with hearing problems. Doctors at the Madras ENT Research Foundation (MERF), along with some European experts, have designed 'Listen App' that works as a hearing aid compatible with a mobile phone. What's more, it works on Bluetooth.

Nearly 6% of the Indian population has different degrees of hearing loss, but only 10% of them have access to a hearing aid. The mobile phone app aims to bridge this gap.

MERF Institute of Speech and Hearing principal Dr Ranjith Rajeswaran said the reason that many people do not use a hearing aid is lack of accessibility, affordability and sustainability. "But with this application, anyone who has a hearing impairment can have access to a hearing aid at a fraction of the cost," he said. He added that the software comes with a music player and television option which would be compatible in movie theatres.

The software was launched at the closing day of a five-day workshop on vocal arts and sciences which was aimed at training speech pathologists in helping voice professionals and singers preserve their voice. Singer T N Seshagopalan, who was the chief guest of the programme, pointed out that there is lack of awareness about voice culture among singers in India, and efforts should be taken to conserve the voice which is the backbone of their career.

The programme also saw the launch of another application, the Classroom App, designed for school children who have a hearing problem. "Almost 80% of school children perform poorly in academics as they have problems listening in class. With this application, they will not be distracted as other environmental noises get filtered through the hearing device and only the teacher's voice that comes through a microphone gets amplified," said MERF founder Dr Mohan Kameshwaran. Studies have shown that an assistive listening device of this kind has the capacity to improve the academic performance of a child by 60% in 10 months, said the doctor.

Siemens Medical Instruments Pte. Ltd.; Patent Application Titled "Method for Operating a Hearing Apparatus" Published Online

Publication info: Electronics Newsweekly (Nov 6, 2013): 7117.

Abstract: According to news reporting originating from Washington, D.C., by VerticalNews journalists, a patent application by the inventors BARTHEL, ROLAND (FORCHHEIM, DE); OTTE, CLEMENS (MUENCHEN, DE); RASS, UWE (NUERNBERG, DE); STEINKE, FLORIAN (MUENCHEN, DE), filed on April 17, 2013, was made available online on October 24, 2013.

Full text: 2013 NOV 6 (VerticalNews) -- By a News Reporter-Staff News Editor at Electronics Newsweekly -- According to news reporting originating from Washington, D.C., by VerticalNews journalists, a patent application by the inventors BARTHEL, ROLAND (FORCHHEIM, DE); OTTE, CLEMENS (MUENCHEN, DE); RASS, UWE (NUERNBERG, DE); STEINKE, FLORIAN (MUENCHEN, DE), filed on April 17, 2013, was made available online on October 24, 2013.

The assignee for this patent application, patent application serial number united state, is Siemens Medical Instruments Pte. Ltd.

Reporters obtained the following quote from the background information supplied by the inventors: "Field of the Invention

"The invention relates to a method for operating a hearing apparatus, in which an operating parameter of the hearing apparatus is determined and smoothed by a filter. The invention further relates to a hearing apparatus having a signal processing apparatus, wherein at least one operating parameter of the signal processing apparatus can be adjusted and smoothed by a filter.

"The term hearing apparatus is understood here to mean any auditory stimulus-producing device which can be worn in or on the ear, in particular a hearing device, a headset, earphones or suchlike.

"Hearing devices are wearable hearing apparatuses which are used to provide hearing assistance to the hard-of-hearing. In order to accommodate the numerous individual requirements, various designs of hearing devices are available such as behind-the-ear (BTE) hearing devices, hearing device with external earpiece (RIC: receiver in the canal) and in-the-ear (ITE) hearing devices, for example also concha hearing devices or completely-in-the-canal (ITE, CIC) hearing devices. The hearing devices listed as examples are worn on the outer ear or in the auditory canal. Bone conduction hearing aids, implantable or vibrotactile hearing aids are also available on the market. With these devices the damaged hearing is stimulated either mechanically or electrically.

"The key components of hearing devices are principally an input transducer, an amplifier and an output transducer. The input transducer is normally a sound receiver e.g. a microphone and/or an electromagnetic receiver, e.g. an induction coil. The output transducer is most frequently realized as an electroacoustic transducer, e.g. a miniature loudspeaker, or as an electromechanical transducer, e.g. a bone conduction receiver. The amplifier is usually integrated into a signal processing unit. This basic configuration is illustrated in FIG. 1 using the example of a behind-the-ear hearing device. One or more microphones 2 for picking up ambient sound are incorporated into a hearing device housing 1 to be worn behind the ear. A signal processing unit 3 which is also integrated into the hearing device housing 1 processes and amplifies the microphone signals. The output signal from the signal processing unit 3 is transmitted to a loudspeaker or receiver 4, which outputs an acoustic signal. The sound may be transmitted to the device wearer's eardrum by way of an acoustic tube which is fixed in the auditory canal by an ear-mold. Power for the hearing device and in particular for the signal processing unit 3 is supplied by a battery 5 which is also integrated in the hearing device housing 1.

"The signal processing unit contains operating parameters, which are dependent on the microphone signals. For instance, the strength of a noise filtering is varied as a function of noise intensity or an additional directional microphone with a given strength is activated as a function of an acoustic environment.

"These operating parameters therefore vary temporally with the acoustic environment. In order to prevent frequent sudden changes in parameter values, it is usual to smooth the temporal curve of the parameter values by a suitable filter.

"One example of this is a smoothing average value filter, such as the exponentially weighted smoothing average value. In order to achieve a smoothing with such a filter, the data to be smoothed relating to the entire window width in which the smoothing is to take place, must be provided in the storage device of the signal processing unit. With conventional operating conditions, for instance a sampling rate of 24 kHz and a window width of 3 s, significant data quantities accumulate which, on account of the limited storage capacity of conventional signal processing apparatuses, may rapidly lead to capacity problems.

"U.S. patent publication No. 2010/0232633 A1 discloses a method for recording operating parameters of a hearing device, in which input data is classified in accordance with its association with value ranges. A digit assigned to the respective value range is incremented for each input value, so that a histogram is obtained which reproduces the distribution of the input values."

In addition to obtaining background information on this patent application, VerticalNews editors also obtained the inventors' summary information for this patent application: "It is accordingly an object of the invention to provide a method for operating a hearing apparatus and a hearing apparatus which overcome the above-mentioned disadvantages of the prior art methods and devices of this general type, which enable a smoothing of temporally varying operating parameter values of a hearing apparatus with as little storage space requirements as possible.

"With an inventive method, the input value is classified for each input value, in other words each unsmoothed value, in accordance with its association with a plurality of predetermined classes and a counter assigned to the respective class, which belongs to the input value, is increased. In the simplest case, the counter value of the counter can in this way be incremented by one, other increments which vary if necessary from step to step can however also be used. The counter with the greatest counter value is then determined and an operating parameter value assigned to the counter with the greatest counter value is output as an output variable of the filter.

"Such a smoothing method manages with significantly less storage compared with algorithms known from the prior art. Instead of having to store the input data relating to the entire window width, only the storage space for the counter assigned to the respective classes is required so that the method is in particular suited to use under the relatively limited conditions of hearing apparatuses.

"In a first variant of the method, only the operating parameter value assigned to the counter with the greatest counter value is then output as an output variable if the counter exceeds a predetermined threshold value. Alternatively, the operating parameter value output last is retained as an output variable. The choice of threshold value essentially determines here the window width of the smoothing algorithm.

"It is expedient in this case, when exceeding the threshold value, by one of the counters after outputting the output variable, to set all counters to zero so that the smoothing effect is retained and the storage space is limited.

"In the embodiment illustrated up to now, the method is in particular suited to smoothing operating parameters of the hearing apparatus, which already exist in a discretized form. This may be for instance the evaluation of the acoustic surroundings of the hearing apparatus according to a number of discrete classes (conversational situation, background music and suchlike).

"The method is however also suited to handling non-discrete, real-valued operating parameters. In this case, the classes are preferably represented by cohesive intervals across predetermined, non-discrete value ranges, in order to achieve a discretization in the first step of the method which enables a particularly storage-efficient processing.

"It is further expedient here to scale all counter values by a predetermined factor .lamda. with 0.ltoreq..lamda..ltoreq.1 prior to increasing the counter value. Such a scaling limits the growth of the counter values and thus indirectly determines the window width of the smoothing algorithm. The scaling further influences the extent to which values present in the past determine the current output variable of the filter so that the characteristics of the filter can be adjusted particularly easily by choosing .lamda.

"Instead, as in the initially described variant, of simply incrementing the counter by one for each class which can be assigned an input value, a more complex method of counting is preferably selected here. All counter values are herewith increased by an amount which is dependent on a distance of the input value from a center point of the interval corresponding to the respective class.

"In other words, an input value in this variant of the method not only influences the counter of the class to which it directly belongs, but also the counter of adjacent classes. This results in an additional smoothing and improves the robustness of the algorithm.

"It is particularly expedient here to increase the counter value vj of a class j of the classes, which is assigned an interval with the center point bj, by (1-.lamda.)max(0,1-(|yi-bj|)/.sigma.)) for each input value yi of the operating

parameter, wherein .sigma. represents a predetermined influence radius.
"Classes, the interval center point of which are further away from the input value than the amount of .sigma., are therefore not influenced so that the smoothing properties of the filter can be set by choosing .sigma.
"Overall, an algorithm is created, which, with a constantly low storage requirement, can smooth real-valued data across any window width both in a discretized and also non-discrete manner, and is in this way robust compared with outliers and transient events.
"The invention further relates to a hearing apparatus of the type cited in the introduction, a signal processing apparatus of which has a filter and is designed, in order to smooth the operating parameter for each input value, to classify the input value in accordance with its association with a plurality of predetermined classes and to increase a counter assigned to the respective class, which belongs to the input value, to determine the counter with the greatest counter value and to output an operating parameter value assigned to the counter with the greatest counter value as an output variable of the filter. As already explained with the aid of the inventive method, a robust and storage-efficient smoothing of the operating parameters of the hearing apparatus can herewith be achieved.
"Other features which are considered as characteristic for the invention are set forth in the appended claims.
"Although the invention is illustrated and described herein as embodied in a method for operating a hearing apparatus and a hearing apparatus, it is nevertheless not intended to be limited to the details shown, since various modifications and structural changes may be made therein without departing from the spirit of the invention and within the scope and range of equivalents of the claims.
"The construction and method of operation of the invention, however, together with additional objects and advantages thereof will be best understood from the following description of specific embodiments when read in connection with the accompanying drawings. BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWING
"FIG. 1 is a schematic layout of a hearing apparatus according to the prior art; and
"FIG. 2 is a schematic representation of a course of an exemplary embodiment of a method according to the invention."

Atypical vertical sound localization and sound-onset sensitivity in people with autism spectrum disorders

Author: Visser, Eelke, PhD;Zwiers, Marcel P, PhD;Kan, Cornelis C, MD, PhD;Hoekstra, Liesbeth, MD;van Opstal, A John, PhD;Buitelaar, Jan K, MD, PhD

Publication info: Journal of Psychiatry & Neuroscience : JPN 38.6 (Nov 2013): 398-406.

Abstract (Abstract): Background: Autism spectrum disorders (ASDs) are associated with auditory hyper- or hyposensitivity; atypicalities in central auditory processes, such as speech-processing and selective auditory attention; and neural connectivity deficits. We sought to investigate whether the low-level integrative processes underlying sound localization and spatial discrimination are affected in ASDs.

Full text: Headnote

Background: Autism spectrum disorders (ASDs) are associated with auditory hyper- or hyposensitivity; atypicalities in central auditory processes, such as speech-processing and selective auditory attention; and neural connectivity deficits. We sought to investigate whether the low-level integrative processes underlying sound localization and spatial discrimination are affected in ASDs. Methods: We performed 3 behavioural experiments to probe different connecting neural pathways: 1) horizontal and vertical localization of auditory stimuli in a noisy background, 2) vertical localization of repetitive frequency sweeps and 3) discrimination of horizontally separated sound stimuli with a short onset difference (precedence effect). Results: Ten adult participants with ASDs and 10 healthy control listeners participated in experiments 1 and 3; sample sizes for experiment 2 were 18 adults with ASDs and 19 controls. Horizontal localization was unaffected, but vertical localization performance was significantly worse in participants with ASDs. The temporal window for the precedence effect was shorter in participants with ASDs than in controls. Limitations: The study was performed with adult participants and hence does not provide insight into the developmental aspects of auditory processing in individuals with ASDs. Conclusion: Changes in low-level auditory processing could underlie degraded performance in vertical localization, which would be in agreement with recently reported changes in the neuroanatomy of the auditory brainstem in individuals with ASDs. The results are further discussed in the context of theories about abnormal brain connectivity in individuals with ASDs.

Introduction

People with autism spectrum disorders (ASDs) display im- paired social interaction and communication skills and a pat- tern of rigid and repetitive behaviour, according to the DSM- IV criteria.1 In addition, ASDs are associated with both hyposensitivity and hypersensitivity to sensory stimuli.2--4 These are not considered primary features of ASDs in the DSM-IV, but they are included as criteria in the DSM-5 (www.dsm5.org). Given the impaired verbal communication skills of people with ASDs, the questions of whether and how auditory processing is affected and of how this relates to the underlying neural substrate are highly relevant. This is also evi- denced by a rapidly increasing interest in auditory and speech perception in individuals with ASDs.5--7 Findings indicate that children with ASDs have enhanced pitch perception, difficulty understanding speech in noisy environments and a reduced likelihood of orienting toward auditory social stimuli.8--13

Auditory brainstem responses have longer and less con- sistent latencies in individuals with ASDs.14 The primary auditory cortex in people with ASDs and auditory hypersen- sitivity show a stronger response to pure tone pip stimuli.15 Studies investigating speech-in-noise perception have shown that people with ASDs have more difficulty than controls understanding speech in noise with (spectro)temporal dips.10 This effect, a weaker comodulation masking release16 in peo- ple with ASDs, was also found in a later study, suggesting that controls were better able to integrate information over temporally separated intervals than participants with ASDs.11 Spatial attention has been shown to be affected and accompa- nied by abnormal event-related brain potentials in people with ASDs in a spatial hearing experiment.17 Recent post- mortem investigations of the brainstem olivary complex (part of the auditory pathway) in decedents who had ASDs re- vealed a greatly reduced size of the medial superior olive (MSO), with lower numbers of stellate and fusiform neurons and, to a lesser degree, reduced size of the other nuclei of the superior olivary complex (SOC).18,19 These are, to the best of our knowledge, the only histological studies investigating these structures in decedents who had ASDs, and unfortu- nately patient and control brains were not perfectly matched for sex and level of functioning.

Nevertheless, they provide an interesting perspective on auditory processing in brains affected by ASDs.
These and other abnormalities reported across a broad range of processes in the auditory domain6,7 suggest that the pathophysiology of ASDs may not be exclusively confined to higher-level (top--down) cognitive processing, but may al- ready be present at the level of primary sensory (bottom--up) processing. The concept of more pervasive neural deficits is closely related to the hypothesis of abnormal connectivity throughout the brain in people with ASDs.20--23 Two specific theories of deficient connectivity focus on deficits in temporal binding21 (reduced ?-band synchronization between local brain networks) and the ratio of excitation to inhibition in the brain.23 Functional and structural imaging studies have also suggested abnormal subcortical connectivity in people with ASDs.24--26 Recent investigations seem to point toward a com- bination of short-range overconnectivity and long-range underconnectivity in people with autism.27 This "connectivity hypothesis" of ASDs claims that the social and cognitive ab- normalities may be explained by poor long-range connectiv- ity between distant regions of the brain and excessive short- range connectivity within and between nearby regions.22 This hypothesis has recently been called into question, as motion- related artifacts may have contributed to findings in func- tional connectivity studies.28--30

The auditory pathway in the human brain is relatively well understood31 and, as such, offers a good opportunity to obtain better understanding of ASDs at the neural level. This is par- ticularly promising for the neural mechanisms underlying sound localization, as the roles and neural connectivities of the different auditory brainstem nuclei in localization are to a large degree described and understood.32,33 We reasoned that global connectivity deficits and abnormal brainstem develop- ment could profoundly and predictably affect sound localiza- tion. We performed 3 behavioural experiments, which are out- lined in the sections that follow; an overview is given in the Appendix (Table S2, available at cma.ca/jpn). While we cannot unambiguously map behavioural measurements to these neural mechanisms, any observed atypicalities would provide a new perspective on auditory processing in individuals with ASDs and could be a starting point for future research.

Horizontal and vertical localization of noise stimuli within background noise

Horizontal localization relies predominantly on the detection of interaural time differences (ITDs), originating from the different distances of the ears to the sound source, and interaural level differences (ILDs), caused by frequency-dependent masking by the head.32 For low frequencies, ITD detection is the primary mechanism. It relies on coincidence detection of spikes travel- ling along the ipsilateral and contralateral auditory nerve fibres. Hence, ITD detection critically depends on the accurate timing of inputs at the ears.34--36 For higher frequencies, starting from about 2 kHz, ILD detection by excitatory--inhibitory (EI) and inhibitory--excitatory (IE) cells becomes the primary mechan- ism.37 These cells are sensitive to the ILD at their best frequency. As ITD and ILD detection integrate binaural information, they rely on intact long-range neural connectivity between the brain- stem nuclei of the left and right pathways.

Sound-source location in the vertical plane is determined from the spectral shape properties of the acoustic input that arise from the complex geometry and associated direction- dependent filtering of the pinna.32 Vertical localization at lat- eral locations38 does not rely on integrating binaural informa- tion, but is primarily a "within-stream" monaural process that is thought to rely on short-range connectivity within auditory nuclei (i.e., within tonotopic maps).34,35 It has been shown that abnormalities in this processing stream can be sensitively demonstrated by adding competing background noise to increase the difficulty of the localization task.39

We designed an experiment to investigate whether hori- zontal and vertical localization performance are affected in people with ASDs and whether difficulties in signal/noise separation add to this.

Vertical localization of sweep stimuli

To investigate impaired temporal integration in participants with ASDs, we performed a localization experiment with repetitive frequency-modulated sweeps of different repeti- tion periods. The instantaneous spectral properties of sweeps are narrowband, but as the moving centre frequency covers all audible frequencies, a fast sweep can be temporally inte- grated by the brain to provide sufficient spectral information for vertical sound

localization.40 The sweep experiment al- lowed us to systematically vary the temporal integration window across sweeps by varying their speeds and thus al- lowed us to test our hypothesis that healthy control partici- pants can integrate spectral information over a longer win- dow than participants with ASDs.

Precedence effect

When the same sound originates from 2 locations with a short temporal delay, there is a temporal window within which the brain will fuse the sounds into a single source; this phenomenon is known as the precedence effect.41,42 In most cases the fused sound will appear to originate from a point between the actual sound locations and weighted by the stimulus delay. The time difference up to which this effect oc- curs (about 5--50 ms) is at least an order of magnitude larger than the maximum ITD caused by the distance between the ears (about 650 μs). The precedence effect can be interpreted as an aspect of temporal integration sensitivity. We hypothe- sized that a shorter temporal integration window in partici- pants with ASDs would result in a shorter time window for the precedence effect in this group than in healthy controls.

Methods

Participants

Measurements were performed in adults with ASDs and healthy controls. We obtained written informed consent from all participants. The study was approved by the local ethical committee (CMO regio Arnhem-Nijmegen). We recruited high-functioning participants with ASDs from referrals to the department of psychiatry at the Radboud Uni- versity Nijmegen Medical Centre and from participants in a previous study.43 People with ASDs were included if they had a clinical diagnosis of autistic disorder or Asperger syndrome according to DSM-IV1 criteria and if they had no comorbid Axis I disorders. Clinical diagnoses were established by expe- rienced clinicians on the basis of a careful developmental his- tory and psychiatric evaluation. Clinical diagnoses were con- firmed by administering a structured interview, the Autism Diagnostic Interview-Revised (ADI-R),44 among the parents or caretakers of participants. We recruited healthy control par- ticipants from the Donders Institute database. We tested the nonverbal intelligence of participants using Raven's Ad- vanced Progressive Matrices (APM). Participants were in- cluded if they were between 18 and 35 years old. We excluded individuals who reported hearing impairment, severe neuro- logic impairment or severe psychiatric comorbidity.

The sweep localization experiment was performed in the groups described above; participants were asked to come back for the noise localization and precedence experiments. Since not all participants were still available, new healthy control participants were included in these experiments.

Experimental setup

Experiments were performed in a dark 3 ×3 ×3 m room with reflection-dampening walls, preventing echoes above 500 Hz. Stimuli were presented from 1 of 58 identical speakers (Visaton SC 5.9) mounted on a motorized hoop measuring 2.5 m in diameter that could rotate around the earth-vertical axis at a precision better than 0.1°. Speakers were mounted on the hoop at 5° increments, from --55° to 85° on the front half, and from --52.5° to 87.5° on the back half, thus allowing for a 2.5° resolution in the elevation direction. The participant was seated comfortably in a modified chair, with his or her head in the centre of the hoop. Two fixed background speakers were positioned at a height of 1.5 m on both sides of the frontal wall (see the Appendix, Fig. S1). Stimuli were generated offline using MATLAB (Mathworks) at a sampling rate of 48.828kHz, had 5ms sinusoidal onset and offset envelopes, and were presented from a real-time processor (RP2.1, Tucker-Davis Technologies, System 3). Custom-made ampli- fiers that allowed for a per-trial attenuation drove the speak- ers on the hoop; an off-the-shelf amplifier (Philips FA569) drove the background speakers. The experiment was con- trolled by custom-written software running on a standard personal computer (Dell).

Two sets of single-turn magnetic-field coils attached along the edges of the side walls (horizontal) and floor and ceiling (vertical) generated the oscillating magnetic fields for the search-coil method at 60 kHz and 80 kHz, respectively. The participant wore a lightweight spectacle frame with a pickup coil attached on its nose bridge, allowing precise measurement of the head orientation at a resolution better than 0.1°. A laser diode attached to

the spectacle frame in the centre of the pickup coil projected onto a small (1 cm2) plate fixed at about 30 cm in front of the head, providing the participant with a convenient head-fixed visual pointer. To convert measurements on the horizontal and vertical channels into azimuth and elevation head orientation angles, we used a visual calibration procedure in which the participant pointed at target light-emitting diodes (LEDs) throughout the relevant region of measurement within the frontal hemifield. Head orientation was expressed in az- imuth and elevation coordinates, defined as the angles with the medial and horizontal planes, respectively.45

Noise localization experiment

In each trial, we presented a white noise background (0.2--20 kHz) with a sound pressure level (SPL) of of 62 dB from the fixed speakers for a duration of 2500 ms. After a random delay of 450--700 ms from white noise onset, 1 of the speakers on the hoop played a broadband target stimulus consisting of quasi--white noise (0.2--20 kHz) looped with a 20ms period (sounding like a buzzer) for a total duration of 150 ms including 50 ms on/offset envelopes. Target locations were selected pseudorandomly from a flat distribution within --75° and 75° azimuth and --45° and 60° elevation. In- tensity varied between --20 and 0 dB in steps of 5 dB with re- spect to the background stimulus. In addition, we included control localization trials without the background noise and at the maximum target intensity.

We instructed participants to aim the visual pointer at a fixation LED (middle of the frontal wall) at the start of the trial and then to quickly aim it in the direction of the target sound stimulus and to maintain fixation for about a second. We included 29 trials per sound level, yielding a total of 174 trials.

Sweep experiment

Stimuli consisted of repeated full-range (0.2--24.4 kHz) fre- quency sweeps, generated using the voltage-controlled oscilla- tor function in the signal processing toolbox in MATLAB. Sweeps had durations of 1, 2, 4, 8, 16 and 32 ms and were re- peated to produce stimuli that all had a total duration of 150ms. All stimuli were presented at 0 azimuth, with eleva- tions between --45° and 60° and with no background sound. Participants received the same visual pointing instructions as they did for the noise localization experiment. There were 132 trials.

Precedence experiment

In the precedence experiment, we presented a 100 ms white noise stimulus at an SPL of 62 dB from both background speakers (located at --45° and 45° azimuth and 0° elevation) with a delay of 0--40 ms in either the left or right channel. Par- ticipants were instructed to push a button if they heard 2 sounds ("2 onsets"). There were 150 trials.

Statistical analysis

Prior to further analysis, we extracted head movement par- ameters (representing pointer position) for the localization and sweep experiments from the measured data. A custom developed toolbox46 automatically detected responses using velocity and acceleration criteria. Some detected intervals needed manual adjustment. The head orientation at the end of the participant's response was the response angle used for further analysis.

We parameterized participant performance in the local- ization experiments with 2 measures: the response gain, which is the slope of a linear fit of response angles to stimu- lus angles, and the Pearson linear correlation coefficient be- tween stimulus and response data. We substituted trials without a response by setting the azimuth and elevation co- ordinates to zero. In the correlation computation, we only included trials where the participant made a response. If the participant responded in fewer than 3 trials for a given con- dition, the correlation was set to zero. This only occurred for the lowest intensity category in the noise localization ex- periment. We assessed group level effects using repeated- measures analysis of variance (ANOVA) with a significance threshold of ? = 0.05. We calculated statistics using SPSS version 19 (IBM Corporation).

In the precedence experiment, we applied logistic regres- sion to model the responses per participant. From the

regres- sion coefficients, we computed the point where 2 sounds were reported in 50% of the cases as the threshold. We as- sessed group differences using a 2-tailed, 2-sample t test with a significance threshold of ? = 0.05.

Results

The characteristics of the included participants are shown in Table 1. Ten participants with ASDs and 6 controls partici- pated in all experiments. One patient with an ASD was ex- cluded owing to neurologic abnormalities and 1 was ex- cluded owing to hearing impairment. Two controls and 1 patient with an ASD were excluded because they had not performed the task correctly. For 9 participants it was not possible to obtain ADI-R data because no parent or care- taker was available. One participant had a score below the cut-off on the social interaction scale, 2 scored below the cut-off for stereotypical behaviour and 4 did not meet the onset cut-off. The clinical picture, however, was very typical in all of these cases. All other ADI-R scores were above the cut-off in all domains.

Figure 1 shows all responses from the noise localization experiment of an example participant from either group, sorted by different signal-to-noise ratios (SNRs). Note that azimuth performance in both participants is very reliable up to the point starting below --15 dB, where the participants had great difficulty hearing the stimulus. In contrast, elevation performance decreased more gradually for all SNRs. This pattern is consistent with earlier findings obtained from healthy controls.39

The group analyses show that azimuth localization had very good trial-to-trial reproducibility for SNRs of --10 dB and higher in both the ASD and control groups, with both gain and correlation decreasing for the low SNRs (Fig. 2A). Differences between the ASD and control groups and interac- tions with SNRs were not significant (all $p > 0.10$). For the elevation response components, both gain and correlation were significantly lower for the ASD than the control group (Fig.2B, C; gain: $F_{1,18} = 6.45$, $p = 0.021$, partial $\eta^2 = 0.26$; corre- lation: $F_{1,18} = 8.28$, $p = 0.010$, partial $\eta^2 = 0.32$). The group ×SNR interaction after Greenhouse--Geisser (GG) correction was significant for gain ($F_{5,90} = 4.00$, $p_{GG} = 0.019$, partial $\eta^2 = 0.18$), but not for correlation ($p_{GG} = 0.637$). We used GG correc- tion, as both ANOVAs violated the sphericity assumption for repeated-measures ANOVA (Mauchly test of sphericity $p < 0.001$ in both tests).

Figure 3A summarizes the results for the sweep localiza- tion experiments. The data show the response gains and cor- relations in the elevation direction as a function of sweep duration of 1--32 ms. Participants with ASDs showed signifi- cantly lower correlation scores than controls (Fig. 3B, $F_{1,36} = 5.70$, $p = 0.022$, partial $\eta^2 = 0.14$; Mauchly test of sphericity $p = 0.05$). The difference in gain was not significant ($p = 0.13$). Group ×period interactions were not significant for either gain or correlation (both $p > 0.10$).

Figure 4A shows the measured psychometric curve from an example participant in the ASD and control groups dur- ing the precedence experiment, in which the relative fraction of perceived double stimuli is plotted against speaker delay. For short delays, the participant reported hearing a single sound in all trials, whereas 2 sounds were reported for the longest delays. In the group results (Fig. 4B), the average 50% response point was 30.1 ±standard deviation (SD) 4.2 ms for healthy control listeners and 24.2 ±7.1 ms for listeners with ASDs; this difference was significant ($t_{14.7} = -2.26$, $p = 0.039$, Cohen $d = 1.0$; equal variances not assumed).

To investigate whether performance in the noise localization and precedence experiments were related, Figure 5 shows both measures per participant. Performance in the 2experiments sig- nificantly correlated across all participants ($r = 0.47$, $p = 0.037$).

See the Appendix for an exploration of age, which was not included in the analyses, as an explanatory variable.

Discussion

Horizontal and vertical localization of noise stimuli within background noise

In the noise localization experiment, participants with ASDs and healthy controls performed equally well in horizontal plane localization for all employed SNRs. The similarity in performance between the groups confirms that both healthy controls and participants with ASDs had few problems hear- ing the stimuli for SNRs above --

20 dB and were attentively performing the task.

Interestingly, participants with ASDs performed markedly worse at vertical localization in this experiment. In contrast to horizontal localization,33 vertical localization is predominantly a monaural process, especially for lateral targets.38 A possible ex- planation for the impairment in performance is abnormal con- nectivity within the cochlear nuclei and the inferior colliculi, which are believed to be involved in elevation detection.47,48 A sharp reduction in the number of fusiform neurons in the MSO in patients with ASDs has been reported in the litera- ture.18,19 It has been suggested that similar neurons in the cochlear nucleus play a role in elevation processing47and orient- ing toward elevated sources.49,50 The efferent fibres from these neurons project to the inferior colliculus and the medial genicu- late body.51 A reduction in the number of fusiform neurons in the cochlear nucleus could, therefore, impair downstream relay- ing of elevation information from the cochlear nucleus.

We observed a significant group ×SNR interaction for the vertical response gain in this experiment. The curves in Fig- ure 2B suggest that the between-group effect of gain could be multiplicative rather than additive, which could potentially explain the interaction. Although the results are compatible with impaired vertical localization at a low SNR in partici- pants with ASDs (a shift of the curve to the left), we cannot, therefore, unambiguously attribute the significant interaction to such an effect.

Vertical localization of sweep stimuli

Like in the noise localization experiment, we also observed that participants with ASDs performed worse on vertical lo- calization in the sweep localization experiment. The differ- ence between groups appeared largest for the fastest sweeps, although the group ×period interaction was not significant. It has been shown previously that the fast sweeps contain ad- equate spectral information and should therefore be the easi- est stimuli to localize in the vertical plane.40 The apparent lack of a between-group difference that is specific to the slower sweeps suggests that there is no difference in the length of the spectrotemporal integration window, but rather that fun- damental elevation processing is affected in people with ASDs (as in the noise localization experiment).

Precedence effect

Participants with ASDs showed a weaker precedence effect than controls. Previously reported thresholds for the prece- dence effect vary greatly with stimulus type and response task. A threshold of 22 ms has been reported for 100 ms noise bursts,42,52 although in that experiment the criterion was "equal loudness of lead and lag," instead of the "double on- set" criterion that we used in the present study. Larger values (30--50 ms) have been reported for speech.42 In light of these previous findings, the thresholds reported in the present study seem plausible. The shorter threshold in participants with ASDs could hint at a reduced ability to integrate infor- mation over time and thus appears to be consistent with the temporal binding hypothesis.21 Moreover, the time scale of the precedence effect falls exactly in the hypothesized time- scale of temporal binding deficit21 (i.e., in the 10--40 ms range of the ?-band frequencies).

General discussion

We will briefly consider how the results we discussed could relate to the theory of abnormal connectivity in people with ASDs.22,27 With respect to vertical localization, connectivity theories of ASDs would suggest local overconnectivity,20 and this seems plausible, as either under- or overconnectivity would likely have a detrimental effect on performance. Find- ings of reduced sizes of the relevant nuclei in people with ASDs and reduced sizes of their neuronal populations, how- ever, could point to reduced connectivity.18,19 As binaural pro- cessing is fundamental for the precedence effect, factors con- tributing to the shorter temporal window may include reduced long-range connectivity between the left and right pathways. Hence, the combination of the localization and precedence experiments is compatible with this part of the connectivity hypothesis. The significant correlation between performance in the noise localization and precedence experi- ments (Fig. 5) suggests that both effects may indeed originate from the same root cause at the neuronal level.

The hypothesis of reduced temporal binding in people with ASDs21 may provide an explanation for a weaker prece- dence effect in this population. Note, however, that there was no indication of deficient coincidence detection in azimuth processing in the first experiment. This indicates that tem- poral binding may indeed be affected, but that this may be more appropriately viewed as having consequences at longer time scales, perhaps in more complex neural systems, rather than a direct problem in neural timing.

Fusiform cells in the auditory brainstem have been described as pyramidal cells as well, and this may hint at a relation be- tween our findings and reported abnormalities in development of other brain areas. Pyramidal cells of smaller size have been observed in layers III, V and VI of Brodmann areas 44 and 45.53 These neurons are involved in longer-range cortical and subcor- tical projections. In the same layers of the fusiform gyrus, neur- ons were found to be smaller and fewer in number.54 In this con- text it should also be noted that, as it seems likely that neuronal atypicalities are present throughout the brain, changes in corti- cal processing could provide complementary or alternative ex- planations for impaired task performance.

It has been speculated19 that the reduced number of fusi- form and stellate cells may be caused by neuroblasts failing to migrate to the SOC or that they may not survive after fail- ing to form connections to the cochlear nuclei. A potentially interesting aspect of these data, although the authors did not mention this, is that in people with ASDs, the number of MSO neurons seems to increase with age until adulthood, whereas in controls, the number seems constant over the age range covered. A delayed development trajectory of the brain is one of the main features of theories on ASDs;55 a potential developmental aspect in the neural structure of the auditory pathway suggests that investigating sound localization in children may prove worthwhile.

Limitations

With the broadband stimuli that we used in the present study, it is not possible to disentangle the ITD and ILD detec- tion mechanisms that contribute to horizontal localization. Follow-up studies could use stimuli with only low- or high- frequency content to distinguish between the 2 mechanisms. Group sizes were relatively small in the experiments inves- tigating localization in noise and in the precedence experi- ment. For this reason it was not possible to perform analyses on performance differences among participants in the ASD group. It may be fruitful to investigate subgroups and correl- ations of localization task performance with other diagnostic measures in future research.

Conclusion

We observed 2 abnormalities in auditory processing in people with ASDs: participants with ASDs performed worse than con- trols on vertical sound localization, and the temporal window for the precedence effect was shorter in participants with ASDs than controls. The functional abnormality in vertical localiza- tion may be a reflection of a reduction in structural connectivity that has been reported in the literature18,19 and is consistent with the hypothesis of reduced long-range connectivity.20,27 The tem- poral binding hypothesis of ASD21 could explain the shorter temporal window in which the precedence effect occurs.

Suhami Associates ltd; Patent Issued for Cellphone Managed Hearing Eyeglasses

Publication info: Telecommunications Weekly (Oct 9, 2013): 1075.
ProQuest document link

Abstract: [...]it can also replace many of the functions of the cellular phone.

Links: Check LinkSource for Full Text

Full text: 2013 OCT 9 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- A patent by the inventor Suhami, Avraham (Petah Tikva, IL), filed on March 27, 2012, was published online on September 24, 2013, according to news reporting originating from Alexandria, Virginia, by VerticalNews correspondents.
Patent number 8543061 is assigned to Suhami Associates ltd (Petah Tikva, IL).
The following quote was obtained by the news editors from the background information supplied by the

inventors: "A Hearing Aid enhances hearing by amplifying voices detected by a sensitive microphone, while bringing an individual's reduced hearing response at various audible frequencies, to the level of hearing of a normal person, which is defined roughly as the ability to hear sounds on an absolute scale of 0 to 25 dB. The modified sound is then delivered into the user's ear canal.

"Hearing Aids also use various algorithms to suppress noise, echo and eliminate receiver-to-microphone acoustic feedback.

"Hearing devices may be situated behind-the-ear (BTE), in-the-ear (ITE) or completely-in-the-ear canal, (CIC).

"In recent years the use of cellphones in relaying voice messages from one person to another has increased enormously. The advent of cellular phones has caused many problems for the hearing impaired people wearing one of the hearing aids in or behind the ear, starting from the electromagnetic interferences between the two devices that are in close distance one from the other and the physical encumbrance caused by placing the cellphone over the hearing aid. Several solutions to these problems have been devised, including the use of inductive communication between the cellphone and the hearing aid device through the use of telecoils or resolving the causes of interferences. However to the best of our knowledge no radical solution to the hearing impaired people in the cellular phone age has been suggested nor implemented.

"One of the technological problems of the (BTE), (ITE) or (CIC) type hearing aids is the determination of the direction of the sound reaching the ear; precise determination of the direction of sound enables to eliminate unwanted sources of sound and greatly improve SNR. This problem is currently dealt by using directional microphones that alleviate the problem (see U.S. Pat. No. 3,770,911). Some previous art solutions have suggested using two microphones and measuring the phase delay between them for determining the sound direction, however if the two microphones are very close the determined direction is not accurate. There have been several applications to put several microphones on the eyeglasses temples (see U.S. Pat. No. 3,247,330, U.S. Pat. No. 4,773,095; U.S. Pat. No. 7,192,136; U.S. Pat. Nos. 7,031,483; 7,609,842, 20090252360) for finding the direction of sounds however the technological implementations of these devices have been unsuccessful. There are also no cellphones that, working collaboratively with 'hearing eyeglasses', eliminate unwanted directional or non-directional sound."

In addition to the background information obtained for this patent, VerticalNews journalists also obtained the inventor's summary information for this patent: "The invention describes a Hearing Aid device composed of a cellphone and eyeglasses where some of the programs are carried out by components embedded onto the temples of eyeglasses and some programs by components which are inherently part of cellphones. The combined device improves the intelligibility of voice messages arriving both through the cellphone speaker, the connected earphones and directly through the free air. The user can call diverse programs suitable for different situations, by using inertial sensors embedded either in the eyeglasses or are inherently part of the cellphone.

"It has to be realized that the core architecture of the classical hearing aid is to detect voice, 'correct' it, and deliver it to the ear of the hearing impaired person.

"A cellphone, in principle can do all these functions, with some reservation though. It can detect voice, directly or through the cellular network, it can determine interactively with the hearing impaired person his hearing profile, it has the computing power to 'boost' certain intensities, and eliminate certain sources of noise and when its speaker is juxtaposed to the ear, it can deliver the 'corrected' sound to the ear of the hearing impaired person.

"There are things that the cellphone cannot do though. In its current architecture, it cannot differentiate between directional sound and surround sound and eliminate unwanted sound and mainly, it cannot be worn all the day connected to the ear.

"Here is where the eyeglasses come. They can be worn inconspicuously all the time, and components embedded on its temples may carry out many of the functions that neither the cellular phone nor the miniscule behind or in the ear hearing aids can. In fact it can also replace many of the functions of the cellular phone.

"The design of the device presented in this application goes half way.
"It comprises a cellphone in its current architecture and eyeglasses where electronic sensors, processors, device conditioners and transceivers are embedded on its temples and can interact with the cellphone through its ports using coded audio instructions. Together they provide to a hearing impaired person, hearing loss corrected speech and sound, arriving either directly or by wireless communications.
"Hearing impaired people communicate with other people directly or using line and wireless communication devices, telephones and cellphones. Intelligibility of a received message is conditional to a faithful reconstruction of the parts of the message that are missing, due to the hearing losses. Amplifying the received message across the board, at all frequencies, is the basic tool that improves intelligibility. When the hearing losses are minimal, amplification may be sufficient. However amplifying both relevant speech and noise may not achieve much. Therefore reduction noise as much as possible is the next goal. In our system we try to substantially eliminate noise using two strategies. One strategy is by letting the hearing impaired person, to limit his 'listening cone' to cover only the space covered by his interlocutor(s). If the noise is omnidirectional, this tool by itself will reduce noise by up to two orders of magnitude. If the noise, on the other hand, is coming from the same direction as his interlocutor, this strategy may not achieve much. Setting a 'listening code' requires at least 4 microphones around the head of the person; consequently this strategy requires to place the microphones on the eyeglasses worn by the user. To increase the accuracy of the limited listening code and the ability to change it quickly in real time, powerful DSPs, that continuously compute cross-correlations between the various microphones, are installed on both temples of the eyeglasses.
"The second strategy we use for reducing noise, is to follow speech components in time with a time resolution of 1-2 milliseconds and try to locate the natural 'pauses' between phonemes, syllables and words. As noise is, with high degree of probability, present both during 'pauses' and during speech segments, subtracting the noise frequencies amplitudes from the following speech frequencies, improves the SNR during speech. This strategy is applicable both to the sound detected by the microphones situated on the eyeglasses temples as it is applicable to the microphone of the cellular phone. The cellphone controls the processors on the temples by emitting high frequency audio instructions in the form of ringtones not heard by most persons.
"The next tool we have, in our endeavour to improve intelligibility of the detected speech is to compensate for the loss of hearing of selected audio notes, mostly at low and high frequencies at each ear. These losses may be measured by the user himself using his cellphone, and the required amplifications at selected frequencies, applied both to the speech detected by the microphones situated on the eyeglasses and at the incoming calls by wireless, before being sent to the respective left and right speakers of the eyeglasses and the cellphone speaker and earphones.
"Next, it is essential to differentiate between the voice of the user and that of other people in order to refrain from amplifying the user's voice and sending it to the respective speakers, thereby starting a regenerative audio loop. This identification of the user's voice may be achieved by cross-correlating the voice segments detected by the microphones at the two opposite sides of the mouth and eliminating those voice segments that are fully correlated. In addition the voice segments detected by the microphones of the eyeglasses or the cellphone, may be compared to the preloaded voice signature of the user, where high correlation approves the identity of the user and therefore are prevented to reach the respective speakers.
"Current Hearing Aid devices, suffer from deficiencies some of which are due to the limited space of several cm.sup.3, into which all the components, including the microphone, the receiver and the batteries, have to be squeezed in. An example is trying to find the direction of sound with two microphones that are 1 cm apart. The limited space, also dictates the use of power-limited data processors that are not powerful enough to perform complex comparisons fast enough.
"In this context it is important to stress the need to process speech rapidly, in order to combine it with speech arriving directly to the ear through the free air, so that the ear will seamlessly integrate the two. Digital hearing

loss compensation comprising spectral decomposition with filters, non-linear amplification depending on the hearing threshold and spectral reconstruction ought to be carried out preferably in milliseconds or less, in order to enable the audio signals emitted by the receiver to be integrated with the sound reaching the ear directly through free air, without much delay.

"The noise subtraction schemes should also abide by the same constraint of speed; they should be able to define and subtract 'noise' from speech, preferably within several milliseconds from the detection by the microphone of said sound wavefront. This kind of quick reaction requires fast and powerful 32 bit DSPs that are hard to squeeze into the miniscule behind-the-ear hearing aids. RF Transceivers embedded on the eyeglasses enable two way communications with the digital world and communication between the temples of the eyeglasses.

"Consequently placing the required powerful DSPs and batteries much larger than the miniscule Zn-air batteries, on the eyeglasses temples, is a major advantage.

"Current 'Hearing Aids' are individualized devices optimized for certain situations by different programs. Change of programs need professional adjustments, requiring frequent visits to the hearing clinic. In this context too, the ability to change programs using the cellphone is a major advantage.

"We also maintain that there is no single solution to hearing impairment. The various situations encountered with different interlocutors and/or sound sources in different locations, are hard to accommodate with one 'ingenious' device. Detecting automatically, the various situations and allocations and maximizing Speech intelligibility accordingly although feasible, is not part of the functionality of the current invention. Different programs are needed to maximize speech intelligibility, in a quiet or noisy room of different sizes, in a Park or in a concert hall. One-on-one dialog is different from Listening to everyone talking at the same time in a meeting. Listening to music at home is different than Listening in a concert hall. Given the breadth of situations, our system opted for letting the user to make the selection between programs, depending on the situation he is in. In our architecture change of programs is done by the user, using his cellular phone by emitting the proper instruction using coded ringtones detected by the microphones embedded on the eyeglasses frames. Some functions like selecting the apertures of the 'Listening cone' may be executed with a number of 'taps' on the 'tap' sensors located on both temples. The selection is then acknowledged by a short message delivered through the receiver of the hearing aid. Large memories are placed on each temple of the eyeglasses to accommodate programs that best satisfy the various situations.

"The Ringtones emitted by the user's cellphone serve a dual purpose, to generate bands of tones of different pitch and timbre of varying intensities for determining the threshold of hearing, and also generate sequences of sounds for controlling the various functions of the system. The coded audio instructions embedded into Ringtones when detected by the microphones of the eyeglasses or that of the cellphone are interpreted by the embedded microcontrollers which then instruct to execute the various functions. A side advantage of relaying instructions to the system by audio is that some people may also relay instructions by just 'whistling' from a distant location. External commands may also be transmitted by the wireless Bluetooth transceiver of the cellphone and detected by the Bluetooth transceiver installed on the eyeglasses.

"The ability to record his own hearing responses, using his cellphone Ringtones, enables the user to do so in real life situations, which is very different from determining a threshold of hearing using pure tones delivered through earphones in a booth of an audio clinic.

"In this context it is important to realize that the 'structure' of the ear changes the spectrum of the sound reaching the inner ear; while higher frequencies are amplified, the lower ones are weakened. Moreover these changes are dependent on the direction of the sound reaching the ear. Consequently, it has to be realized that the 'hearing threshold' measured in the audio clinic with pure tones, is only a first approximation when it comes to improve the hearing ability in real life situations, where sounds arrive from different directions. The correction implemented in hearing aids usually consists in amplifying the various frequencies in different amounts, given

the 'hearing threshold' measured in the clinic, so that the resultant frequency response is that of a 'normal person'. We maintain that this procedure is grossly incorrect; the correction should be different when for example the sound is coming from someone in front of you, from the side or from a 'surround sound' system with 6 loudspeakers in a room.

"Another aspect of defining a suitable 'threshold of hearing' is the intelligibility aspect, which takes in account the brain perception of speech. A person will 'hear' a sound's higher harmonics although he may not hear the fundamental frequency and will substitute the unheard frequency in trying to decode a word that should have contained the unheard or unresolved frequency. This substitution will help the brain 'understand' the word.

"An additional aspect of measuring the 'hearing threshold' is the 'masking' effect, where a note at certain frequency may be masked from being 'heard' if another note at a near frequency but higher energy, is present within a 'short' time window. Thus for example a 250 Hz note followed within 200 millisecond by a 350 Hz note of the same amplitude (double the energy) will prevent the 250 Hz note of being heard. These and other brain related effects make the 'hearing threshold' measured with pure tones in a noiseless booth with earphones that discard the amplification effects of the ear pinna, less of an objective measurement of hearing loss. Consequently we maintain that the 'threshold of hearing' should not be measured with pure tones only but with complex Ringtones that include in addition to the fundamental notes also several of their harmonics. As the hearing mechanism is energy cumulative, the loudness of the complex notes for testing the 'hearing threshold' should at least be 200 msec long.

"Therefore the different 'thresholds of hearing' should be measured in the field and stored for use in these very different situations.

"We foresee at least 5 different 'thresholds of hearing' for each ear: when the sound is coming from the front, from a side or from all around the person, from earphones or from a cellphone juxtaposed to the ear. Consequently at least 10 'hearing thresholds' should be measured, stored and used as a base for amplification in similar situations.

"Measuring the hearing threshold with the cellular phone is beneficial not only for oneself for correcting incoming calls, before reaching the ears, but may also be used for correcting outgoing calls, given the threshold of hearing of the receiving party. The threshold of hearing may be measured and recorded either by oneself or from remote through a Q&A session for finding the hearing threshold of the party at the other end of the line. Thus, when transmitting a call, the specific correction needed for the receiving party to better understand the call, can be inserted into the transmission. Consequently, the 'Hearing correction' should figure side by side with the cellphone number of a party if this person is interested to receive calls better suited to his hearing quality.

"In a preferred embodiment the Hearing Eyeglasses components embedded in each of the eyeglasses temples include a Codec, a Microcontroller, a DSP, a large Flash memory, a Bluetooth RF transceiver, a rechargeable battery, an efficient receiver, 3 microphones and several MEMS sensors, all commercial off-the-shelf components. The microcontrollers situated in the temples may communicate between them by NFC (Near Field Communication) or by wire embedded in the temples of the eyeglasses or by a loose micro-cable connecting the back tips of the temples.

"The main modes of operation are 'Speech' and 'Surround sound' which are further divided into 'Noisy' or 'Quiet' selections and further depending on the size of the space where the sound source and the 'hearing' person are located. In addition some specific sources of sound may be selected, in order to optimize the characteristics of the 'sound source' to those of the user's hearing impairment. Such specific 'sound source' selections may for example include close family members with whom the user has frequent conversations. Their voice signatures may be recorded and stored for use in preferential processing of their calls. Voice signatures that are useful for making incoming calls more intelligible comprise, the adjustment of the dynamic range of the largely logarithmic compression of speech and accentuation of certain frequencies. These and other features may be analyzed given previous calls of certain frequent callers, such as family members, and preferential features specific to the

caller such as amplification of certain frequency bands and optimal loudness range may be stored and applied when calls from said persons are received.

"4 microphones 'around' the head are used to determine the direction of the 'Sound source' in a 'Noisy' environment. Fast cross-correlations between pairs of 4 microphones determine the relative'LEAD' or 'LAG' of the sound waves; in other words the differences in the time of arrival of the sound to the microphones. For example a maximal cross-correlation of (1) or (-1) means that the sound source is located on a plane perpendicular to the line connecting the two microphones. This is the case of a one-on-one frontal conversation. In this case the audio levels detected by both microphones are equal, while the volume is inverse proportional to the square of the distance. However the cross-correlations between the front and back microphones will 'LEAD' or 'LAG' depending on their relative locations 'LEAD' or 'LAG' will determine the 'altitude' of the source of sound relative to the plane determined by the four microphones around the head.

"In the 'Surround Sound' mode which is applicable when Listening to music at home or in a concert hall, the 'pause' period is not only harder to automatically define, but it is also wrong as in a 'pause' period, noise made by the crowd, may increase. In this case a user signaling is required, by activating one of the external signaling devices mentioned above, in order to define 'noise' only when the user thinks it to be proper.

"Two LED illuminators placed on the front of the temples and activated by a 'touch' sensor, are directed forward and illuminate a limited area in front of the eyeglasses; they serve several purposes in dark areas and may be used for example to illuminate the scene being photographed by the eyeglasses camera or to read in the dark, whether in an airplane or in bed or for indicating the eyeglasses location by generating an audio code, for example when triggered by a proper whistle or ringtone. One of the LED illuminators may be in the NIR wavelength for illuminating a scene being photographed in the dark, without drawing attention.

"The large flash memory connected to the microcontroller allows to record and store all the available programs that may be implemented depending the situation and place where the Hearing Eyeglasses are utilized to improve hearing. It may also be used to store conversations whether face-to-face or through the cellphone or store Audio programs detected by the FM receiver. The two 3-axis gyroscopes on the temples, sense the mutual positions of the eyeglasses temples and shut the battery whenever the eyeglasses are posed horizontally with the temples crossed over the frames.

"In the 'sleep' mode a limited number of components on the eyeglasses wake-up periodically for a short time and listen for short external coded signals. In the case that a properly coded audio or wireless signal is received and authenticated, the hearing eyeglasses emits a sound signal and a flashing light by a LED. These signals help find the location of misplaced eyeglasses. The search signal may also be a proprietary whistle, previously recorded, digitized and stored in the memory."

I may lack hearing, but not ambition

Author: Gounden, Yuven.

Publication info: Accountancy SA (Oct 2013): 56.

Abstract: Leigh Burton was always encouraged by her parents, regardless of her hearing disability, to complete a degree that would enable her to support herself and allow her, as a woman, to be financially independent. Her career of choice was that of a Chartered Accountant (CA (SA)). Burton always saw how much her father enjoyed his career and this motivated her to follow the same route as him. She is one of the first deaf CAs(SA) to qualify in South Africa. A further motivation for choosing this career is her love of travel. And travel she did indeed. Visiting exotic destinations such as the Caribbean, Mauritius, Singapore, Indonesia, Australia, London and the US gave her a sense of fulfillment.

Full text: Headnote

A deaf CA(SA) shares how qualifying was her ticket to the world.

leigh Burton was always encouraged by her parents, regardless of her hearing disability, to complete a degree that would enable her to support herself and allow her, as a woman, to be financially independent. Her career of choice was that of a Chartered Accountant [CA(SA)]. Leigh always saw how much her father enjoyed his career and this motivated her to follow the same route as him. Leigh is one of the first deaf CAs(SA) to qualify in South Africa.

A further motivation for choosing this career is Leigh's love of travel. And travel she did indeed. Visiting exotic destinations such as the Caribbean, Mauritius, Singapore, Indonesia, Australia, London and the United States gave her a sense of fiilfilment.

"I also wanted to complete a qualification that had international recognition and would allow me to travel all over the world if need be since one of my passions is travel. I have always enjoyed numbers and shared this passion with my father who is also a CA(SA)."

It is said that when one sense is lost the others are doubled. It seems that this rings true of Leigh and it also enhanced her sixth sense, making her more receptive to lessons in life and to what teachers and mentors had to offer. This Johannesburg based 30-something young lady was not short of role models - and she took on their advice and philosophies with gusto!

"My biggest role model throughout my life has been my father and I strive every day to live up to the ideals and values he upholds. I also wouldn't be where I am today without the support of my mother. She has great strength and has always showed unwavering belief in me. My mother has always focused on giving me a sense of independence.

"During my school years, two people had a profound effect on the person that I am today. They were my guidance councillors, Mr. Ken Hovelmeier and Mrs. Maureen Groch, who taught me to never doubt myself and that even with my hearing disability I could achieve my dreams and be all that I wanted to be. That moulded my belief to not use my disability as an excuse or 'cop out' in life".

Leigh attended the mainstream private schools Kingsmead College for Girls and St. Stithians Collegiate and she excelled in her studies. This was extrapolated to Wits University where she faced many challenging situations: the biggest being her ability to filter the messages from the 'noise' from her hearing aid. However, with great support from the Accounting Department at Wits, this did not deter her insatiable desire to excel - and excel she did! When she wrote her board examination, she found that the South African Institute of Chartered Accountants (SAICA) gave her lots of support and this helped her to qualify as a CA(SA).

"Kicking off my career at Deloitte Johannesburg brought me into contact with a great family of mentors and

friends. Alan Munitich, a Deloitte partner, played a pivotal role in my career at Deloitte right through articles and also in my role as a manager. He shared great passion for his work and for enjoyment of life as well as travel. Alan was also a great support in all facets of my work at Deloitte. I know that even though time has passed since I started my career in commerce that I can always phone Alan for a chat and advice. I must also mention Grant Krog [former partner] and Ryan Duffy [partner], who exerted a positive and strong motivational influence on me."

Leigh's area of speciality is tax and financial consulting, which can be a demanding area to work in. In her capacity as a financial/ tax consultant she assists in all aspects of taxation for all taxpayer types ranging from the calculation of Income Tax, Secondary Tax on Companies (now Dividend Withholding Tax), Provisional Tax, Employees Tax, VAT and Capital Gains Tax. Other responsibilities include assisting with SARS audits and liaising with SARS directly to clear any queries or disputes pertaining to any year of assessment. Additional responsibilities include the provision of accounting and financial services, comprising preparation of annual financial statements, completion of annual returns and other statutory returns including registering of new entities, and liaison with auditors. Ad hoc duties include monitoring clients' investment portfolios and administration of share trusts, obtaining exchange control approval for non-resident clients where necessary.

Can a person with a hearing disability handle such an intimidating portfolio?

"Anything is possible. If you want to be a CA(SA) go out and achieve that goal. Nothing is stopping you, not even your disability. It may take a bit longer than most people but that doesn't matter when you cross that goal line. Always remember to believe in yourself and know that you are capable of anything."

When she is not crunching numbers, Leigh relishes surfing the social media platforms, and keeping abreast of the changes in the technological world. Leigh believes that Twitter and Facebook are just two examples of the many social media platforms that are changing the face of how we interact with people, not only on a personal level, but also in business. Leigh is of the opinion that social media is definitely a big player in our lives today. She also enjoys taking time out in the gym, socialising with her friends, planning holidays and catching up on good reads when she has spare time.

Leigh encourages young people to pursue a career as a CA(SA).This is sound advice considering that South Africa has a shortage of about 5 000 CAs(SA).

"In as much as the career of a CA(SA) is challenging it is also very rewarding. My advice to youngsters would be if being a CA(SA) is your dream never give up pursuing it until you get it. The world is definitely your oyster once you have your CA(SA) qualification."

It is clear that Leigh did not perceive her disability as an obstacle. Instead she chose to rise above her circumstances and to pursue her goals with enthusiasm. Leigh epitomises the adage that 'the sky is the limit'.

Siemens Medical Instruments Pte. Ltd.; Patent Issued for Hearing Apparatus with Low-Interference Receiver Control and Corresponding Method

Publication info: Telecommunications Weekly (Sep 11, 2013): 1151.
ProQuest document link

Abstract: According to news reporting originating from Alexandria, Virginia, by VerticalNews journalists, a patent by the inventors Nikles, Peter (Erlangen, DE); Ruckerl, Gottfried (Nurnberg, DE); Schatzle, Ulrich (Forchheim, DE), filed on April 16, 2008, was published online on August 27, 2013.

Full text: 2013 SEP 11 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- According to news reporting originating from Alexandria, Virginia, by VerticalNews journalists, a patent by the inventors Nikles, Peter (Erlangen, DE); Ruckerl, Gottfried (Nurnberg, DE); Schatzle, Ulrich (Forchheim, DE), filed on April 16, 2008, was published online on August 27, 2013.

The assignee for this patent, patent number 8520881, is Siemens Medical Instruments Pte. Ltd. (Singapore, SG).

Reporters obtained the following quote from the background information supplied by the inventors: "Hearing devices are portable hearing apparatuses which are used to supply the hard-of-hearing. To accommodate the numerous individual requirements, different configurations of hearing devices such as behind-the-ear hearing devices (BTE), in-the-ear hearing devices (ITE), e.g. including conch hearing devices or completely-in-the-channel hearing devices (CIC), are provided. The hearing devices designed by way of example are worn on the outer ear or in the auditory canal. Furthermore, bone conduction hearing aids, implantable or vibrotactile hearing aids are also available on the market. In such cases the damaged hearing is stimulated either mechanically or electrically.

"Essential components of the hearing devices include in principle an input converter, an amplifier and an output converter. The input converter is generally a receiving transducer, e.g. a microphone and/or an electromagnetic receiver, e.g. an induction coil. The output converter is mostly realized as an electroacoustic converter, e.g. a miniature loudspeaker, or as an electromechanical converter, e.g. a bone conduction receiver. The amplifier is usually integrated into a signal processing unit. This basic configuration is shown in the example in FIG. 1 of a behind-the-ear hearing device. One or a number of microphones 2 for recording the ambient sound are incorporated in a hearing device housing 1 to be worn behind the ear. A signal processing unit 3, which is similarly integrated into the hearing device housing 1, processes the microphone signals and amplifies them. The output signal of the signal processing unit 3 is transmitted to a loudspeaker and/or receiver 4, which outputs an acoustic signal. The sound is optionally transmitted to the ear drum of the device wearer via a sound tube, which is fixed with an otoplastic in the auditory canal. The power supply of the hearing device and in particular of the signal processing unit 3 is provided by a battery 5 which is likewise integrated into the hearing device housing 1.

"The pulse-density modulation (PDM) or pulse-width modulation (PWM) is frequently used to control the loudspeaker and/or receiver of a hearing device for instance. The digital control is advantageous in that the stage of the digital-analog converter can be dispensed with in the case of digital hearing devices. Digital control circuits also have a significantly higher efficiency rate than analog control circuits. By contrast, analog control circuits are less prone to interference, i.e. they occupy a frequency spectrum which is restricted to an acoustic signal with a small harmonic wave part. The very strongly developed harmonic waves in the case of digital control nevertheless interfere with the wireless transmission of data between hearing devices and the transmission between a hearing device and an external accessory (remote controller, wireless programming device, wireless relay device etc.).

"One possible solution to this problem could lie in the following compromise: The receiver is controlled analogously in the case of hearing devices with wireless transmission and in the case of hearing devices without the wireless function, a power-saving digital control takes place. Hearing devices with wireless transmission may however thus not profit from the power-saving digital control."

In addition to obtaining background information on this patent, VerticalNews editors also obtained the inventors' summary information for this patent: "The object of the present invention thus consists in enabling a power-saving digital control of the loudspeaker of the hearing apparatus, also especially for digitally operating hearing apparatuses. A corresponding method for operating a hearing apparatus is also to be provided.

"This object is achieved in accordance with the invention by a hearing apparatus with a transmission facility for wireless data transmission in a main frequency band, a loud speaker and a control facility for controlling the

loudspeaker with a control signal, with the frequency spectrum of the control signal having a significant notch in one range of the main frequency band.

"Provision is also made in accordance with the invention for a method for operating a hearing apparatus by wirelessly transmitting data in a main frequency band and controlling a loudspeaker of the hearing apparatus with a control signal, with the frequency spectrum of the control signal having a significant notch in one range of the main frequency band.

"By separating the signals for the data transmission and for the control of the loudspeaker in the frequency range, alternate interferences hardly occur any more so that a hearing apparatus, which is designed for wireless data transmission, can also digitally control the internal receiver and/or loudspeaker.

"The control signal of the control facility is preferably pulse-density modulated or pulse-width modulated. An inductive loudspeaker which operates as a low pass can thus be controlled by a digital signal processing circuit without considerable signal processing outlay.

"The data transmission through the transmission facility can take place in a broadband fashion in several frequency bands and the frequency spectrum of the control signal can have a significant notch in the range of each of the frequency bands in each instance. The principle according to the invention can thus also be applied to a broadband transmission of high data rates.

"The transmission facility can also comprise a band pass filter, which essentially only allows frequency parts to pass, which lie in the main frequency band or in the main frequency band and in the range of multiples thereof. The interference resistance of the wireless transmission can herewith be additionally increased.

"In a special embodiment, the hearing apparatus according to the invention can be configured as an in-the-ear hearing device, even if the current consumption there and the space available are extremely limited. The minimal space available forces the receiver, which is generally a magneto-acoustic converter, very close to the receiver coil. The position and alignment with each device is also individual with in-the-ear hearing devices. In any case, the receiver induces more or less large interference signals into the receiver coil. The signal-to-noise ratio there is thus generally clearly impaired. The poor signal-to-noise ratio could be improved by an increased transmission power, which can however only be achieved by an enormous energy requirement. Therefore the inventive solution involving spectrally separating the control signal for the receiver from the transmission signal for the wireless data transmission is even more welcome.

"According to a further embodiment, a hearing system with two hearing devices is provided in accordance with the invention, which each have the design of the hearing apparatus described above, with the transmission facilities of both hearing devices allowing a bidirectional, wireless data transmission and a data transmission in one direction taking place in a different frequency band to a data transmission in the other direction. A real bidirectional connection can thus be made available with synchronized directional transmissions."

For more information, see this patent: Nikles, Peter; Ruckerl, Gottfried; Schatzle, Ulrich. Hearing Apparatus with Low-Interference Receiver Control and Corresponding Method. U.S. Patent Number 8520881, filed April 16, 2008, and published online on August 27, 2013. Distortion product otoacoustic emission level maps from normal and noise-damaged cochleae

Author: Meinke, Deanna;Clavier, Odile;Norris, Jesse;Kline-Schoder, Robert;Allen, Lindsay;Buckey, Jay

Publication info: Noise & Health 15.66 (Sep-Oct 2013): 315-25.

Abstract: Distortion product otoacoustic emission (DPOAE) level mapping may be useful for detecting noise-induced hearing loss (NIHL) early. Employing DPOAE mapping effectively requires knowledge of the optimal mapping parameters to use for detecting noise-induced changes. The goal of this project was to show the map regions that differ most between normal and noise-damaged cochlea to determine the optimal mapping parameters for detecting NIHL. DPOAE level maps were generated for the $2f_1-f_2$ and the $2f_2-f_1$ DPOAEs for 17 normal hearing male subjects and 19 male subjects with NIHL. DPOAEs were measured in DPOAE frequency steps of approximately 44 Hz from 0.5 kHz to 6 kHz using constant f_2/f_1 ratios incremented in 0.025 steps from 1.025 to 1.5 using both unequal-level (L1,L2 = 65,55 dB sound pressure level (SPL)) and equi-level (L1,L2 = 75,75 dB SPL) stimulus paradigms. Maximal responses for the $2f_2-f_1$ emission at L1,L2 = 65,55 dB SPL were found at lower ratios compared to previous studies. The map regions where NIHL eliminated or reduced DPOAE magnitude were identified. DPOAE level mapping using higher-level, equi-level primaries produced significantly more detectable emissions particularly for the $2f_2-f_1$ emission. The data from this study can be used to optimize DPOAE level mapping parameters for tracking noise-exposed subjects longitudinally.

Full text: Introduction

The ability to detect noise-induced hearing loss (NIHL) early and implement preventive strategies would reduce the social and economic burdens attributed to this disorder. Distortion product otoacoustic emission (DPOAE) level mapping is a potential new approach to detect NIHL and monitor individuals for early signs of cochlear damage from hazardous noise exposure over time. The Knight and Kemp, [1],[2] DPOAE level and phase mapping approach has been used in rabbits to display DPOAE data with normal cochlear status and after noise exposure. [3] These researchers suggested that DPOAE level/phase mapping may provide a sensitive indicator of cochlear damage due to evidence of a strong DPOAE place-fixed component in rabbits with normal cochlear function and in rabbits with NIHL where DPOAEs exist. To date, there are limited human data using the Knight and Kemp, [1],[2] DPOAE level mapping approach in normal and noise-damaged cochleae, perhaps due to the time-intensive nature of the testing paradigm and the customized testing protocols needed to collect comprehensive data sets.

Time-intensive DPOAE level mapping has been utilized to investigate differences in DPOAEs for 20 male subjects with normal hearing and 10 subjects with NIHL. [4] The experimental paradigm used an f 2 /f 1 fixed-ratio approach incremented in 0.025 steps between 1.025 and 1.5 in response to three equi-level primary tone sweeps (L1,L2 = 80,80; 75,75 and 65,65 dB SPL). The extended DPOAE frequency range encompassed 0.5-6.0 kHz in DPOAE frequency steps of 44 Hz. Both wave- and place-fixed emissions were evident for the 2f 1 -f 2 emission and place-fixed emissions were evident for the 2f 2 -f 1 emission in both normal and NIHL subjects with measurable emissions. The outcomes did not support the hypothesis that an increase in place-fixed DPOAEs may occur due to potential changes in cochlear structural irregularities caused by hazardous noise exposure as evidenced in the prior rabbit study. However, in this initial study, DPOAE levels differed for the NIHL group as compared to the normal hearing group in regions that extended beyond the conventional 2f 1 -f 2 optimal f 2 /f 1 ratio of 1.2. These initial data suggested that DPOAE level mapping might provide a more comprehensive evaluation of cochlear function that could be useful in the assessment of NIHL. Investigating this potential application was severely limited by the duration of the initial mapping protocol (45 min/DPOAE level map), which required a high degree of cooperation and tolerance from the subjects. More efficient and flexible

instrumentation, test protocols, and analysis techniques were needed.

New technology developed for the present study allows for comprehensive maps to be completed within a clinically reasonable time (maps can be completed in times ranging from 5 min to 25 min depending on the number of points desired), but the optimal parameters to use to collect mapping data for the early detection of NIHL are not known. The objective of this study was to determine the DPOAE frequencies and ratios on a DPOAE level map most affected by noise exposure, and to use this information to develop DPOAE level mapping protocols designed for the early detection and monitoring of cochlear damage from hazardous noise exposure. To accomplish this, mapping data from 17 normal hearing male subjects were compared to data from 19 men with NIHL. We hypothesized that some map regions would show minimal differences and could be omitted from future mapping protocols and that higher-level primaries (e.g., L1,L2 = 75,75) would produce more detectable emissions in the NIHL group. We also hypothesized that the technology developed for this study, combined with the data from the normal and noise-exposed study groups, would yield mapping protocols to assess NIHL that could be completed within a clinically acceptable amount of time.

Methods

Participants

DPOAE level maps were recorded from male subjects aged 18 to 50 years from the University of Northern Colorado geographical community, which includes veteran/military service members. Inclusion criteria for all subjects included a negative otologic history, no history of neurological disorders, normal otoscopy and normal middle ear status (based upon normative values for static admittance, equivalent ear canal volume and tympanometric peak pressure between -150 daPa to +50 daPa). Additional subject inclusion criteria were dependent upon the experimental grouping; either "normal hearing non-noise exposed" (NHNN) or "NIHL noise exposed." (NIHL) Pure-tone air-conduction thresholds were used to classify the subjects into each experimental group: (1) NHNN where thresholds were <20 dBHL for 250-8000 Hz bilaterally and (2) NIHL defined as thresholds <20 dBHL at 250-500 Hz and <60 dBHL for 1000-6000 Hz. Only one ear was used for the study and right versus left ear was randomized at the time of enrollment for the NHNN group and in cases of bilateral NIHL.

Noise exposure status was determined by an extensive occupational and non-occupational noise exposure case history survey and interview. Subjects classified as NHNN reported either no past or present noise exposures or only rare exposures in the past. Subjects classified as NIHL reported routine and consistent participation in noise hazardous activities in the past and in some cases, ongoing noise exposure at the time of the study enrollment. The use of hearing protection during noise exposed activities varied across subjects and activities, and was typically used either inconsistently or not at all by the majority of NIHL subjects. Trained audiology graduate research assistants and the first author obtained consent, and conducted the case history interviews and experimental testing. The study was approved by the University of Northern Colorado Institutional Review Board.

Audiometry and acoustic-immittance testing

Pure-tone audiograms were obtained manually at 250, 500, 1000, 2000, 3000, 4000, 6000 and 8000 Hz using a Hughson-Westlake procedure performed with an acoustically calibrated Grason Stadler GSI 16 audiometer and TDH-50P supra-aural earphones. [5] Testing was completed in a Tracoustics single-walled sound booth meeting ANSI S3.1-1999 (R2008), [6] permissible ambient noise levels.

Normal tympanometry patterns (Type A) and pressure equalization (-150 to +50 daPa) were verified for the test ear prior to conducting DPOAE measurements using routine acoustic-immittance measurements with a Maico EroScan Pro (i.e., the 226-Hz tympanogram).

Distortion Product Otoacoustic Emission Level Mapping

DPOAE level maps were collected using the hardware and software developed specifically for this research project in collaboration with Creare Inc., (Hanover, NH). The prototype hearing assessment system

specifications are provided in Appendix A.[SUPPORTING:1]

Experimental DPOAE level maps were collected with the human subjects awake and seated in a recliner within the single-walled sound booth after receiving instructions to remain as quiet and still as possible. Subjects were permitted to read or operate electronic games/devices with the audio disabled during the testing. All data were collected during a single 1.5 h experimental session. Rest periods were offered between the two mapping level protocols; however, no subjects requested removal of the probe or a change of position necessitating probe removal and reinsertion. DPOAE probes were sealed in the ear canal using the standard-sized rubberized tube-phone ear tips.

The researchers subjectively determined an adequate seal in the ear canal by visualization, tug-test for resistance, and subjective feedback from the subject. To assist with proper probe placement, a frequency sweep (chirp) was presented in the ear canal before the DPOAE testing. The results from three chirps (500 Hz to 5000 Hz) at 65 dB SPL were averaged, smoothed, and displayed to the research assistant. In the case of a poor seal, the probe was reseated and the chirps were repeated. Every effort was made to assure an adequate first seal and the final acoustic sweep test was stored as a baseline reference for future DPOAE level-mapping testing. If the probe did need to be reinserted, the baseline acoustic frequency-sweep spectrum could be used as a reference and the probe could be adjusted until the sweeps were consistent with baseline measures. For this cross-sectional study, however, the probes did not need to be reseated and baseline acoustic frequency-sweeps were consistent between mapping primary tone stimulus levels (L1,L2 = 65,65 and 75,75).

DPOAEs were measured in DPOAE frequency steps of approximately 44 Hz for both the 2f 1 -f 2 and 2f 2 -f 1 emissions from 0.5 kHz to 6 kHz using constant f 2 /f 1 ratios incremented in 0.025 steps from 1.025 to 1.5. Over this parameter space, f 2 ranged from 0.258 kHz to 18.023 kHz while f 1 ranged from 0.388 kHz to 12.016 kHz. This produced a map composed of 5160 points. Using a total of 4 averages per point, each map required 25 min to complete. DPOAE level maps were collected for two primary tone levels: 65,55 dB SPL (consistent with conventional DP-Grams), and 75,75 dB SPL. There was no evidence of artifactual distortion at levels above -20 dB SPL when these high-level primary stimuli were measured in an artificial ear (Brüel and Kjaer Model 4157, Nærum, Denmark).

[Figure 1] provides a general description of the plotting to orient the reader to the data presentation. The 2f 1 -f 2 and 2f 2 -f 1 DPOAEs were shown within the same area plot, consistent with the Knight and Kemp, [1] and Martin, [3] data presentations. The 2f 1 -f 2 DPOAE was plotted in the upper half of the panel and was contiguous with the 2f 2 -f 1 emission in the lower half of the same panel frame [Figure 1]. Emission levels were mapped (z-axis) by aligning vertically on the y-axis the DP (distortion product) frequency (~500 Hz to 6000 Hz) and in ascending ratio order on the x-axis for both the 2f 1 -f 2 and 2f 2 -f 1 DPOAEs [Figure 1]a. This 3-dimensional approach (DP Frequency, DP Level and f 2 /f 1 ratio) was then color coded for DPOAE level [Figure 1]b in 0.8 dB SPL color gradients and converted to a 2-dimensional plot [Figure 1]c. DPOAE level data were plotted using warmer colors (reds, yellows) for high-level emissions and cooler colors (light green, light blue) for low-level emissions. DPOAEs that most likely reflect noise floor (NF) values were plotted as a dark blue color. The color range was set from -20 dB to 30 dB SPL. Values in the map either lower or higher than these bounds were displayed using the value for the lower or upper bound limit respectively.{Figure 1}

When the DP level was plotted as in [Figure 1]c, the map tended to show a concentration of higher level DPs at the lower DP frequencies, which were also contaminated by higher NF levels. To illustrate this more clearly, the data were also presented as a signal-to-noise ratio (SNR) map. In this case, the DP minus NF was plotted, rather than just the DP level [Figure 1]d. The color range was set from 0 dB to 30 dB for SNR and values either lower or higher than these bounds were displayed using the value for the lower or upper bound limit respectively.

The trajectory of the more commonly referenced f 2 frequency is provided in [Figure 1]c for 3 kHz and 6 kHz, since this is a region typically damaged by hazardous noise exposure. These plots span a larger frequency

space and utilize a larger frequency increment (44 Hz versus 12 Hz) when compared with the Knight and Kemp's, [2] report's figures.

Statistical analysis

Each map was a matrix of 129 frequencies and 40 ratios (5160 DPOAEs). To create average maps, the individual DP levels (for a level map) and the individual DP minus NF values (for an SNR map) were averaged point-by-point across subjects within an experimental group. For the average SNR maps, the percentage of overall points greater than or equal to 3 dB SNR, 6 dB SNR and 9 dB SNR were calculated for each group. The percentage of points at or above the 3 cut-off values (>3 dB, >6 dB and >9 dB) were compared between the NHNN and NIHL groups using the non-parametric statistics (Kruskal-Wallis test). To compare the average NHNN and NIHL maps, the maps were first median filtered, and then compared point-by-point using a one-way ANOVA with an alpha of 0.05. A compensation for multiple comparisons was not used, since the objective of the point-by-point comparison was to outline areas on the map with the highest likelihood of showing significantly different DPOAE levels between the NHNN and NIHL groups. The goal was to create a map of the points where the two average SNR maps differed significantly, with the understanding that some of these points might represent type I errors. This overall approach provides a way to define the areas of the map most likely to show differences between a NHNN and NIHL group, which is needed to provide the greatest opportunity to detect subtle early changes in mapping for noise-exposed individuals.

Results

Subjects

A total of 36 male subjects participated in the study (NNHN n = 17; NIHL n = 19). The mean age of the NHNN group was 28.2 years +- 8.8 years. The NIHL group was slightly older with a mean age of 35.7 years +- 9.3 years. Unpaired Student's t-testing reveals a statistically significant age difference between the two groups using an alpha of 0.05 (P = 0.018).

Pure-tone audiometry

All subjects had measureable thresholds between 250 Hz and 8000 Hz. Average audiometric thresholds for test ears in NHNN and NIHL groups are provided in [Figure 2]. The NHNN group was comprised of 53% right and 47% left ears while the NIHL group was comprised of 37% right and 63% left ears. The average thresholds from 250 Hz to 8000 Hz for the NIHL group were significantly poorer than the NHNN group (P <0.01).{Figure 2}

DPOAE equal-ratio level and signal-to-noise ratio maps

Qualitative observations: General

[Figure 3] provides a single subject example of a level and SNR map for a NHNN subject. [Figure 4] provides an example for a NIHL subject. The maps for the individual subjects were unique, but on average patterns of DPOAE response were evident. [Figure 5] shows the average level and SNR maps for the NHNN and NIHL groups.{Figure 3}{Figure 4}{Figure 5}

A qualitative review of the DPOAE level maps revealed obvious visual differences between the experimental groups. The NHNN group had more high-level DPOAEs, a wider band of ratios in the 2f 1 -f 2 area where DPOAEs were detected, and a larger area where 2f 2 -f 1 DPOAEs were detected compared to the NIHL group.

Qualitative observations: Amplitude features

The DPOAE level data are consistent with a band of maximal response centered at the f 2 /f 1 frequency ratio of 1.2 across DP frequencies for all subjects at both L1,L2 = 65,55 and 75,75. This is consistent with the findings of Harris et al., at L1,L2 = 65,55. [7]

The 2f 2 -f 1 emissions were present over a smaller area of the map as illustrated in [Figure 5]. For the NHNN group, the optimal 2f 2 -f 1 emission for 65,55 level maps occurred at an f 2 /f 1 ratio of 1.025 and for the 75,75 map, a ratio of 1.075.

At both stimulus levels, there was visual evidence of a low-frequency color band (reds) or vertical stripe at the

lowest DP frequencies [Figure 5]a, c, e and g, which was not apparent in the SNR map. This color band did not occur when the system was tested using a cavity indicating that low frequency physiologic noise was the likely source of the response observed in the level maps. The SNR maps further suggest that the low-frequency response is dominated by noise.

Quantitative observations: Amplitude maps

For the NHNN subjects at L1,L2 = 65,55 dB SPL, the highest DPOAE level response occurs near the f 2 /f 1 ratio of 1.275 for the lowest DP frequencies (<2000 Hz) but occurs near a ratio of 1.15 for the highest DP frequencies (>5000 Hz). At primary levels of 75,75 dB SPL, the highest response occurs at ratios of about 1.3 at low DP frequencies, and 1.15 at highest DP frequencies. This is similar to the DP frequency/ratio function reported by Harris et al. [7] Higher-level DP amplitudes corresponded with higher SNRs at the same ratio and DP frequency. When the primary tone levels were increased to L1,L2 = 75,75 dB SPL [Figure 5]e and f the averaged response region was enhanced with higher level emissions for the 2f 1 -f 2 region and a broad response for the 2f 2 -f 1 region of the map. The higher DP levels at low frequencies were also correlated to relatively high SNR levels for the 2f 1 -f 2 emission at ~ 1.2 ratios, but not at other ratios or for the 2f 2 -f 1 emission [Figure 5]e and f. This would indicate the presence of DPOAEs around the 1.2 ratio, but not at other ratios (despite the high levels shown at all ratios at low frequencies on the map), at low frequencies (<2000 Hz).

For subjects with NIHL, lower level amplitude 2f 1 -f 2 DPOAE responses (L1,L2 at 65,55 dB SPL) were evident at all DP frequencies for the 1.2 ratio region when compared to NHNN subjects. The range of ratios that exhibit a response is narrower as well. For both groups, the region of relative higher DPOAE levels was near 3-4 kHz, which correlates to an f 2 range of ~4.5-6 kHz when referencing an f 2 /f 1 of 1.2. There was little or no response evident for the 2f 2 -f 1 region of the map when using moderate level primary tones. Stimulation with high level primary tones of L1,L2 = 75,75 dB SPL elicited higher level DPOAE responses in impaired ears. For high level primary tones, a broader frequency and ratio region of response for the 2f 1 -f 2 and the 2f 2 -f 1 emissions became evident at the DP frequencies of 3-4 kHz.

Analysis

SNR

SNR averages for each group were analyzed to determine relative areas of the map with significant levels of emissions. [Figure 6] shows the results for each experimental group and for each emission type. Each plot shows the cumulative number of points with an SNR at or above 3 dB, 6 dB and 9 dB as a function of primary tone level and experimental group for each emission type. [Table 1] summarizes the statistical significance of the differences.{Figure 6}{Table 1}

For the NHNN group, approximately half the points in the upper portion of the map have an SNR of at least 3 dB and 25% of all points are above 9 dB SNR indicating a high probability of DPOAE presence for the L1,L2 = 65,55 dB SPL protocol. In contrast, the NIHL group shows fewer points when referencing a SNR of 3 dB (46% versus 62% for NHNN) and less than half as many as for the NHNN group with an SNR of 9 dB. At L1,L2 = 75,75 dB SPL stimulus levels, both group show increases in the number of points with higher SNR values, but with the same relative differences evident between the two groups.

In general, the number of points with SNR of 3 dB or more is 30-50% less on the lower half of the map (2f 2 -f 1) than the upper half of the map (2f 1 -f 2), for either group. The difference between the two stimulus level protocols is more striking for the 2f 2 -f 1 emission. Indeed, for either group, the number of points with 9 dB SNR or higher quadrupled when increasing stimulus levels from 65, 55 dB to 75, 75 dB SPL (from 6.5% to 30% of the measurements for the NHNN group, and from 3.5% to 15% for the NIHL group). [Table 1] provides the P values when the NHNN and NIHL results are compared using the Kruskal-Wallis test. The percentage of points at each SNR threshold was significantly lower ($P < 0.05$) for the NIHL group for all comparisons, except for values >3 dB at 65,55 for the 2f 2 -f 1 emission. The most significant differences were seen for the percentage of points >9 dB

at L1,L2 = 75,75 for the 2f 2 -f 1 emission.

The box and whisker plots [Figure 6] illustrate the variability within the NHNN and NIHL groups. Although the medians for the NHNN and NIHL groups were significantly different at each cut-off level (>3 dB, >6 dB, or >9 dB), the interquartile range overlapped at all SNR cut off levels.

Statistical comparison of averaged DPOAE level maps

To reduce noise within the averaged DPOAE level maps, the data points were spatially averaged using a 3 ×3 median filter and then a one-way ANOVA was applied to each DPOAE level in the map. The results are plotted in [Figure 7].{Figure 7}

For the 2f 1 -f 2 DPOAE elicited with a moderate level primaries (65,55 dB SPL), the area of differentiation occurred at ratios between 1.125 and 1.275 at DP frequencies ranging between 1 kHz and 5 kHz, with the largest differences occurring between 2.5 kHz and 4.5 kHz. This correlates to an f 2 frequency range of about 3-6.8 kHz at a 1.2 ratio. For the 75,75 dB SPL protocol, a larger region of significance was evident. In addition, one small area of difference between the two groups appeared at the higher frequencies, where DP values are greater than 5 kHz and at ratios between 1.25 and 1.3 (corresponding to f 2 values of 8-9.5 kHz at these ratios).

For the 2f 2 -f 1 DPOAE there was minimal evidence of significant differences at the 65,55 dB SPL primary tone levels; however, at the L1,L2 = 75,75 dB SPL stimulus level there were lobes of responses that differed significantly between the two experimental groups. Areas of particular significance occur at DP frequencies ranging between 4 kHz and 5 kHz at small ratios as well as above 5.5 kHz at ratios ranging between 1.025 and 1.35.

Technical development

As part of this study, the technology was further developed to minimize the time required for each individual map. A new DPOAE mapping system using a dedicated digital signal processor and CODEC (analog-to-digital and digital-to-analog encoder/decoder) to generate and process each measurement was designed and built. The updated system also records both the lower side-band, 2f 1 -f 2 , and upper side-band, 2f 2 -f 1 , emissions simultaneously. This resulted in a time reduction of almost 50% as a single stimulus captures two points in equal level maps. This improved system developed by Creare Inc., (Hanover, NH) can compute a map at a rate of 0.24 s/stimulus, which is 140% of the theoretical limit. This is a marked improvement over the ~0.48 s/stimulus in the system used at the Jerry Pettis Memorial Veterans Medical Center (JPMVMC) for previously published maps, and the 0.3 s/stimulus for the system used to generate the maps in the present study.

This reduction brings the time to complete a map from approximately 25 min with the research prototype used for the present study, to approximately 12 min for an equal level stimulus (e.g., L1,L2 = 75,75 dB SPL) and 16 min for an unequal stimulus (e.g., L1,L2 = 65,55 dB SPL). (Unequal stimulus maps require additional time because the 2f 2 -f 1 emissions are measured with L1,L2 = 55,65 dB SPL and therefore cannot be measured at the same time as the 2f 1 -f 2.)

Discussion

DPOAE level mapping offers potential for detecting and tracking NIHL, but the appropriate parameters to use and the areas of the DPOAE level map that change the most with noise exposure have yet to be defined. In this study, we performed DPOAE level maps on 17 individuals without a history of noise exposure and compared those results to maps from 19 individuals with mild-moderate NIHL. The results show that: (a) both DPOAE levels, and the range of ratios where DPOAEs are detected, are reduced in the NIHL group for both the 2f 1 -f 2 and 2f 2 -f 1 emissions, (b) higher level primaries (L1,L2 = 75,75 dB SPL) increase the number of measureable emissions with an SNR of 3, 6 or 9 dB or greater in both groups, (c) the DPOAE ratios and frequencies that elicited the largest DPOAE SNRs were also generally the same ones that were significantly different between the NHNN and NIHL groups, (d) the 2f 1 -f 2 emission is reduced significantly for both L1,L2 = 65,55 dB SPL and 75,75 dB SPL primary levels for the NIHL group, (e) the 2f 2 -f 1 emission is reduced significantly in NIHL,

but the changes are evident only when using L1,L2 = 75,75 primary tone levels, (f) the optimal ratio for the 2f 2 -f 1 emission at L1,L2 = 65,55 dB SPL is smaller than has been described previously and (g) displaying DPOAE level map data plotted as a function of SNR, rather than as DPOAE level, improves map interpretation at lower DPOAE frequencies (<2000 Hz).

Overall DPOAE level mapping results

As expected, DPOAE levels were significantly reduced in the NIHL group for both experimental protocols. The overall DPOAE levels, as well as the range of f 2 /f 1 ratios where emissions were detectable, were reduced. This effect was likely due predominately to the history of noise exposure in the NIHL group. Although the NIHL group was statistically significantly older than the NHNN group; the mean age differed by only 7 years. Currently, there is no definitive support for the premise that age alone significantly affects DPOAEs amplitude. [8] There are no age-corrections applied to the clinical interpretation off DPOAE magnitude measurements. Although the reduction in DPOAE levels in subjects with NIHL is not surprising, these data suggest that there may be potential benefit in examining more than just the optimal DPOAE level at a single ratio when monitoring individuals for changes over time. Low-level 2f 1 -f 2 emissions and the 2f 2 -f 1 emission may disappear early on due to noise exposure. This hypothesis needs to be more fully explored in a longitudinal study.

One benefit of the DPOAE level map is that it presents a large amount of DPOAE data in a color pattern, so that the map image provides a visual snapshot of cochlear function between the DP frequencies of 0.5 kHz and 6.0 kHz across a wide range of stimulus ratios. This form of data presentation allows for more detailed data collection and analyses than standard DP-Grams, and also allows for a quick visual comparison of maps from a given individual. The results from this study show that the DPOAE SNR map, shown in combination with a DPOAE level map, improves the interpretation of the measurements, revealing areas where higher noise levels dominate the response.

Effect of primary tone level

Stover et al. [9] suggested that moderate-level primaries in the 50-60 dB SPL range are optimal for distinguishing normal-hearing versus mild to moderately hearing impaired ears when comparing to conventional pure-tone audiometry. The data from this study show that higher primary tones produce higher amplitude emissions in both the noise-exposed and non-noise exposed group. Since DPOAE level mapping takes time, testing at multiple primary tone levels may be feasible for a research application, but impractical for field use in hearing conservation programs. Helleman et al. [10] also suggested that higher level primary tones may be advantageous in terms of minimizing the effect of background noise when DPOAE monitoring was implemented as part of an occupational hearing conservation program. The data from this study show that higher level primaries provide higher SNRs in both the NHNN and NIHL groups, and are especially important for the measurement of DPOAEs in a mild-moderately NIHL impaired ear. Therefore, the higher-level primaries may be more useful for DPOAE level mapping studies in these populations. Although, since lower-level primaries are generally believed to be more sensitive to cochlear damage compared to higher level primaries, lower-level primaries may still be useful in individuals with normal DPOAE levels at baseline.

2f 2 -f 1 emissions

DPOAE level maps provide data on both 2f 1 -f 2 and 2f 2 -f 1 emissions; however, it is not clearly established if measuring the 2f 2 -f 1 emission adds value in detecting NIHL. Results from this study show significant changes in the 2f 2 -f 1 region when comparing the NHNN to the NIHL group. This difference was only apparent at the higher primary tone levels. These data suggest that when using the mapping for longitudinal tracking, the 2f 2 -f 1 emission area may be useful in detecting early cochlear changes due to hazardous noise exposure. This finding also provides further evidence that "coherent linear reflection" emission sources are useful in the detection of NIHL. [3],[4]

The data also revealed that the optimal 2f 2 -f 1 emission occurred at an f 2 /f 1 ratio of 1.025 at L1,L2 = 65,55 dB SPL, which is a smaller ratio value than has been seen in other studies. This may be because none of the

cited works other than Fitzgerald and Prieve, [11] tested at such a low ratio and their results yielded the lowest ratio at which they did test. Although Fitzgerald and Prieve tested ratios as low as 1.025, they selected a single ratio that maximized the emission over a range of primary level combinations, and not specifically L1,L2 = 65,55. In addition, previous studies used DPOAE level to determine the optimal ratio, [11],[12],[13],[14] whereas the present study relies on both DPOAE levels and SNR to determine the optimal ratio in part because of the very short averaging time used in the protocol.

Technical factors for DPOAE level mapping

One factor limiting the use of DPOAE level maps as a clinical tool is the amount of time each map takes. As part of this study, the technology was developed to minimize the time required for each individual map. Testing time can be shortened further by using data from this study to reduce the number of points in each map. The data obtained in this study established the outlines of a smaller-sized map containing the most useful information [Figure 7]. Another approach to reducing test time is to use a flexible map protocol that allows for longer averaging times at some frequencies and ratios, and shorter times at frequencies not contaminated by noise. This could lead to an adaptive clinical DPOAE mapping protocol wherein frequencies, ratios and averaging time are optimized to maximize the response of the ear while maintaining a reasonable clinical testing time of about 5-10 min. Further, research and development will be required to design an efficient and clinically relevant DPOAE mapping protocol.

Analytical considerations

Using a point-by-point ANOVA after median filtering has limitations when applied to these data (e.g., multiple comparisons). As mentioned previously, this approach was undertaken in order to determine the areas with the highest likelihood of illustrating differences in DPOAE levels between the NHNN and NIHL groups as the mapping technology and protocol are being developed. This serves a different purpose than quantifying exact differences between groups. It is also recognized that DPOAE level maps are highly individualized, and consequently group comparisons are further confounded. As the mapping technology is advanced, more sophisticated statistical analysis can be undertaken to longitudinally monitor for individual changes in DPOAE level maps over time using fewer data points.

Conclusions

DPOAE level mapping provides a comprehensive overview of the changes in DPOAE magnitude for both the 2f 1 -f 2 and the 2f 2 -f 1 emissions in NIHL. DPOAE level mapping using higher level, equi-level primaries (75,75) provides more measureable DPOAEs in both the NHNN and NIHL groups than the lower level, unequal-level primaries (65,55). On average, the changes in DPOAE level maps in the NIHL group are concentrated in particular map areas and this knowledge could be used to design more efficient mapping protocols. Using SNR to display map results provides additional information for an improved interpretation of the mapping data, particularly at lower DPOAE frequencies in humans. Advances in the technology for acquiring DPOAE level maps have been made, which allow DPOAE level maps to be collected in clinically-acceptable times (5-10 min). DPOAE level mapping may offer a novel approach for differentiating and monitoring changes in cochlear function due to hazardous noise exposures.

Acknowledgments

We thank Dr. Brenda Lonsbury-Martin, Dr. Glen Martin and Barden Stagner for their support and assistance in developing and validating the instrumentation and software used in this research. We appreciate the work of Abigail Fellows, Ashley Huerta, Amber Powner, Kathy Pritzl and numerous personnel at Creare Inc. who supported the project.[15]

Teacher's good vibrations

Author: Foley, Peter.

Publication info: The Queensland Times [Ipswich, Qld] 27 Aug 2013: 10.
ProQuest document link

Abstract: The Baha sound processor is attached to the skull and converts sound waves to vibrations in the cochlear that are read by the brain.

Links: Check LinkSource for Full Text

Full text: CHRISTINE New jokes that there are times she wishes she could switch it off but she seriously couldn't live without her Baha.

Mrs New has a Baha (Bone Anchored Hearing Aid) and it has helped her to keep teaching.

The Amberley District State School prep teacher has been an early childhood teacher for 34 years.

The Baha sound processor is attached to the skull and converts sound waves to vibrations in the cochlear that are read by the brain. Mrs New has had hearing aids for about 20 years after losing her hearing through infection and has a Baha on her right side.

"I got my first hearing aid in my early 30s and then went to two hearing aids and then I went to the Baha and I still wear a behind the ear hearing aid on the other side," she said. "The reason I needed it is that because of infection I could no longer wear a hearing aid.

"This is a little bit different to the cochlear implant because the cochlear is still working but at the start, it's like you're listening inside a bubble, but it's quite subtle and it's a better sound in your head."

Having the Baha helps her keep working where noises - especially voices - fly thick and fast.

"It helps in the classroom," she said. "I can work out which child's talking to me and what they're saying."

But after teaching preschool, prep and grades one, two and three, are there times she'd like to turn off her hearing aids?

"Yes," she said with a laugh. "And sometimes when you go home. You shouldn't do it because you don't take your ears off when you go home - but sometimes you feel like doing it.

"But it's best if you wear your hearing aids all the time during the day so you learn to filter out the sounds you don't want to hear; that's what the natural ear does."

She has been upfront about the Baha with her students who were keen to know all about it.

"A couple of them asked me whether I was a robot," she said. "They've made robots and put a Baha on the back of its head."

Hearing Awareness Week

Held this week, it aims to raise community awareness of hearing impairment and ways to protect your hearing. It gives the 22% of Australians 15 and over who have a hearing impairment a chance to share their experience and help to create a greater understanding of their needs.

Full text: 2013 AUG 14 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- Widex A/s has been issued patent application serial number 845721, according to news reporting originating out of Washington, D.C., by VerticalNews editors.

The patent's inventors are ANDERSEN, Henning Haugaard (Birkerod, DK); KNUDSEN, Niels Ole (Humlebak,

DK).
This patent application was filed on March 18, 2013 and was made available online on August 1, 2013.
From the background information supplied by the inventors, news correspondents obtained the following quote:
"This application relates to hearing aids. More specifically, it relates to hearing aids comprising digital output stages for driving acoustic output transducers. The invention further relates to a method for driving a digital output stage of a hearing aid.
"In this context, a hearing aid is defined as a small, battery-powered device, comprising a microphone, an audio processor and an acoustic output transducer, configured to be worn in or behind the ear by a hearing-impaired person. By fitting the hearing aid according to a prescription calculated from a measurement of a hearing loss of the user, the hearing aid may amplify certain frequency bands in order to compensate the hearing loss in those frequency bands. In order to provide an accurate and flexible amplification, most modern hearing aids are of the digital variety.
"Contemporary digital hearing aids incorporate a digital signal processor for processing audio signals from the microphone into electrical signals suitable for driving the acoustic output transducer according to the prescription. In order to save space and improve efficiency, some digital hearing aid processors use a digital output signal to drive the acoustic output transducer directly without performing a digital-to-analog conversion of the output signal. If the digital signal is delivered to the acoustic output transducer directly as a digital bit stream with a sufficiently high frequency, the coil of the acoustic output transducer performs the duty as a low-pass filter, allowing only frequencies below e.g. 15-20 kHz to be reproduced by the acoustic output transducer. The digital output signal is preferably a pulse width modulated signal, a sigma-delta modulated signal, or a combination thereof.
"An H-bridge is an electronic circuit for controlling inductive loads such as electric motors or loudspeakers. It operates by controlling the direction of a flow of current through a load connected between the output terminals of the H-bridge by opening and closing a set of electronic switches present in the H-bridge. The switches may preferably be embodied as semiconductor switching elements such as BJT transistors or MOSFET transistors. This operating principle permits a direct digital drive output stage to be employed in order to enable a suitably conditioned digital signal to drive a loudspeaker directly, thus eliminating the need for a dedicated digital-to-analog converter and at the same time reducing the power requirements for the output stage.
"A sigma-delta modulator is an electronic circuit for converting a signal into a bit stream. The signal to be converted may be digital or analog, and the sigma-delta modulator is typically used in applications where a signal of a high resolution is to be converted into a signal of a lower resolution. In this context, a sigma-delta modulator is used for driving the H-bridge output stage in the hearing aid.
"The diaphragm of a loudspeaker has a resting or neutral position assumed whenever no current flows through the loudspeaker coil and two extreme positions assumed whenever the maximal allowable current flows in either direction through the loudspeaker. By applying a sufficiently fast-changing bit stream from an H-bridge represented by positive and negative voltage impulses to the loudspeaker terminals, any position between the two extreme diaphragm positions of the loudspeaker may be attained. The higher the number of positive impulses in the bit stream is, the more the loudspeaker diaphragm will move towards the first extreme position, and the higher the number of negative impulses in the bit stream is, the more the loudspeaker diaphragm will move towards the second extreme position. Due to the low-pass filtering effect of the loudspeaker coil, no audible switching noise will emanate from the loudspeaker when driven in this way, provided the switching period of the bit stream is well above the reproduction frequency limit of the loudspeaker. Thus, a digital bit stream may control a loudspeaker directly.
"From EP-B1-1716723 is known a digital output stage for a hearing aid, said output stage comprising a sigma-delta converter and an H-bridge for driving an acoustic output transducer for a hearing aid. The output stage is denoted a three-state output stage because it is capable of delivering a bit stream consisting of three individual

signal levels to the acoustic output transducer. In the following, these levels are denoted '+1', '-1' and '0', where '+1' equals the maximum positive voltage across the acoustic output transducer, '-1' equals the maximum negative voltage across the acoustic output transducer, and '0' equals no voltage. This utilizes the fact that a positive voltage pulse makes the diaphragm of the acoustic output transducer move in one direction, and a negative voltage pulse makes the diaphragm of the acoustic output transducer move in the other direction. By delivering a clocked bit stream consisting of '+1'-levels and '-1'-levels interspersed with '0'-levels as voltage pulses to the acoustic output transducer, any position deviation within the confinements of the mechanical suspension of the acoustic output transducer diaphragm may thus be obtained, as the loudspeaker coil acts as an integrator of the voltage pulses. The digital output stage of the prior art generates the '0'-level by applying a '+1'-level and a '-1'-level simultaneously to both terminals of the acoustic output transducer.

"This way of generating the '0'-level for the acoustic output transducer has the advantages of being very easy to implement, as no extra components are needed to provide the '0'-level, and to save power, as the '0'-level uses no extra current and the provision of three separate levels effectively doubles the possible voltage swing across the acoustic output transducer. However, it also has some inherent drawbacks, which will be explained in greater detail in the following.

"The '+1'-levels and '-1'-levels both generate differential voltages over the wires and terminals of the acoustic output transducer. This is not the case with the '0'-level. With the '0'-level, both wires carry the same voltage simultaneously, and since this is a rapidly switching voltage it radiates more common mode signal to its immediate surroundings. This radiation results in increased crosstalk to nearby surroundings, such as telecoils or wireless transmission receiver coils typically present in the hearing aid. Since this crosstalk has frequencies above 1 MHz, it does not possess a problem to the telecoil, since a telecoil is configured to convey frequencies below 8-10 kHz. The wireless receiver coil, however, suffers a very considerable reduction in signal-to-noise ratio from the capacitive interference resulting from this crosstalk phenomenon, often to a degree where reliable signal reception becomes impossible.

"This capacitive interference emanates mainly from electrically exposed parts of the output circuit, primarily the wires connecting the output pads of the electronic circuit chip of the hearing aid to the input terminals of the acoustic output transducer. It is not possible to shorten these wires further for mechanical reasons, but some reduction in the capacitive coupling between these wires and sensitive electronic circuits in the vicinity may be achieved by twisting the wires and keeping them physically close together.

"The voltage pulses are presented to the output transducer at a frequency of 1-2 MHz, and the resulting noise components may thus disturb the operation of electronic circuits sensitive to capacitive interference at high frequencies. In cases where the afflicted electronic equipment incorporates a wireless remote control for the hearing aid the problems caused by electromagnetic interference are exceptionally severe, as the effective operating range of the wireless remote control is limited considerably by the capacitive interference emanating from the output stage and masking the remote control signals from proper reception.

"WO-A1-03/047309 discloses a digital output driver circuit for driving a loudspeaker for a mobile device such as a hearing aid or a mobile phone. The digital driver circuit comprises an input, a modulator and a three-level H-bridge and is integrated into the loudspeaker enclosure in order to shield the driver circuit from electromagnetic interference and to keep the wires connecting the driver output to the loudspeaker short. The driver circuit further comprises a feedback circuit connected to the loudspeaker for regulating the supply voltage for the driver circuit.

"An output driver integrated into a loudspeaker in the way described in WO-A1-03/047309 is not interchangeable with dynamic standard loudspeakers of the kind used in hearing aids. If, for example, a hearing aid housing and circuitry may be adapted for use with a range of different loudspeakers having different impedance values, e.g. for treating different degrees of hearing loss, a loudspeaker having an integrated output driver would not be well suited for this configuration. In cases where this type of flexibility is desired, long wires

between the output stage terminals of the hearing aid circuit and the terminals of the loudspeaker of the hearing aid are unavoidable. An extra set of long wires for the signal from the loudspeaker to the feedback circuit would also be required by the prior art output driver, which would further increase capacitive interference noise."
Supplementing the background information on this patent application, VerticalNews reporters also obtained the inventors' summary information for this patent application: "The invention, in a first aspect, provides a hearing aid comprising an input transducer, an analog-to-digital converter, a digital signal processor, a three-level output modulator connected to a three-level output driver, a first voltage source, a second voltage source, a common voltage node and an acoustic output transducer, wherein the output driver comprises an H-bridge output stage configured to control the connection of a first and a second terminal of the acoustic output transducer, the H-bridge being configured to connect the first voltage source to the first terminal of the acoustic output transducer and the common voltage node to the second terminal of the acoustic output transducer when the output modulator generates a first level, to connect the second voltage source to both the first and the second terminal of the acoustic output transducer when the output modulator generates a second level, and to connect the first voltage source to the second terminal of the acoustic output transducer and the common voltage node to the first terminal of the acoustic output transducer when the output modulator generates a third level.
"It is a feature of the present invention to devise an output stage for a hearing aid having an output converter capable of providing the benefits of a three-stage output converter without having the capacitive noise and interference problems associated with output converters of the prior art, regardless of having long wires connecting the output stage to the loudspeaker of the hearing aid.
"The invention, in a second aspect, provides a method of driving an output stage of a hearing aid, said method comprising providing a single-bit digital signal representing an audio signal to be reproduced by the hearing aid, providing a first voltage source for generating a first voltage, providing a second voltage source for generating a second voltage, providing an acoustic output transducer, converting the single-bit digital signal into a three-level control signal comprising a positive level, a negative level, and a zero level, connecting the first voltage source to a first terminal of the acoustic output transducer, and connecting a second terminal of the acoustic output transducer to ground, whenever the control signal produces a negative level, connecting the first voltage source to the second terminal of the acoustic output transducer, and connecting the first terminal of the acoustic output transducer to ground, whenever the control signal produces a positive level, and connecting the second voltage source to both the first terminal and the second terminal of the acoustic output transducer whenever the control signal produces a zero level. BRIEF DESCRIPTION OF THE DRAWINGS
"The invention will now be described in further detail with respect to the drawings, where
"FIG. 1 is a schematic of an output stage for a hearing aid according to the prior art,
"FIG. 2 is a schematic of an output stage for a hearing aid according to an embodiment of the invention,
"FIG. 3 is a schematic illustrating a first condition in the output stage of FIG. 2,
"FIG. 4 is a schematic illustrating a second condition in the output stage of FIG. 2,
"FIG. 5 is a schematic illustrating a third condition in the output stage of FIG. 2,
"FIG. 6 is a graph illustrating a typical input signal to the output stage of FIG. 2, and
"FIG. 7 is a schematic of a hearing aid with an output stage according to an embodiment of the invention."

Widex A/S; Patent Issued for FSK Receiver for a Hearing Aid and a Method for Processing an FSK Signal

Publication info: Telecommunications Weekly (Aug 14, 2013): 1030.
ProQuest document link

Abstract: [...]a receiver is usually embodied as a tiny coil configured to pick up electromagnetic base band (i.e. unmodulated) audio frequency signals from a telecoil transmitter surrounding the hearing aid comprising the receiver. [...]external equipment enables communication with the hearing aid in various ways. [...]e.g. a cable connection may be provided for the purpose of programming the hearing aid, an FM-receiver may be connected for use in public address situations where a speaker is wearing a microphone with a wireless FM transmitter, and a Bluetooth.RTM. receiver may be used for streaming audio signals from a mobile telephone or the like.

Full text: 2013 AUG 14 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- A patent by the inventors Andersen, Henning Haugaard (Birkerod, DK); Kilsgaard, Soren (Smorum, DK), filed on May 11, 2010, was published online on July 30, 2013, according to news reporting originating from Alexandria, Virginia, by VerticalNews correspondents.

Patent number 8498434 is assigned to Widex A/S (Lynge, DK).

The following quote was obtained by the news editors from the background information supplied by the inventors: "This application relates to hearing aids. More specifically, it relates to hearing aids comprising wireless receivers. Still more specifically the invention relates to hearing aids comprising frequency-shift-keying (FSK) receivers.

"A common signal source in a hearing aid is one or more microphones picking up acoustic sound signals occurring in the vicinity of the hearing aid. Another common signal source in hearing aids is a telecoil receiver. Such a receiver is usually embodied as a tiny coil configured to pick up electromagnetic base band (i.e. unmodulated) audio frequency signals from a telecoil transmitter surrounding the hearing aid comprising the receiver.

"State-of-the-art hearing aids are usually designed to accept more than one signal source for advanced functionalities for the purpose of amplifying, conditioning and reproducing them by virtue of the hearing aid circuitry.

"Some behind-the-ear (BTE) hearing aids have means for connecting external equipment to the hearing aid circuitry, such as FM-receivers, Bluetooth.RTM. receivers, cables etc. Such external equipment enables communication with the hearing aid in various ways. Thus e.g. a cable connection may be provided for the purpose of programming the hearing aid, an FM-receiver may be connected for use in public address situations where a speaker is wearing a microphone with a wireless FM transmitter, and a Bluetooth.RTM. receiver may be used for streaming audio signals from a mobile telephone or the like.

"Some newer hearing aid types also comprise internal wireless receivers. Most of these wireless receiver types draw their power directly from the hearing aid battery. Prolonged use of wireless receivers known in the art may lead to rapid depletion of the hearing aid battery necessitating frequent battery changes and adding to the cost of operation of the hearing aid. Receiver types having integral power supplies comprising a separate battery add to the weight, size and complexity of the receiver. A more power-efficient wireless receiver would thus be of great benefit to hearing aid users.

"Power-efficiency may, e.g., be enhanced by reducing the total power consumption of the receiver circuitry. However, this should be performed without impairing the noise performance of the receiver, which would lead to reduced signal quality. Provided that signals to be transmitted are in a digital format, an FSK transmitter-receiver configuration, well-known to persons skilled in the art, is generally preferred.

"FSK signals may be demodulated in several different ways, each having different advantages, topologies and complexity. The demodulators can be subdivided into several categories: FM to AM demodulator types (e.g. Slope, Foster-Seeley and Ratio), PLL demodulators, Zero-crossing demodulators and Quadrature demodulators.

"One quadrature demodulator type well known in the art comprises a local oscillator and two signal branches denoted the in-phase branch and the quadrature branch, respectively, the received signal being splitted into an in-phase (I) component and a quadrature (Q) component. In the (binary) quadrature signal, one component is assigned binary zero, and the other component is assigned binary one. As the two signal components I and Q are mutually exclusive, a digital bitstream consisting of ones and zeroes is generated whenever the transmitter is active. Both branches are connected to a CPU, which completes the demodulation process. Generally, each branch comprises a multiplier, a filter and a decision device. The multiplier in the in-phase branch is connected directly to the local oscillator, whereas the multiplier in the quadrature branch is connected to a 90.degree. phase-shifted version of the local oscillator. The information in the frequency-shift-keyed signal is then decoded and utilized according to its intended purpose.

"Such an FSK demodulator is, for instance, described in U.S. Pat. No. 4,987,374, in the name of Burke. This demodulator comprises a local oscillator feeding a first and a second branch, each branch comprising a mixer and a detection stage. The mixer in the first branch mixes the incoming signal with the direct signal from the local oscillator, and the mixer in the second branch mixes the incoming signal with a 90.degree. phase-shifted version of the signal from the local oscillator.

"FSK receivers according to the prior art work satisfactorily in a multitude of applications. However, if the available power is only small, as is the case in hearing aids, the effective transmission range is very short, and reception errors, e.g. due to noise present in the signal, may severely corrupt the quality of the received signal.

"More confident means of detecting the signals for the purpose of improving the noise-immunity of an FSK receiver without a significant increase in power consumption is thus desired."

In addition to the background information obtained for this patent, VerticalNews journalists also obtained the inventors' summary information for this patent: "The invention, in a first aspect, provides a wireless FSK receiver for use in a hearing aid, said receiver comprising a first amplifier stage, a limiter stage, a plurality of phase detection stages, the number of phase detection stages being greater than two, and a lookup table, said first amplifier stage being connected to the input of said a limiter stage, the output of said limiter stage being split up into a first plurality of respective inputs said plurality of phase detection stages, each phase detection stage comprising a local oscillator, a mixer stage, a filter stage, and a comparator stage, respectively, the input of each phase detection stage forming a first input of the respective mixer stage, each of the respective local oscillators being connected to a second input of the respective mixer stage, the output of each mixer stage being connected to an input of the respective filter stage, the output of each of the filter stages being connected to an input of the respective comparator stage, the output of each of the comparator stages being connected to an input of said look-up table, the output of said lookup table forming an Arc tan 2-value from a set of arguments produced by said plurality of phase detection stages, wherein the frequency of each of the local oscillators is tuned to the carrier frequency of an FSK signal and wherein the phase angles of the local oscillators of the phase detection stages are mutually staggered by 180.degree./n, where n is the number of local oscillators.

"By increasing the number of demodulator branches from two to three, four, five, or more branches, the total bit-resolution, i.e. the number of discrete symbols sent per data bit, of the FSK receiver according to the invention is comparatively increased. Utilizing state of the art microelectronic technology, the increased power

consumption resulting from the addition of more demodulator branches has been found to be acceptable in spite of the added complexity of the receiver. A more effective, yet power-efficient approach to FSK receiver design is thus achieved. Wireless FSK receivers comprising from five to ten demodulator branches are considered to provide the most optimum balance between noise-immunity, circuit complexity, and total receiver power consumption.

"The invention, in a second aspect, provides a wireless FSK receiver and a method for processing a wireless FSK signal for providing a signal for a hearing aid, including the steps of receiving said FSK signal, amplifying said FSK signal, limiting the amplified FSK signal, splitting the amplified, limited FSK signal into a plurality of signal branches, the number of branches being greater than the number of distinctly detectable phase angles to be received, detecting the phase of the FSK signal in each branch of the plurality of signal branches, calculating a logical signal vector based on the detected phase of the FSK signal in each of the plurality of signal branches, summing the signal vectors of the plurality of signal branches, deriving information from the FSK signal based on the result of the summation, and presenting the derived information to the hearing aid, wherein the step of detecting the phase of the FSK signal in each branch of the plurality of signal branches includes the steps of creating a mixed signal by mixing the FSK signal with the signal from a local oscillator, band-limiting the mixed signal using a low-pass filter, comparing the mixed, band-limited signal to a fixed, predetermined level, and generating a logical value based on the comparison.

"The invention, in a third aspect, provides a hearing aid comprising a wireless frequency-shift-keying (FSK) receiver, said receiver comprising an antenna, a first amplifier stage, a limiter stage, a plurality of parallel phase detection stages and a lookup table block, wherein each phase detection stage comprises a local oscillator, a mixer stage, a filter stage, and a comparator stage, respectively, the outputs of each of the respective comparator stages being connected to the input of the look-up table block, characterized in that the number of phase detection stages is greater than two.

"Further features and advantages appear from the dependent claims."

Listening Effort With Cochlear Implant Simulations

Author: Pals, Carina; Sarampalis, Anastasios; Baskent, Deniz.

Publication info: Journal of Speech, Language and Hearing Research (Online) 56.4 (Aug 2013): 1075-1084.
ProQuest document link

Abstract: Fitting a cochlear implant (CI) for optimal speech perception does not necessarily optimize listening effort. This study aimed to show that listening effort may change between CI processing conditions for which speech intelligibility remains constant. Nineteen normal-hearing participants listened to CI simulations with varying numbers of spectral channels. A dual-task paradigm combining an intelligibility task with either a linguistic or nonlinguistic visual response-time (RT) task measured intelligibility and listening effort. The simultaneously performed tasks compete for limited cognitive resources; changes in effort associated with the

intelligibility task are reflected in changes in RT on the visual task. A separate self-report scale provided a subjective measure of listening effort. All measures showed significant improvements with increasing spectral resolution up to 6 channels. However, only the RT measure of listening effort continued improving up to 8 channels. The effects were stronger for RTs recorded during listening than for RTs recorded between listening. The results suggest that listening effort decreases with increased spectral resolution. Moreover, these improvements are best reflected in objective measures of listening effort, such as RTs on a secondary task, rather than intelligibility scores or subjective effort measures.

Full text: Headnote

Purpose: Fitting a cochlear implant (CI) for optimal speech perception does not necessarily optimize listening effort. This study aimed to show that listening effort may change between CI processing conditions for which speech intelligibility remains constant.
Method: Nineteen normal-hearing participants listened to CI simulations with varying numbers of spectral channels. A dual-task paradigm combining an intelligibility task with either a linguistic or nonlinguistic visual response-time (RT) task measured intelligibility and listening effort. The simultaneously performed tasks compete for limited cognitive resources; changes in effort associated with the intelligibility task are reflected in changes in RT on the visual task. A separate self-report scale provided a subjective measure of listening effort.
Results: All measures showed significant improvements with increasing spectral resolution up to 6 channels. However, only the RT measure of listening effort continued improving up to 8 channels. The effects were stronger for RTs recorded during listening than for RTs recorded between listening.
Conclusion: The results suggest that listening effort decreases with increased spectral resolution. Moreover, these improvements are best reflected in objective measures of listening effort, such as RTs on a secondary task, rather than intelligibility scores or subjective effort measures.

Key Words: cochlear implants, listening effort, dual task, reaction time, computer simulation, hearing, speech perception

Cochlear implants (CIs) are implantable auditory prostheses that partially restore hearing to people with profound hearing impairment. To accomplish this, a sound processor translates the incoming acoustic signal to electrical pulse trains, which are transmitted to the auditory nerve by an electrode array inserted in the cochlea. From the early days of CI research, the primary focus has been on improving the ability to understand speech (e.g., Fishman, Shannon, &Slattery, 1997; Fu, 2002; Manrique et al., 1999; Pfingst, Zwolan, &Holloway, 1997; Skinner et al., 1994; Wilson et al., 1991). In this context, CI benefit has typically been measured using speech intelligibility tests. Research on hearing impairment, however, has shown that cognitive measures (e.g., the response times on a verbal sentence verification test [Baer, Moore, &Gatehouse, 1993], the dual-task paradigm [e.g., Anderson Gosselin &Gagné, 2011; Sarampalis, Kalluri, Edwards, &Hafter, 2009], and pupillometry [Zekveld, Kramer, &Festen, 2010]) can provide an additional layer of information to complement intelligibility measures. The additional performance information these measures provide has been linked to ease of listening (e.g., Baer et al., 1993), or listening effort (e.g., Anderson Gosselin &Gagné, 2011), which was the focus of the present study.

Research on effort in general is based on the historical work of Broadbent (1958), Baddeley and Hitch (1974), and Kahneman (1973), each of whom proposed a shared, limited cognitive resource, later commonly referred to as working memory, that can be allocated to various tasks, as necessary. A more recent version of Baddeley's theory proposes a phonological loop for storing and manipulating incoming auditory information, a visuospatial sketchpad for visual information, an episodic buffer that stores and retrieves information from long-term memory, and a central executive that coordinates the execution of complex tasks (Baddeley, 2012). An effortful task requires a large proportion of the resources relevant to the task or a considerable involvement of the

central executive, or both. Listening effort can then be defined as the proportion of limited cognitive resources engaged in interpreting the incoming auditory signal. It has been suggested that the presence of noise or distortions in a speech signal increases cognitive demand and thus listening effort (Schneider &Pichora-Fuller, 2000; Stenfelt &Rönnberg, 2009). Spectral degradation of a speech signal, such as in CI processing or CI simulations, has been shown to tax top-down cognitive processes involved in speech perception (Baskent, 2010, 2012). Thus, we argue that, especially when the fitting of a CI is less than optimal, interpreting the impoverished signal requires substantial cognitive resources, making listening for CI users effortful.

If minimizing listening effort is to be taken into consideration when fitting CIs, it is essential to have a measure that reliably reflects listening effort. Traditionally, the fit of CIs and the benefit of new processing strategies have been determined using speech intelligibility measures. Baer et al. (1993) have shown, however, that a benefit of processing strategy measured in response times on a verbal task, which they linked to ease of listening, was more pronounced than the benefit expressed in improved intelligibility. This suggests that other measures may be more suitable for reflecting benefits in listening effort. Supporting this idea, Rabbitt (1968, 1991) has shown that a degraded bottom-up auditory signal, while not affecting the ability to repeat each word of a list at the moment it is heard, can have a significant effect on later recall of the words. This performance on the memory task is a measure of working memory load, which can be interpreted to reflect listening effort. Sarampalis et al. (2009) have shown, in normal-hearing participants, that hearing-aid-like noise reduction strategies can result in an improvement in performance on a secondary task, even when no improvement in speech intelligibility is seen. This finding implies that a hearing device feature, such as noise reduction, though it may be deemed not beneficial when assessed only with an intelligibility test, may in fact be beneficial due to a reduction in listening effort. Other studies in hearing aid research also suggest that signal-processing benefits may sometimes be better reflected by tests of listening effort (Lunner, Rudner, &Rönnberg, 2009; Rudner, Foo, Rönnberg, &Lunner, 2009; Sarampalis et al., 2009).

The hypothesis of the current study was that listening effort may change independently from speech intelligibility for different processing settings of the CI, and therefore an advantage in effort may not be accurately reflected by speech intelligibility measures. This hypothesis was tested using speech stimuli, which were generated using a noise-band vocoder to simulate CI processing. The use of simulations allowed intelligibility to be systematically manipulated by changing the spectral resolution (i.e., number of processing channels). Normal-hearing participants listened to the CI-simulated sentences and repeated what they heard, thus providing speech intelligibility data for each level of processing. The variations in listening effort resulting from the different processing conditions were assessed using a dual-task paradigm chosen based on Sarampalis et al. (2009). In a dual-task paradigm, a primary and a secondary task are performed simultaneously. If the tasks are similar, they compete for resources, and an increase in effort associated with the primary task will thus be reflected in decreased performance on the secondary task (Broadbent, 1958; Rabbitt, 1966). For more complex cognitive tasks, dual-task interference is less straightforward. However, simple psychometric tasks, such as an image-judgment task, appear to show most interference when performed simultaneously with such complex tasks (Hegarty, Shah, &Miyake, 2000).

In the current study, the primary task was a speech intelligibility task using the CI-simulated stimuli. The measure chosen to reflect listening effort was the response times (RTs) on a visual secondary task. This choice was based on the argument that one of the central cognitive resources relevant to speech understanding is speed of processing (Kramer, Zekveld, &Houtgast, 2009), and thus a secondary task using this resource will reflect effort associated with the primary speech intelligibility task. The secondary task of choice would need to be affected by effort associated with the speech task, while not affecting performance on the speech task itself. For this reason, we used two different secondary tasks in this experiment, which we expected to show different degrees of interference with the speech task: a rhyme-judgment task (e.g., Baddeley &Salamé, 1986; Wilding &White, 1985) and a simplified, two-dimensional version of the mental-rotation task (Caissie, Vigneau, &Bors,

2009; Hegarty et al., 2000; Hoyek, Collet, Fargier, &Guillot, 2012). Rhyme judgment and mental rotation tap verbal and visuospatial speed of processing, respectively (Heydebrand, Hale, Potts, Gotter, &Skinner, 2007). Research has shown the rhyme-judgment task to be a predictor of speech understanding (Heydebrand et al., 2007; Lunner, 2003), which suggests that this task relies at least partly on the same cognitive resources as speech perception, and thus we expected it to show strong interference with the primary task. The mental-rotation task showed no correlation with speech comprehension (Heydebrand et al., 2007), and for this reason, we expected it to interfere less with the primary task.

In addition to the dual-task paradigm, which was used as an objective measure of effort, listening effort was measured on a subjective multidimensional self-report scale. Although self-report measures of subjective effort are easy to administer, it is not certain whether they reflect the proportional demand on cognitive resources (Wickens, 1992). Objective measures of effort, such as the dual-task paradigm, are specifically designed to reflect cognitive demand and may therefore be more sensitive to small changes in listening effort. However, such measures are less practical to use in, for example, a clinical setting. Although both subjective and objective measures are used to quantify listening effort, studies combining both often report no statistical relation between the two (AndersonGosselin &Gagné, 2011; Feuerstein, 1992; Zekveld et al., 2010), suggesting that objective and subjective measures of listening effort may tap different aspects of listening effort and may be complementary.

Method

Participants

Twenty-three normal-hearing young adults were recruited for participation in this study, four of whom were excluded during data analysis because of missing values in their data sets (either due to problems with the digital voice recorder or inconsistent filling out of the subjective workload questionnaire). The remaining 19 ranged in age from 19 to 25 years (average age about 22 years). Three were male, 16 were female. All participants were native Dutch speakers, and they reported having no dyslexia or other language impairment. Prior knowledge of Japanese or similar scripts was an exclusion criterion based on the stimuli used in one of the secondary tasks. Normal hearing was confirmed by pure-tone thresholds (below 20 dB HL at audiometric frequencies between 250 and 6000 Hz). All participants were given sufficient explanation about the experiment and voluntarily signed an informed consent form prior to data collection and were reimbursed for their time and effort.

Speech Stimuli

The stimuli used for the intelligibility task were full sentences, eight to nine syllables in length, of on average 1.8-s duration. Using sentences rather than single words would allow for a full secondary task trial, from stimulus presentation until response, to be completely contained within the presentation of one auditory stimulus. The sentences of the VU corpus (Vrije Universiteit, Amsterdam, the Netherlands; Versfeld, Daalder, Festen, &Houtgast, 2000), of the female speaker set, were used. These are digitally recorded (sampled at 44.1 kHz) and organized in 39 balanced lists, each list consisting of 13 Dutch sentences. The sentences were processed using a noise-band vocoder (Dudley, 1939), implemented in MATLAB, to simulate CI processing (Shannon, Zeng, Kamath, Wygonski, &Ekelid, 1995). The experimental variable in the listening task was the spectral resolution of the simulated speech, manipulated by using different numbers of spectral channels in the vocoder. Normalhearing listeners can usually understand CI-simulated speech quite well with four to eight channels (Baskent, 2006; Friesen, Shannon, Baskent, &Wang, 2001). On the basis of these studies, the conditions for the listening task were chosen to cover the range from nearly unintelligible to perfectly intelligible: 2-, 4-, 6-, 8-, 12-, 16-, and 24-channel CI simulations and a control condition using unprocessed speech stimuli. The filter bandwidths and cutofffrequencies varied depending on the number of channels. The bands were chosen such that they corresponded to evenly spaced regions in the cochlea; this was achieved by calculating the -3 dB cutofffrequencies using Greenwood's frequency-to-place mapping formula (Greenwood, 1990). For some

examples of -3 dB cutofffrequencies, see Figure 1.

The vocoder processing was implemented as follows: First, the original acoustical signal was separated into a number of spectral bands (the analysis bands) as determined by the experimental condition, using sixth-order Butterworth bandpass filters. From each analysis band, the slow-changing envelope was extracted by means of half-wave rectification and filtering with a third-order low-pass Butterworth filter with -3 dB cutofffrequency of 160 Hz. A set of noise-band carriers (the synthesis bands) was constructed by similarly dividing white noise into spectral bands using sixth-order Butterworth bandpass filters. For this experiment, the center frequencies and bandwidths of the analysis bands were the same as those of the synthesis bands in order to simulate matching frequency-to-place mapping of the CI electrode array (Baskent &Shannon, 2007; Greenwood, 1990). The CI simulationswere then constructed bymodulating each synthesis band with the envelope extracted from the corresponding analysis band and then adding these modulated noise bands together to form the final stimulus.

Visual Stimuli

The stimuli for the secondary tasks were rhyme words for one task and Japanese characters for the other. The reason for using Japanese phonetic symbols was to ensure that the stimuli for the mental-rotation task were linguistically meaningless to the participants. The words used in the rhymejudgment task were monosyllabic Dutch words, vetted for their pronunciation by a native speaker of Dutch. The 75% most frequently occurring words, as determined by the CELEX lexical databases of Dutch (Baayen, Piepenbrock, &Gulikers, 1995), were used in the experiment. The words in the display were clearly visible, one above another, centered on a computer monitor in big, black capital letters on a white background, each letter approximately 7 mm wide and 9 mm high, with a 12-mm vertical white space between the words. The Japanese characters used for the mental-rotation task were taken from the hiragana, one of the two syllabaries in use in Japanese. For those pairs of characters that can easily be mistaken as the same when rotated by 90° (for example: and), only one of the two characterswas used. The characters in the display were clearly visible, positioned side by side, and centered on a computer monitor in black on a white background, each character approximately 3 cmwide and 3 cmhigh, with a 4-cm horizontal white space between the characters, as illustrated in Figure 2.

Equipment

The participants were seated in a soundproof booth, in front of a wall-mounted computer screen at approximately 50-cm distance. A computer program, implemented using the Psychophysics Toolbox Version 3 for MATLAB and run on an Apple Macintosh computer, coordinated the presentation of both the auditory stimuli for the primary task and the visual stimuli for the secondary task. The verbal responses on the primary listening task were recorded for later scoring on a PalmTrack 24-bit digital audio recorder (Alesis, LP). The key-press responses and the RTs on the secondary task were automatically logged by the experimental program. The digital audio stimuli were sent via the AudioFire 4 external soundcard (Echo Digital Audio Corporation) to open-back HD600 headphones (Sennheiser electronicGmbH&Co.KG), to be presented to the participant diotically. The participants were instructed to adjust the volume to a comfortably loud, clearly audible level, within the range of 65-75 dB SPL. The calibration was done using the processed stimuli, measuring root-mean-square sound pressure with integration time constant of 1 s.

Procedure

Listening effort was measured objectively with a dualtask paradigm, consisting of a listening task (primary) and two different visual decision-making tasks (secondary); and subjectively with a multidimensional subjective rating scale.

Listening task. The primary task was designed to measure the participant's intelligibility score for sentences of varying spectral resolution. This task was presented three times for each of the eight levels of spectral resolution: once as a single task and once combined with each secondary task. The presentation order of these 24 conditions was randomized for each participant. Blocks of presentations for the single-task listening conditions consisted of one list of 13 sentences. For the dual-task conditions, no more than one RT

measurement could be recorded during the presentation of each sentence. Therefore, each block of presentations included a total of 26 sentences. This way it was possible to gather a sufficient amount of RT data recorded during the presentation of an auditory stimulus for statistical analysis. The interval between the onsets of the sentences was timed 8 s apart, and the average duration of the sentences was approximately 2 s. The intelligibility task was to listen to the processed sentences and repeat out loud what was heard. The participants were encouraged to guess if they were not sure what they heard. Their responses were recorded for offline scoring by a native Dutch speaker. The percentage of correctly identified words served as a measure of intelligibility.

Visual tasks. The visual decision-making tasks were designed to measure RTs, from stimulus onset until a key was pressed by the participant. In the rhyme-judgment task, a randomly chosen pair of words was displayed, one above the other, on the computer monitor. The participant's task was to indicate whether the two words rhymed or not by pressing one of two buttons on the keyboard. In the mentalrotation task, a randomly chosen pair of Japanese characters was displayed side by side on the monitor, one of which was rotated by 90°. The location of the rotated character (leftor right) and the direction of the rotation (clockwise or counterclockwise) were randomly determined by MATLAB, with equal probabilities for each possible combination. On this task, participants indicated whether the two characters were the same (except for the rotation) or different by pressing one of the same two buttons used in the rhyme-judgment task.

The rest of the procedure was the same for both visual tasks. The stimulus combination was chosen at random, with a 50% chance for a pair that required a "yes" answer. The stimuli were presented until a key was pressed in response or for a maximum of 2.7 s, after which the next trial would begin. Consecutive stimuli were separated by an interstimulus interval during which a fixation cross would appear in the center of the screen for the participants to focus on. The duration of this interval was pseudorandomly varied between 0.5 and 2.0 s, based on a uniform distribution. If no key was pressed, the trial was logged as a "miss." This variation ensured that the participants were unable to predict when a stimulus would appear and that in dual-task conditions the timing of the auditory and visual stimuli varied.

Subjective rating scale. For subjective assessment of listening effort, the NASA Task Load Index (TLX) was used (Hart &Staveland, 1988). The NASA TLX is a multidimensional scale that measures a range of aspects contributing to perceived workload: mental demand, physical demand, temporal demand, performance, effort, and frustration (Hart &Staveland, 1988). The total score is the weighted mean of the scores from the different dimensions. The weights are determined after the experiment by pairwise comparison. For all possible pairs of dimensions, the participants are asked to indicate which of two contributed most to the overall workload of the tasks. This procedure of weighting the ratings is designed to reduce intersubject variability resulting from differences in individual interpretation of workload and its factors.

Results

The average speech intelligibility scores are depicted in Figure 3. In each panel, the scores are plotted separately for listening task only, listening task combined with rotation task, and listening task combined with rhyme-judgment task. In the leftpanel of Figure 3, the intelligibility scores are plotted in units of percentage correct, as a function of spectral resolution. In the right panel of Figure 3, the scores are plotted in rationalized arcsine units (RAU; Studebaker, 1985), as a function of spectral resolution. The conversion to RAU was performed to allow a closer examination of the effects near ceiling; RAU scores are easier to interpret because, unlike with proportional scores, the variance is independent of the mean, and thus differences in percentage scores on different parts of the scale (e.g., the difference between 50% and 60% is not comparable to the difference between 90% and 100%) are not comparable, whereas differences in RAU are. Because the maximum possible value in RAU depends on the number of items in a task, the RAU scores were calculated based on an average number of words per list (80 words) and a proportion of words repeated correctly for each task. This ensures that a score of 100% correct always corresponds to the same RAU value, in this case,

117.83. The leftpanel of Figure 3 shows that, in terms of percentage correct, speech intelligibility appears to reach a plateau at six channels. The right panel shows that there might still be some improvement in intelligibility between six and eight channels. To examine these effects and differences between percentage correct and RAU scores, we carried out further analyses on both sets of scores.

Two repeatedmeasures analyses of variance (ANOVAs) were performed with task and spectral resolution as factors (with three and eight levels, respectively), one on the percentage correct scores and one on the RAU scores. Both ANOVAs showed a significant main effect of spectral resolution-percentage correct, $F(7, 126) = 396.84$, $p < .001$; RAU, $F(7, 126) = 412.89$, $p < .001$-and a significant interaction between task and spectral resolution-percentage correct, $F(14, 252) = 2.11$, $p = .012$; RAU, $F(14, 252) = 1.85$, $p = .033$. A post hoc analysis using Tukey's honestly significant difference test (HSD) indicated that the sole cause of the significant interaction was a significant difference in intelligibility between the mental-rotation task and the single task for the four-channel condition, while there was no significant difference between the single task and the rhymejudgment task. To confirm that there was no difference in performance between the two dual tasks, we performed twoway ANOVAs for these two tasks over the eight levels of spectral resolution, again for both the percentage correct scores and the RAU scores. These ANOVAs showed no significant interaction between task and processing. From this, we concluded that there was no significant difference between the two dual tasks in terms of speech intelligibility. Therefore, we then grouped the data for the two dual tasks together to examine the differences between listening conditions. As expected, speech intelligibility with two channels was very low, with about 13% of the words identified correctly. Increasing the number of channels to four provided a dramatic improvement in intelligibility; participants scored on average 70% correct. For six channels, speech intelligibility was near perfect, on average 98% correct. The significance of these differences was determined using Tukey's HSD, which showed that there were significant improvements in intelligibility from two to six channels of CI simulations and that further increases in spectral resolution resulted in no significant improvement in intelligibility. This was true for both the percentage correct scores and the RAU scores.

Upon examining the RTs from individual participants, we discovered a reduction over time, regardless of the listening conditions, suggesting training effects. Figure 4 shows the mean dual-task RT data as a function of presentation order, with each visual task in a separate panel. Despite each participant being presented with the listening conditions in a different, randomized order, the fit lines in these figures do show that there were strong learning effects during the course of the experiment. In order to reduce the betweensubject variance introduced by these training effects, they were modeled and compensated for using the following procedure. First, an exponential function was fitted to the overall mean RT data for each of the two secondary tasks. The proportion of variance accounted for (R2) by these fits was 0.975 for the rhyme-judgment task and 0.841 for the mental-rotation task. The horizontal asymptote of the exponential fit line is interpreted as the value on which the RT converges when all training effects have stabilized. For each individual participant, the learning effects were then compensated for by subtracting the deviation from the asymptote predicted by the fit line for each condition on the basis of the order of presentation. These manipulations of the data had no visible effect on the shape of the RT data as a function of spectral resolution. They did, however, considerably reduce the variance; for the raw RT data, standard deviations of the mean RTs per level of spectral resolution ranged from 0.35 to 0.63 s; compensating for learning effect reduced the standard deviations to values between 0.15 and 0.27 s. Further analyses of the RTs were performed on the data corrected for learning effects.

The first two panels of Figure 5 show the RT data (adjusted for learning effects) for the rhyme-judgment task and the mental-rotation task. Because wrong answers may be the result of a strategy or accidental button press, these RTs may be unrealistically short and thus distort the data. Therefore, RTs for trials on which a wrong answer was given were leftout of the analysis. In both panels, the mean RTs are shown for trials presented during listening (dashed line) and for trials presented between the auditory stimuli (dotted line). The overall mean RTs, recorded during and between auditory stimuli grouped together, are represented by the solid

line. These two plots show that the reduction in RTs from two to eight channels was greater for trials presented during a sentence than for trials presented in between. A three-way repeated measures ANOVA, with the factors task, visual stimulus timing, and spectral resolution, indicated that the interaction between stimulus timing and processing was indeed significant, $F(7, 126) = 18.37$, $p < .01$. The results of the ANOVA also showed a significant main effect of processing on RT, $F(7, 126) = 28.78$, $p < .01$. Comparison between mean RTs for consecutive processing conditions using Tukey's HSD showed a significant decrease in RT for listening conditions up to eight channels. Interesting to note is that there were significant RT improvements even for conditions in which speech intelligibility had reached a plateau.

The third panel in Figure 5 shows the mean NASA TLX scores for the listening task performed alone and with both secondary tasks. Both dual tasks were consistently judged more effortful than the single-task conditions. It can also be seen from the figure that the NASA TLX scores, like the RTs, decrease as the number of channels CI simulations increases, at least for low numbers of channels. However, the decrease in effort between six- and eight-channel CI simulations for NASA TLX scores was not significant. A twoway ANOVA of the NASA TLX scores showed significant main effects of spectral resolution as well as task, which we attribute to the difference between the single and dual task. An ANOVA performed only on the NASA TLX data for the two dual tasks did not show a significant effect of task. Because there was no significant difference between the two dual tasks, we averaged the mean RTs over both dual tasks to further examine them. The mean RTs for consecutive listening conditions were compared using Tukey's HSD, which showed a significant decrease in NASA TLX scores for listening conditions up to six channels.

Discussion

The hypothesis of the present study was that, with different settings of CI processing, listening effort may change differently from speech intelligibility. Furthermore, the conventional speech intelligibility tests may not be sufficient to capture these effects accurately. To explore this hypothesis, listening effort was assessed using an objective and a subjective measure. These measures were then compared with speech intelligibility scores to examine whether they were sensitive to differences in listening effort between conditions in which no improvement in intelligibility was seen. The participants were presented with speech stimuli processed to simulate CI output with different levels of spectral resolution and asked to repeat back what they heard. This was the primary task of the dual-task paradigm used, and this task resulted in speech intelligibility scores for each level of spectral resolution. Two different secondary tasks-a rhymejudgment task and a mental-rotation task-served to provide an objective measure of the listening effort associated with each level of processing, in the form of RTs on a visual decision-making task performed simultaneously with the intelligibility task. In addition to this, a multidimensional workload questionnaire was administered after each task to serve as a subjective measure of listening effort.

The results of the primary speech intelligibility task, in line with the findings of previous research (e.g., Baskent, 2006; Friesen et al., 2001), showed an increase in intelligibility with increased spectral resolution. The present study closely reproduced the speech intelligibility results reported by Friesen et al. (2001) for normal-hearing listeners presented with CIsimulated English sentences in quiet. In both studies, amarked increase in intelligibility was observed between two- and six-channel CI simulation. Intelligibility appeared to reach about 98% for six spectral channels, and further increases in spectral resolution produced no significant improvement.

The main interest of the present study was listening effort. The results from the subjective workload questionnaire, the NASA TLX, showed consistently higher scores for dual task compared with single task. This is not surprising because the NASA TLX is designed to measure overall task load, and a dual task can be considered to be cognitively more demanding than a listening task alone (Wickens, 2008). For all three tasks (the single listening task, the rhymejudgment dual task, and the mental-rotation dual task) the NASA TLX showed a significant decrease in workload from two to six spectral channels. For an increased number of

spectral channels beyond six, no significant decrease in subjective workload was found. The results of the two visual decision-making dual tasks showed that, although both speech intelligibility and NASA TLX scores improved only from two up to six spectral channels, RTs on both secondary tasks improved significantly from two up to eight channels. In other words, the RT measures captured an improvement, or benefit, of increasing spectral resolution from six to eight spectral channels that the intelligibility task and the NASA TLX did not capture.

One can argue whether the benefit captured by a decrease in RTs is indeed due to reduced listening effort. Recall that what we call "listening effort" is the proportion of a shared, limited cognitive resource that is allocated to the listening task. The larger the effort, the larger is this proportion assigned to the listening task, and thus the less of this resource is available to perform another task simultaneously. The RTs recorded between presentations of auditory stimuli showed a significantly shallower effect of spectral resolution than the ones recorded during presentation of auditory stimuli (Figure 5). This observation supports the idea that the effects of simulated CI processing present in the RT data are indeed caused by changes in demands on shared resources due to these differences in processing. In short, the observed pattern suggests that the reduced RTs are caused by a decrease in listening effort associated with the increase in spectral resolution. The literature shows that effects of effort are rather elusive, and effects in RT, though significant, can be as small as about 50 ms (e.g., Baer et al., 1993; Sarampalis et al., 2009). Although the results show a significant effect in RT only for conditions with constant intelligibility between six and eight channels, this effect was observed for both secondary tasks; therefore, we are convinced that it is a persistent and repeatable effect. Although both intelligibility and subjective workload measures are likely to reflect changes in listening effort to some degree, as these two measures showed a pattern similar to that of the RT measures, they appear to be less sensitive to changes in listening effort; they showed no significant improvement between six and eight spectral channels, whereas the RT measures did.

The NASA TLX scores do not show the same sensitivity to changes in listening effort as the RT measures. This difference in sensitivity between the NASA TLX and the RT measures can be explained in two ways. As mentioned in the beginning of this article, several studies combining objective and subjective measures have reported no statistical relation between the two (Anderson Gosselin &Gagné, 2011; Feuerstein, 1992; Zekveld et al., 2010). Anderson Gosselin and Gagné (2011) suggested that these different types of measures reflect different aspects of listening effort. They referred to the distinction between "effort" and "ease" made by Feuerstein (1992) and suggested that whereas performance on the secondary tasks reflect effort, a subjective self-report measure reflects ease. Another possible explanation attributes this difference to the "performance" dimension in the NASA TLX. Rubio, Diaz, Martin, and Puente (2004) compared different subjective workload measures and concluded that, of the three measures they compared, the NASA TLX showed the highest correlation with performance. This could explain why the NASA TLX results in the present study follow the intelligibility results more closely and, like the intelligibility measures, are less sensitive to changes in listening effort.

In the present study, the rationale for using two different visual RT tasks, one linguistic in nature and one purely visual, was based on the hypothesis that these two types of secondary tasks tap different aspects of working memory, the phonological loop and the visuospatial sketchpad (Baddeley, 2012; Heydebrand et al., 2007), and thus might be affected differently by the primary intelligibility task. We originally expected that this could result in different patterns of the RT outcomes for the two tasks as a function of spectral resolution or differences in interaction with the primary speech perception task. Against our expectation, the patterns of average RTs for the two secondary tasks looked very similar, and there was indeed no significant interaction between the type of secondary task and spectral resolution. Furthermore, neither task affected the performance on the primary task. One possible explanation for these similarities between the two tasks could be that, because of the nature of the Dutch language, most rhyming word pairs were orthographically similar, whereas most nonrhyming pairs were

dissimilar. Therefore, although we assumed the task to be purely linguistic, it was possible for the participants to adopt a visual strategy. Alternatively, mental rotation is such a complex operation that it is not limited to the visual modality but rather requires central processing as well (Ruthruff, Miller, &Lachmann, 1995). Thus, even though the task used in this study was a simplified version of the classical mental-rotation task, it could well be affected by a concurrent task in a different modality-such as a listening task. Regardless of the nature of the secondary task, both versions showed effects of listening effort where speech intelligibility scores and subjective effort scores did not.

Overall, we take the findings of the present study to mean that decreased spectral resolution, as manipulated by reducing the number of vocoder channels in CI simulations, results in increased listening effort, which is reflected in longer RTs on a secondary task. Supporting our observations, Lindenberger and Baltes (1994) hypothesized that, in a manner similar to the interference between tasks in a dualtask paradigm, interpreting degraded sensory input may require an increased allocation of cognitive resources, leaving fewer resources available for other cognitive tasks at hand. Schneider and Pichora-Fuller (2000) referred to this as the "information degradation hypothesis." Further support for such coupling between degraded speech and the increased cognitive resources needed for its processing was presented by Pichora-Fuller, Schneider, and Daneman (1995), who have shown that effects of age on cognitive performance can, at least partially, be explained by a decrease in sensory function; older listeners were found to have more trouble recalling lists of spoken items, whereas for both young and old listeners, decreasing the signal-to-noise ratio of auditory stimuli reduced their ability to store the items in memory. This finding suggests that a reduction in signal quality increases cognitive demand similarly in both young and old listeners. Two more recent studies showed increased cognitive demand as a result of decreased spectral resolution with both CI simulations and CI users (Baskent, 2012; Chatterjee et al., 2010).

In short, auditory processing, working memory, and speed of processing seem to interactively affect both speech understanding and the resources available for additional tasks (Lunner, 2003). In this light, changes in the effort needed to interpret the auditory signal can be reflected in both measures of working memory performance and speed of processing, such as the RTs on a secondary task used in this study. In their study, Sarampalis et al. (2009) showed a benefit of noise reduction strategies reflected both in better working memory performance and faster RTs, even for conditions in which noise reduction provides no benefit in speech intelligibility. The current study shows similar results: A significant decrease in RTs was found as the number of channels for CI simulations increased from six to eight, although this produced no significant increase in intelligibility.

To summarize, the present study used a dual-task paradigm in which normal-hearing participants were asked to simultaneously perform a speech intelligibility task using CI-simulated speech stimuli with different numbers of spectral channels and a visual RT task. The results showed that RTs decreased with an increasing number of channels, even for some conditions that showed no more improvement in speech intelligibility. This finding suggests that it is possible to further improve the listening experience for CI users, even when no improvement is observed in speech intelligibility. Currently, there is no clinical test that can show such benefits of different programs.

This line of research will help identify processing features and strategies for improving listening effort for CI users and help develop a method for measuring listening effort in a clinical setting to assist in improving CI fitting to optimize listening effort. Considering that a large proportion of Dutch CI users report increased listening effort with a CI compared with preimplantation (van Hardeveld, 2010), such optimization would be beneficial to a large population. The dual-task paradigm used in this study is not yet suitable for measuring listening effort in one individual, because of large individual variance and training effects, and is thus not suitable for use in clinical settings. However, it has proven to be sensitive enough to show effects of listening effort across a group of participants and hence presents a useful method that can be used in research settings, such as in developing

new signal-processing algorithms.

Acknowledgments

This research was supported by Cochlear Ltd, Dorhout Mees, Stichting Steun Gehoorgestoorde Kind, the Heinsius Houbolt Foundation, a Rosalind Franklin Fellowship from the University of Groningen, the Netherlands Organization for Scientific Research (NWO, VIDI Grant 016.096.397), and the Cochlear Implant Center Northern Netherlands and is part of the research program Communication Through Hearing and Speech.

We gratefully acknowledge Thomas Lunner for his insightful suggestions concerning this research; Thomas Stainsby and Ruben Benard for their comments on earlier versions of this article; and Frits Leemhuis, Annemieke ter Harmsel, Nico Leenstra, and Marije Sleurink for their help in seeing this project through.

Abstract: The contributions of voice onset time (VOT) and fundamental frequency (F0) were evaluated for the perception of voicing in syllable-initial stop consonants in words that were low-pass filtered and/or masked by speech-shaped noise. It was expected that listeners would rely less on VOT and more on F0 in these degraded conditions. Twenty young listeners with normal hearing identified modified natural speech tokens that varied by VOT and F0 in several conditions of low-pass filtering and masking noise. Stimuli included /b/-/p/ and /d/-/t/ continua that were presented in separate blocks. Identification results were modeled using mixed-effects logistic regression. When speech was filtered and/or masked by noise, listeners' voicing perceptions were driven less by VOT and more by F0. Speech-shaped masking noise exerted greater effects on the /b/-/p/ contrast, while low-pass filtering exerted greater effects on the /d/-/t/ contrast, consistent with the acoustics of these contrasts. Listeners can adjust their use of acoustic-phonetic cues in a dynamic way that is appropriate for challenging listening conditions; cues that are less influential in ideal conditions can gain priority in challenging conditions.

Full text: Headnote

Purpose: The contributions of voice onset time (VOT) and fundamental frequency (F0) were evaluated for the perception of voicing in syllable-initial stop consonants in words that were low-pass filtered and/or masked by speech-shaped noise. It was expected that listeners would rely less on VOT and more on F0 in these degraded conditions.
Method: Twenty young listeners with normal hearing identified modified natural speech tokens that varied by VOT and F0 in several conditions of low-pass filtering and masking noise. Stimuli included /b/-/p/ and /d/-/t/ continua that were presented in separate blocks. Identification results were modeled using mixed-effects logistic regression.
Results: When speech was filtered and/or masked by noise, listeners' voicing perceptions were driven less by VOT and more by F0. Speech-shaped masking noise exerted greater effects on the /b/-/p/ contrast, while low-pass filtering exerted greater effects on the /d/-/t/ contrast, consistent with the acoustics of these contrasts.
Conclusion: Listeners can adjust their use of acoustic-phonetic cues in a dynamic way that is appropriate for challenging listening conditions; cues that are less influential in ideal conditions can gain priority in challenging conditions.
Key Words: speech perception, noise, voicing contrast, bandwidth

Consonant voicing contrasts are very common in the world's languages (Ladefoged &Maddieson, 1996), and

the perception of acoustic cues underlying these contrasts has been explored thoroughly for normal-hearing listeners and other listeners in quiet conditions. Much less is known about how voicing is perceived by individuals who rely on low-frequency hearing (e.g., individuals with hearing impairment [HI]) or individuals listening in background noise. It is clear that perception of voicing remains accurate across a wide range of signal degradations, including highor low-pass filtering (Miller &Nicely, 1955), masking noise (Miller &Nicely, 1955; Phatak &Allen, 2007; Phatak, Lovitt, &Allen, 2008; Wang &Bilger, 1973), hearing impairment (Bilger &Wang, 1976), spectral degradation (Shannon, Zeng, Kamath, Wygonski, &Ekelid, 1995; Xu, Thompson,&Pfingst, 2005), or cochlear implantation (Friesen, Shannon, Baskent, &Wang, 2001). It is thus often stated that the amount of "information transfer" is high for the voicing feature relative to other consonant features. This finding is so consistent that some studies dispense with potential voicing confusions in the very design of the experiment (Dubno &Levitt, 1981). Despite this generalized high level of success, the constraints that face listeners in noise and/or those who rely on low-frequency hearing (e.g., listeners with hearing loss) are likely to change the means by which voicing is perceived-that is, the voice information could be recovered via different cues in varied listening conditions. In the current study, we show that in some degraded conditions, the role of voice onset time (VOT) decreases and the role of fundamental frequency (F0) increases for the perception of wordinitial voicing in stop consonants.

Cues for Voicing in Stop Consonants

Although perception of voicing in word-initial stop consonants has been largely attributed to VOT (i.e., the duration between consonant release and the onset of voicing for the following vowel; Lisker &Abramson, 1964), F0 plays a role as well. F0 is higher after voiceless stops than after voiced stops (House &Fairbanks, 1953), and this difference generally lasts roughly 100 ms into a vowel (Hombert, 1975). Although F0 is not a very potent cue for stop sounds with canonical voiced or voiceless VOTs (Abramson &Lisker, 1985), it can exert potent influence under certain conditions, such as for sounds with ambiguous VOTs (Abramson &Lisker, 1985; Haggard, Ambler, &Callow, 1970). When F0 contour conflicts with VOT, reaction time is slowed (Whalen, Abramson, Lisker, &Mody, 1993), suggesting that listeners are sensitive to F0 information even when identification curves suggest otherwise.

Another acoustic cue that may be useful to voicing perception is F1. Word-initial stop sounds are followed by transitioning formants, the first of which begins at a low frequency (e.g., 300 Hz) and ascends to its target frequency for the following sound. As VOT grows longer, that rising transition becomes increasingly devoiced, resulting in a higher F1 frequency at the onset of voicing; long VOT values yield higher F1 onsets, whereas low F1 onsets are characteristic of short VOT values (Lisker, 1975). An exception to this trend is for high vowels (e.g., /i/, /u/), whose voicing-related F1 perturbations are minimal because F1 begins and ends at low frequencies; F1 is thus not thought to aid the voicing contrast in high vowel environments. In this experiment, we focused on the contributions of VOT and F0 and hence relied on the /i/ vowel to provide an environment in which VOT perception could be measured without confounding changes in F1.

Both low-pass filtering and masking noise should affect VOT and F0 disproportionately. The aspiration noise that characterizes the VOT cue contains considerable energy in the high-frequency regions, particularly for the /t/ consonant (see Figure 1). Eliminating high-frequency energy from the signal would render the aspiration less audible while maintaining lower frequency harmonics in the vowel that drive F0 perception. Competing noise should more effectively mask the VOT than the vowel because the aspirated portion of the word is less intense than the vowel portion; the F0 is recovered from the vowel and should thus be relatively less affected by the noise.

The Effect of Low-Pass Filtering

Exploring the effect of limited bandwidth in terms of a low-pass filter (LPF) has particular relevance for understanding the experience of people with HI. High-frequency hearing loss can render some phonetic cues inaudible, potentially compelling listeners with HI to rely on different cues than those used by people with normal

hearing. Furthermore, the lack of access to high-frequency auditory filters is likely to compromise temporal resolution because the wideband highfrequency filters are considerably superior in the temporal domain compared with the narrow-band low-frequency filters (Eddins, Hall, &Grose, 1992). For example, noise gap detection thresholds become smaller as bandwidth grows wider (Eddins &Green, 1995; Eddins et al., 1992; Grose, 1991). For this reason, it is likely that listeners who rely solely on low-frequency energy have poorer ability to use temporal cues (such as VOT) but remain receptive to residual information that should include F0.

Role of F0 in Noise

Previous research has shown that F0 is a useful cue for listening to speech in noise (Brokx &Nooteboom, 1982; McAdams, 1989). When the F0 contours of masked sentences are flattened or inverted around the mean, intelligibility decreases (Binns &Culling, 2007) and self-reported difficulty increases (Laures &Weismer, 1999), particularly when the masker is competing speech. It is likely that the F0 contour can help direct listeners' attention to the timing of target words to aid in intelligibility (Cutler &Foss, 1977). Although the utility of a natural F0 contour is well established at the sentence level, relatively little is known about the contributions of F0 contour to the intelligibility of individual segments or phonetic features. Fogerty and Humes (2012) showed that the flattening of F0 contours or the removal of F0 information (i.e., whisper-like speech) resulted in deficits for both vowels and consonants. Therefore, although vowels are the primary periodic element in the speech signal, consonant sounds stand to benefit from natural F0 contours as well.

Objectives and Hypothesis

The present study was designed to test whether F0 would become a more prominent cue for voicing in wordinitial stop consonants in conditions of low-pass filtering and/or masking by speech-shaped noise. Unlike aspiration noise that characterizes the VOT cue, F0 should be perceptible even without high-frequency information. F0 has been previously shown to be a beneficial cue for listening to sentences in noise, but its use at the segmental level has not been fully understood. We hypothesized that in the aforementioned degraded signal conditions, listeners' voicing judgments would be driven more heavily by F0 and less by VOT.

Method

Participants

Participants included 20 adult listeners (15 women; mean age = 24.3 years) with normal hearing, defined as having pure-tone thresholds ≤20 dB HL from 250 to 8000 Hz in both ears (American National Standards Institute, 2010). All participants were native speakers of American English and were screened for self-reported unfamiliarity with tonal languages (e.g., Mandarin, Cantonese, Vietnamese) to ensure that no participant entered with a priori increased bias toward using F0 as a lexical or phonetic cue. Informed consent was obtained for each participant, and the experimental protocol was approved by the institutional review board at the University of Maryland. Participants were reimbursed for their participation.

Stimuli

Two sets of stimuli were created using modified natural speech. The words "Pete," "beat," "teen," and "Dean," spoken by a male native speaker of English, were recorded in a double-walled sound-treated room with a 44.1 kHz sampling rate. We sought to measure the contribution of VOT without the added complementary cue of F1, so a high vowel /i/ was used for all consonant environments. Stimuli varied by VOT (in seven or eight steps for /b/-/p/ and /d/-/t/, respectively) and F0 (in eight steps). Following the method used by Andruski, Blumstein, and Burton (1994), onset portions of words with /b/ or /d/ onsets were progressively replaced with equivalently long portions of onset aspiration from /p/ or /t/, respectively, in 10-ms increments from the onsets (bound at the closest zero crossing) to create continua of VOT. Thus, the vowel from each stimulus item came from the /b/- or /d/-initial tokens. For the /d/-/t/ continuum, the VOT range spanned from 0 ms to 70 ms, and the range for the /b/-/p/ continuum spanned from -10 ms (prevoicing) to 50 ms, as suggested by previous studies (Abramson &Lisker, 1970; Lisker &Abramson, 1964).

Intensity of items in the /b/-/p/ series varied within 2.7 dB, and all items in the /d/-/t/ series varied within 1 dB;

overall root-mean-square intensity was affected by VOT step because lower intensity aspiration noise progressively replaced higher intensity phonated vowel onsets. Volume was calibrated such that the end-point "voiced" stimulus of each series in the optimal (full-spectrum, in quiet) condition was 65 dBA.

The F0 contour of each stimulus was manipulated using the pitch synchronous overlap-add method in Praat (Boersma &Weenink, 2011). Steps in the F0 continuum were interpolated in eight steps along a log scale ranging from 94 to 142 Hz, which reflects the general range for male speech, as indicated by previous work (Abramson &Lisker, 1985; Ohde, 1984; Whalen et al., 1993). F0 was kept steady over the first two pitch periods of the vowel and fell (or rose) linearly until returning to the original contour at the 100-ms point in the vowel (the time indicated by Hombert, 1975). Following the 100-ms timepoint, all F0 contours were equal within each continuum.

Masking noise. Speech-shaped noise (SSN) was extracted offline from the iCAST program (Fu, 2006). Its spectrum was strongest in the 200-600 Hz region and decreased by roughly 6 dB per octave (see Figure 1). This noise was chosen to reflect the long-term average spectrum (LTAS) of conversational speech rather than the LTAS of our stimuli (the presence of only one vowel in our stimuli would yield a LTAS of only very limited utility with regard to everyday experience). Stimulus timing within the noise was roved so that there was 280-360 ms of noise before the stimulus and 380-450 ms of noise after the stimulus. To present varying signal-to-noise ratios (SNRs), noise levels varied while speech signals were kept at constant amplitude within each condition. Noise levels were set relative to the vowel onset so that SNR was not affected by intensity differences stemming from VOT continuum steps or by syllable type (stop-final or nasal-final). As most studies do not reference one particular point in a syllable to calculate SNR, caution is encouraged when comparing SNR levels in the current study with those from other publications. For example, the SNR at vowel onset for "Pete" is roughly 4 dB greater than that calculated from the entire word, resulting in greater masking to reach equivalent SNR.

Low-pass filtering. Stimuli were low-pass filtered using the Hann band filter function in Praat (Boersma &Weenink, 2011), illustrated by the filter responses in Figure 2. Cutofffrequencies of 4 kHz, 2 kHz, and 1 kHz were used to investigate various degrees of residual acoustic information. Filtering was done after the addition of background noise to model the order of signal degradations encountered by a listener with HI. Therefore, the level of noise (and, hence, the overall signal) for conditions at poorer SNRs was more intense than those at better SNRs, and signals with higher LPF cutoffs were more intense that those with lower LPF cutoffs. It should be noted that although the vowels and final consonants in all speech stimuli were degraded by the masking noise and filtering, these segments were already identified by the visual word choices.

Conditions

The levels of low-pass filtering and SNR in this experiment were chosen to measure specific effects highlighted in Table 1.

The arrangement of conditions was inspired by preliminary experiments (Table 1, top row) that suggested that either 0 dB SNR or a 1 kHz LPF permitted use of the VOT cue, but the combination of these factors promoted the use of F0 nearly exclusively. The combination of the 1 kHz LPF and the 0 dB SNR condition could be improved by either ameliorating the LPF settings or making the SNR more favorable. Thus, questions following this pilot testing included the following: (a) What LPF cutoffis necessary to facilitate the use of VOT when the SNR is 0 dB (middle row)? and (b) What SNR is needed to facilitate the use of VOT when the LPF is 1 kHz (bottom row)? Each of these conditions was tested for the /b/-/p/ stimuli and for the /d/-/t/ stimuli, resulting in a total of 16 conditions (note that some conditions are used for multiple comparisons but were tested just once).

Procedure

All testing was conducted in a double-walled soundtreated booth. Stimuli were presented in the free field through a single TannoyReveal studiomonitor loudspeaker (frequency response: 65 Hz-20 kHz, ±3 dB) at a distance of 1-2 ft, placed in front of the listener at eye level. Listeners responded to these stimuli by clicking a

button on a computer screen labeled with two word choices (either Pete-beat or teen- Dean). There was no time limit on their response, and they were permitted to enable stimulus repetitions up to three times; stimulus repetitions were very rare.

Conditions were defined by SNR and LPF cutoff(e.g., [0 dB SNR, 4 kHz], [10 dB SNR, 1 kHz]; see Table 1). There were 56 items (7 VOT ×8 F0) for the /b/-/p/ blocks and 64 items (8 VOT ×8 F0) for the /d/-/t/ blocks; stimuli within each block were presented in random order. Each block was presented five times, which resulted in well-defined psychometric functions along the stimulus parameters. Each participant began with at least one block of the optimal (quiet, no LPF) condition before hearing any masked-LPF conditions. Because of the large number of conditions, participants generally did not volunteer enough time to complete five blocks of each condition; condition selection and ordering was constrained within participants' scheduling availability. Listeners heard a variable subset of the conditions (that were not necessarily limited to one contrast), depending on their scheduling availability; most completed between 5 and 10 different conditions. The final data set included at least 10 listeners for each condition, for a total of over 800 tested blocks. Each repetition of a single block took roughly 3-5 min.

Before performing the group analyses, we used Sigmaplot 9.01 (Systat, 2004) to initially fit individual listeners' response functions to a simple logistic model. When listeners' data for a particular condition did not reach satisfactory convergence to the model, one or two more repetitions of that condition were conducted to smooth the function to allow a better fit. This was done for 5 of 20 listeners in some of the more challenging conditions (i.e., those where signal degradations were harsh enough to inhibit consistent use of the cues).

Analysis

Listeners' responses were fit using generalized linear (logistic) mixed-effects models (GLMMs). This was done in the R software interface (R Development Core Team, 2010), using the lme4 package (Bates &Maechler, 2010). A random effect of participant was used, and the fixed effects were the stimulus factors described above (Consonant Place, VOT, F0, LPF, SNR). The binomial family link function was used. The models included each main factor and all possible interactions (the four-way interactions were significant, necessitating the inclusion of all nested factors and interactions). The goal of these models was similar to that used by Peng, Lu, and Chatterjee (2009) and by Winn, Chatterjee, and Idsardi (2012); the models tested whether the coefficient of the resulting parameter estimate for an acoustic cue was different from zero and, crucially, whether the coefficient was different across conditions of LPF and SNR levels. Changes in this coefficient represent changes in the log odds of voiceless perceptions resulting from the condition or cue level change. Following previous studies (Morrison &Kondaurova, 2009; Winn et al., 2012), we interpreted the factor estimate from the GLMM as an indication of the strength of the factor (i.e., a higher estimate indicates higher perceptual weight).

Results

Averaged group responses to the continua of VOT and F0 are displayed in the tiled grids in Figures 3, 4, and 5. Grayscale intensity represents the proportion of voiced responses. Listeners who solely used VOT to distinguish these contrasts would yield grids with rows of different grayscale intensity, whereas listeners who solely used F0 would yield grids with columns of different grayscale intensity; each grid reflects the use of both cues in varying proportions. Sharper grayscale contrasts in successive rows and columns are akin to steeper psychometric functions.

Three GLMMs were used to describe listeners' responses for each of the three planned comparisons. Model terms along with the intercept and parameter estimates are given in Tables 2, 3, and 4. Simplified parameter estimates from the GLMMs are summarized in the supplemental table of coefficients (see online supplemental materials) and are illustrated in Figure 6.

In the first comparison (initial exploration of LPF and noise; Figure 3; Table 2), there were significant main effects of VOT, F0, SNR, and LPF (all ps <.001). Alveolar consonants were less likely to be heard as voiced (consistent with acoustics of these consonants;Lisker&Abramson, 1964). F0 was a stronger cue for the /d/-/t/

contrast (p <.001). The effect of VOT was significantly reduced when the signal was either low-passed (p <.001 for both contrasts) or in noise (p <.001 for both contrasts) and significantly reduced further in the presence of both filtering and noise (p <.001). The effect of F0 was significantly stronger for both contrasts when the signals were masked by noise (p <.001); when signals were low-passed, F0 became stronger only for the /b/-/p/ contrast. When the signal was both low-passed and in noise, the use of F0 significantly increased for both contrasts compared with either degradation alone (p <.001).

In the second comparison (effects of LPF in 0 dB SNR noise; Figure 4; Table 3), the effect of VOT significantly decreased for both contrasts with each successive reduction in LPF cutoff(p <.001), with the exception of the 1 kHz condition, which was not significantly different from the 2 kHz condition. The use of VOT for the /d/-/t/ contrast was greater than that for the /b/-/p/ contrast when the full spectrum was available, but in any LPF condition, there was a significant advantage for the /b/-/p/ contrast for the use of VOT (all ps <.001). The effect of F0 was significantly stronger for the /d/-/t/ contrast in all low-pass filtered conditions (p <.001 for 4 kHz and 2 kHz; p <.05 for 1 kHz). The effect of F0 for the /b/-/p/ contrast did not significantly increase in any LPF condition.

In the third comparison (effects of SNR with a 1 kHz LPF; Figure 5; Table 4), the use of VOT significantly decreased with each successive reduction in SNR for both contrasts (all ps <.001). The use of F0 increased for the /b/-/p/ contrast for 5 and 0 dB SNR (both ps <.001), while it increased for the /d/-/t/ contrast in all conditions with noise (all ps <.001).

A question that remains from the results presented thus far is whether a listener can achieve the same or similar level of accuracy for voicing recognition via F0 as with VOT. Because the analyses presented thus far do not speak to correctness per se, a final analysis was conducted to evaluate the identification of stimuli where both the VOT and F0 cues cooperated at typical "voiceless" or "voiced" values. Figure 7 illustrates performance levels for these end-point stimuli by listeners in all conditions. Voicing was correctly identified with 80% accuracy or greater in all conditions except for /b/ in the 1 kHz LPF with 0 dB SNR noise condition. The cue estimate for VOT showed a significant positive correlation with accuracy for end-point accuracy (r = .76 for /b/-/p/, r = .74 for /d/-/t/; p <.05 for each). The cue estimate for F0 showed a significant negative correlation with end-point accuracy for the /d/-/t/ contrast (r = -.68, p <.05) but did not show a significant correlation with accuracy for the /b/-/p/ contrast. Thus, although listeners were able to mostly compensate for the degraded VOT cue via the F0 cue, they performed better when relying on VOT.

Discussion

In this experiment, listeners perceived voicing contrasts in signals that were low-pass filtered and/or masked by SSN. These two signal degradations generally yielded a decline in the use of VOT that was accompanied by an increase in the use of F0. Thus, as acoustic degradations compromised the availability of the VOT cue, listeners did not simply guess at the words-they recruited appropriate information from a different acoustic cue. The one condition common to all three comparisons (0 dB SNR, 1 kHz LPF; the most challenging condition) was theoretically the most challenging in the experiment. It was distinct because while the use of VOT decreased, the use of F0 was less than the use of F0 for some other, more favorable masked and/or filtered conditions. For the most challenging condition, it appears that the acoustic signal is so degraded that even F0 is difficult to perceive in a useful way.

Speech-shaped masking noise and low-pass filtering had disproportionate effects on the /b/-/p/ and /d/-/t/ contrasts. To the extent that voicing perception can be framed as detection of aspiration noise, these disproportionate effects can be explained by the acoustics of labial and alveolar stop sounds in this study. The use of cues for labial sounds was influenced more by the level of masking noise, presumably because the spectrum of SSN competes more directly with the /p/ burst and aspiration (see Figure 1). Low-pass filtering the sounds had little effect on the use of cues for labial sounds, presumably because the spectrum of the /p/ aspiration contains sufficient low-frequency components that remain after filtering. Conversely, the use of VOT

for the /d/-/t/ contrast was heavily reduced by low-pass filtering. Consistent with earlier literature on the acoustics and perception of /t/ (Régnier &Allen, 2008), the audibility of energy above 4 kHz is essential for the perception of /t/ aspiration; all conditions that used a LPF of 4 kHz or lower saw dramatic reductions in VOT use along with increased use of F0 for alveolar sounds, even for modest SNRs. Table 5 shows that the SNR advantage of /p/ compared with /t/ is evident in the lower frequency regions (i.e., from 0 to 4 kHz), whereas in higher frequency regions (i.e., between 4 and 8 kHz), /t/ has an advantage (all relative to the masking noise used in this experiment). The pronounced asymmetry in energy at the upper and lower regions for labial and alveolar aspiration noise helps to explain differences in cue weighting across these two places of articulation and accords with previous reports of individual consonant advantages in SSN (Phatak &Allen, 2007).

Other types of noise may have different effects than those shown in this study. With the entire spectrum available and audible, the SNR of stimuli in white noise may affect the /t/-/d/ contrast more heavily than the /p/-/b/ contrast. Amplitude-modulated noise or competing speech might momentarily provide a favorable SNR for these cues via a dip in amplitude concurrent with the onset of the target words; there is no reason to think that modulation would differentially affect /p/ versus /t/. It should be noted that listeners with hearing loss are less able to capitalize on shortterm valleys of a masker (Carhart &Tillman, 1970; Festen &Plomp, 1990) and, thus, may not recover segmental information in such conditions.

Although listeners were able to reliably identify the voicing of the most natural (i.e., "end-point") stimuli (Figure 7), it is not yet known whether the signal degradation requires listeners to use greater cognitive resources to perceive voicing. Given listeners' general tendency to rely on VOT rather than on F0 (Abramson &Lisker, 1985), conditions driven by F0 could have been more difficult than those driven by VOT, despite similar accuracy scores. Accuracy for end-point stimuli in this experiment was significantly correlated to the strength (i.e., factor estimate) of VOT. Thus, scores in phoneme identification tasksmay tell only part of the story; similar scores could have arisen because of different perceptual strategies. Pupillometry during speech perception tasks suggests that extra effort is required to maintain equal intelligibility of speech in the presence of different types of maskers (Koelewijn, Zekveld, Festen, &Kramer, 2012) or if listeners have hearing loss (Kramer, Kapteyn, Festen, &Kuik, 1997). It is not yet known whether alternative phonetic cue-weighting strategies would elicit similar signs of increased listening effort.

In this experiment, the role of F1 was minimized via the use of the high vowel /i/. Jiang, Chen, and Alwan (2006) showed that F1 can play a role in the perception of voicing in noise for non-high vowels, confirming a prediction by Hillenbrand, Ingrisano, Smith, and Flege (1984). It is not yet known whether F1 or F0 is more dominant in compensating for degradations of VOT in masked and/or filtered conditions.

The motivation for this experiment was to model potential listening strategies that could arise when a person experiences HI. Because HI is more complex than a simple LPF, the results of this study should be interpreted with caution. There are suprathreshold deficits in the spectral and temporal domains that might limit a listener's ability to utilize either of the acoustic cues explored in this study. These deficits are frequently attributed to poor frequency resolution and/or temporal fine structure coding (Bernstein &Oxenham, 2006; Lorenzi, Gilbert, Carn, Garnier, &Moore, 2006). Turner and Brus (2001) showed that although the amplification of low-frequency energy (including F0) provided benefit for listeners with HI, this benefit was smaller than that observed for those with normal hearing.Grant (1987) suggested that listeners with HI are not able to detect subtle F0 contrasts and would therefore benefit fromF0 contours only if they were exaggerated by roughly 1.5-6 times those observed in natural speech. Thus, it remains unclear whether listeners with cochlear hearing loss can capitalize on F0 cues in noise to the same extent as the participants in this study. Further difficulties might be experienced by older listeners, who have been shown to experience deficiencies in auditory temporal processing in basic psychophysical tasks (Gordon-Salant &Fitzgibbons, 1993, 1999) and tasks involving perception of temporal phonetic cues in isolated words (Gordon-Salant, Yeni-Komshian, Fitzgibbons, &Barrett, 2006) and in sentence contexts (Gordon-Salant,Yeni-Komshian,&Fitzgibbons, 2008).

The use of F0 as a segmental cue in this study may partly explain the benefit of a natural F0 contour of sentences presented in noise (Binns &Culling, 2007; Laures &Weismer, 1999; Miller, Schlauch, &Watson, 2010). It is not known whether the segmental use of F0 cues in this study would generalize to longer utterance contexts, where F0 contrast is likely constrained by other sources of variability (e.g., intonation) and phonetic reduction. It should be noted that the current experiment used a two-alternative forcedchoice task that assessed only voicing perception in single words; it is likely that these stimuli would be confused with other consonants (but perhaps not with consonants of different voicing) if a larger response set were used. Conversely, the influence of sentence context and other top-down factors may compensate for the added difficulty of an open response set (McClelland, Mirman, &Holt, 2006).

Emergent models of phonetic perception and categorization increasingly acknowledge the integration of multiple covarying acoustic cues in the speech signal (McMurray &Jongman, 2011; McMurray, Tanenhaus, &Aslin, 2002; Toscano &McMurray, 2010). The presence of multiple cues for voicing can at least partly explain why voicing is such a robust feature in phoneme identification tasks in adverse listening conditions like low-pass filtering and masking noise. Listeners are capable, without any explicit instructions, of increasing reliance on residual cues in a speech signal when otherwise stronger cues have been degraded.

Abstract: In this study, the authors assessed the influence of masking level (29% or 71 % sentence perception) and test modality on the processing load during language perception as reflected by the pupil response. In addition, the authors administered a delayed cued stimulus recall test to examine whether processing load affected the encoding of the stimuli in memory. Participants performed speech and text reception threshold tests, during which the pupil response was measured. In the cued recall test, the first half of correctly perceived sentences was presented, and participants were asked to complete the sentences. Reading and listening span tests of working memory capacity were presented as well. Regardless of test modality, the pupil response indicated higher processing load in the 29% condition than in the 71 % correct condition. Cued recall was better for the 29% condition. The consistent effect of masking level on the pupil response during listening and reading support the validity of the pupil response as a measure of processing load during language perception. The absent relation between pupil response and cued recall may suggest that cued recall is not directly related to processing load, as reflected by the pupil response.

Purpose: In this study, the authors assessed the influence of masking level (29% or 71 % sentence perception) and test modality on the processing load during language perception as reflected by the pupil response. In

addition, the authors administered a delayed cued stimulus recall test to examine whether processing load affected the encoding of the stimuli in memory.
Method: Participants performed speech and text reception threshold tests, during which the pupil response was measured. In the cued recall test, the first half of correctly perceived sentences was presented, and participants were asked to complete the sentences. Reading and listening span tests of working memory capacity were presented as well.
Results: Regardless of test modality, the pupil response indicated higher processing load in the 29% condition than in the 71 % correct condition. Cued recall was better for the 29% condition.
Conclusions: The consistent effect of masking level on the pupil response during listening and reading support the validity of the pupil response as a measure of processing load during language perception. The absent relation between pupil response and cued recall may suggest that cued recall is not directly related to processing load, as reflected by the pupil response.
Key Words: speech recognition, speech recall, pupil response, processing load, text reception threshold (TRT)
Challenging listening conditions imposed by back- ground noise or hearing loss can impair the ability to perceive parts of spoken information. There is ample evidence that such speech perception difficulties increase the reliance on cognitive and linguistic processes during conversation (Kramer, Zekveld, &Houtgast, 2009; Shinn-Cunningham &Best, 2008; Zekveld, George, Kramer, Goverts, &Houtgast, 2007) and, thus, result in increased listening effort (see, e.g., Kramer, Kapteyn, Festen, &Kuik, 1997; Kramer et al., 2013; McCoy et al., 2005; Sarampalis, Kalluri, Edwards, &Hafter, 2009; Zekveld, Kramer, &Festen, 2010, 2011).
In recent years, many researchers acknowledged the need to examine the effects of background noise and hearing loss on both speech perception performance measures and on measures reflecting the effort ox processing load required during listening (Edwards, 2007; Mackersie &Cones, 2011; Piquado, Isaacowitz, &Wingfield, 2010). Examination of both types of measures is important because the effects of signal characteristics and individual factors like hearing impairment and cognitive abilities may affect both aspects of speech perception differently. Researchers have applied various measures of processing load, including physiological measures like the pupil response, functional magnetic res- onance imaging (fMRI), and event-related potentials (Just, Carpenter, &Miyake, 2003). In the current study, we used the pupil response to examine the effects of masking on processing load during listening and reading.
The task-related pupil response reliably reflects the cognitive processing demands of tasks in multiple domains (Beatty, 1982; Janisse, 1977). The pupil dilates when cog- nitive load increases (see, e.g., Granholm, Asarnow, Sarkin, &Dykes, 1996). The pupil responds to memory load (Beatty, 1982), as well as to processing load, when listening to speech (Piquado et al., 2010; Schluroff, 1983; Stanners, Headley, &Clark, 1972; Wright &Kahneman, 1971). Task-evoked changes in pupillary dilation are phasic changes time-locked to the onset of stimuli requiring cognitive processing. In addition, research indicates that the response is closely related to the reticular formation and locus coeruleus in the brain stem (Aston-Jones &Cohen, 2005).
In recent studies (Koelewijn, Zekveld, Festen, &Kramer, 2012; Kramer et al., 1997, 2013; Zekveld, Kramer, &Festen, 2010, 2011), we examined the pupil response during listening to speech presented against a background of noise. The re- sponse proved to be sensitive to speech intelligibility, type of masking noise, age, hearing loss, and cognitive abilities. Additionally, the results acquired thus far indicate that this measure validly reflects processing load. For example, if the intelligibility level is manipulated by varying the signal-to- noise ratio (SNR), the pupil response is affected such that, with increasing speech comprehension difficulty, the pupil response is increasing. In the current study, we aimed to further validate this application of pupillometry. We assessed whether equivalent differences in task-difficulty level in a visual and an auditory sentence perception test had similar effects on the task-evoked pupil response.
Also, we assessed the effect of task difficulty (i.e., masking level) and test modality on the recall of sentences correctly perceived in the listening and reading tests. Several researchers (Heinrich, Schneider, &Craik, 2008;

Kjellberg, Ljung, &Hallman, 2008; McCoy et al., 2005; Rabbitt, 1991) have suggested that the processing resources required during listening may affect recall of the perceived stimuli. They argued that higher levels of background noise and poorer hearing acuity require extra processing resources. As a result, fewer processing resources are available for stimulus encoding, which negatively influences recall of the spoken information. The data observed by McCoy et al. (2005), Surprenant (1999, 2007), Kjellberg et al. (2008), Rabbitt (1968, 1991), and Heinrich et al. (2008) indeed showed that more challenging listening conditions reduced stimulus recall, even if it was likely that the stimuli were correctly perceived by the participants.

Researchers have applied various methods in these studies. Kjellberg et al. (2008) did not find a relation between listening condition and stimulus recall when sentences, rather than words, were presented. In some of the studies, word identification was not directly assessed and, thus, not con- trolled for (McCoy et al., 2005) or not 100% correct (Murphy, Craik, Li, &Schneider, 2000; Surprenant, 2007). As de- scribed by Kjellberg et al. (2008) and Surprenant (1999), impaired stimulus perception could also affect recall by degrading the stored physical representation of the stimuli (i.e., dual code model). If stimulus perception is controlled for by asking participants to repeat each stimulus, the dual code model is a less likely explanation for the effect of noise on recall (Kjellberg et al., 2008).

In the current study, we obtained a physiological measure of processing load (i.e., pupil response) during the perception of partly masked speech (as assessed by the Speech Reception Threshold [SRT] test; Plomp &Mimpen, 1979) or text (as assessed by a visual equivalent of the SRT test, the Text Reception Threshold [TRT] test; Zekveld et al., 2007). The primary aim of the current study was to further validate the pupil response as a measure of processing load by com- paring (a) the processing load evoked while someone is listening to speech in noise with (b) the load evoked by the visual TRT test. If the pupil response reflects processing load, equivalent difficulty changes in both tasks (i.e., 29% vs. 71% sentence perception) should similarly affect the pupil response during perception. Additionally, we created a cued recall test by visually presenting the first half of sentences that were correctly perceived in the TRT and SRT tests. Participants were asked to complete the sentence from memory. We aimed to assess whether the difficulty level in the listening and reading tests would affect delayed recall of the correctly perceived sentences. The final aim was to assess the relation between several cognitive variables (read- ing and listening span tests [RSpan and LSpan, respectively]), the processing load during performance of the SRT and TRT tests (pupil response), and cued recall test performance. Therefore, we additionally administered complex, relevant working memory tasks: the RSpan and LSpan tests (Daneman &Carpenter, 1980).

In numerous studies, researchers have demonstrated the association between cognitive abilities, such as those relevant for the TRT and RSpan tests, and speech perception performance in challenging conditions (see, e.g., Kramer et al., 2009; Rönnberg, Rudner, Foo, &Lunner, 2008). Researchers have proposed several hypotheses regarding the relation between cognitive abilities and the processing load during sentence perception (see, e.g., Ahern &Beatty, 1979, 1981; van der Meer et al., 2010; Verney, Granholm, &Marshall, 2004). First, persons with high cognitive ability may exploit more resources during the task, resulting in higher performances and more cognitive processing load regardless of task difficulty (see, e.g., Zekveld, Kramer, &Festen, 2011). Second, participants with large capacity may allocate this additional capacity only when the task is difficult (see, e.g., van der Meer et al., 2010). Third, processing efficiency could be larger for persons with high cognitive ability, re- sulting in less processing load, regardless of task difficulty (see, e.g., Heitz, Schröck, Payne, &Engle, 2008). Consistent with several studies-Kramer et al. (1997); Zekveld, Kramer, and Festen (2010, 2011); and Koelewijn et al. (2012)-we expected that more challenging listening and reading conditions would be associated with larger processing load, as indicated by a larger pupil response. Because both the SRT and TRT tests require the completion of partly masked sentences, the tests likely tap into similar linguistic processes. Therefore, we did not expect an inter- action effect between test modality (auditory or visual) and task performance (percent correct sentence perception) on the pupil response. In line with multiple other studies-Pichora- Fuller,

Schneider, and Daneman (1995); Heinrich et al. (2008); McCoy et al. (2005); and Piquado, Cousins, Wingfield, and Miller (2010)-we expected that cued recall performance would be lower in the conditions in which sentence perception performance was lower. Furthermore, consistent with other studies-Zekveld, Kramer, and Festen (2011); Zekveld, Rudner, Johnsrude, Heslenfeld, and Rönnberg (2012); Tun, Wingfield, and Stine (1991); and Kjellberg et al. (2008)-we expected that the processing load as reflected by the pupil response would be larger for participants with good TRT performances and smaller for those with high-quality RSpan and LSpan performances.

Main Experiment

Method

Participants

Twenty-four students (15 women and nine men) with normal hearing participated. Their ages ranged from 18 to 27 years, with a mean age (Magc) of 22 years (SD = 2.9 years). They were recruited among students of the Vrije Universiteit (VU University), Amsterdam, the Netherlands. All partici- pants were native Dutch speakers who reported normal or corrected-to-normal vision, no dyslexia, and no history of neurological disease. None of the participants wore glasses or eye makeup during the tests, and seven participants used contact lenses during the tests. The project was approved by the Ethics Committee of the VU University Medical Center. All participants provided written informed consent.

Stimuli and Tests

Near vision screening. Near vision was screened with a visual acuity Snellen equivalent (Bailey &Lovie, 1980). During the screening, a word chart is digitally presented at 40 cm, and participants are asked to read the words aloud. The words are presented with decreasing font size on each line, ranging from 80 points to 2 points. The smallest font size that the participant was able to read had to be <8 points for inclusion in the current study (i.e., at least 18 points below the smallest point size used in the tests).

Pure-tone audiometry. We measured participants' pure- tone hearing thresholds to ensure that the thresholds in both ears were <20 dB HL at the octave frequencies be- tween 125 and 8000 Hz.

SRT test. In each SRT test, 36 short, everyday Dutch sentences, as developed by Versfeld, Daalder, Festen, and Houtgast (2000) and recorded by a female speaker, were presented in background-interfering speech. Sentences from this set are pronounced clearly, at a natural rate. An example sentence (translated into English) is, The shop is within walking distance. The sentences were equalized regarding intelligibility (see Versfeld et al., 2000, for more details).

The speech uttered by the female speaker was masked with speech uttered by a male speaker (a stream of single sentences played without intermissions). The sentences in the masking speech were different from those used in the target speech but were chosen from the same set (Versfeld et al., 2000). The masking speech was spectrally shaped in order to obtain the same long-term average frequency spectrum as the target female speech. For each sentence, the audio file containing the single-talker masker was started at a random time point; the presentation of the masker started 3,000 ms before speech onset, and masker offset was 4,000 ms after speech offset. After masker offset, an answer prompt (a 1-s, 1 -kHz tone presented at 70 dB SPL) indicated that the listener was allowed to give his or her verbal response. This paradigm allowed measurement of the baseline pupil size during the time in which participants were listening to the mask alone and prevented the target pupil response from being con- founded by the pupil response to the previous sentence and to the act of responding. Participants were asked to report each sentence aloud and to repeat each word in case they had not understood the entire sentence. Also, they were instructed to say, "I haven't understood anything," in case they were not able to perceive any of the target words. The experimenter scored whether the sentence was reproduced completely correctly. We varied the SNR by adapting both the speech and the masker levels while keeping the overall intensity fixed at 70 dB SPL. We presented the first sentence at an SNR below threshold (-12 dB SNR) and then repeatedly presented it while increasing the SNR by 4-dB steps until the participant was

able to reproduce the entire sentence correctly. Each of the following sentences was presented once at an SNR deter- mined by the adaptive procedure. Two adaptive procedures were applied: a l-up-2-down procedure estimating the SNR required for perceiving 29% of the presented sentences cor- rectly (SRT29%) and a 2-up-l-down procedure estimating the SNR required for 71% sentence perception (SR l ı : see Levitt, 1971). The SRT was the mean SNR of Sentences 5-36. The data of the first four sentences were not included in the analyses (Plomp &Mimpen, 1979).

TRT test. The TRT test is conceptually equivalent to the SRT test in that it measures the ability to perceive degraded verbal information. In the TRT test, 36 partly masked written sentences (Versfeld et al., 2000) were presented on a PC screen set 40 cm from the participant (Zekveld et al, 2007). Sentences did not overlap with those used in the SRT test. Text was masked with a bar pattern. First, we created a bitmap image that was proportionally filled with black bars, depending on the required percentage of unmasked text. Then, we stretched the bitmap image to the fixed dimensions of the field in which the words appeared. For each trial, the bar pattern consisted of bars of equal thickness. Between trials, we varied the percentage of unmasked text by changing the thickness of the presented bars.

The colors of the text, background, and bar pattern mask were equiluminant (i.e., 21 cd/m2). This specification prevented a confounding of the pupil response by illumina- tion differences between text stimuli presented with different degrees of masking. The field background color was gray, the text color was orange, and the mask color was green.

Similar to the SRT test, at the start of each trial, the mask became visible for 3,000 ms. Then, the text appeared "behind" it in a word-by-word fashion, with one word presented at a time. The display duration of each word was equal to the duration of the utterance of each word in the corresponding audio file (Versfeld et al., 2000). The mask remained visible for 4,000 ms after the last word of each sentence disappeared. The disappearance of the mask acted as a response prompt for the participants, who were asked to report each sentence aloud. Similar to the SRT test, either a l-up-2-down or a 2-up-l-down adaptive procedure was applied, targeting 29% or 71% sentence readability, respec- tively (TRT29% and TRTyi»,,.). The step size applied in the TRT test was a 6% change of the percentage of unmasked text. The TRT was the mean percentage of unmasked text of Sentences 5-36.

RSpan test. In the RSpan test (Daneman &Carpenter, 1980), short (five-word) sentences were visually presented. Half of these were nonsense sentences (e.g., The table sings a song); the other half made sense (e.g., The friend told a story). The Dutch sentence material and test were developed to be equivalent to the Swedish version described by Andersson, Lyxell, Rönnberg, and Spens (2001; see Besser, Koelewijn, Kramer, Zekveld, &Festen, in press). First, three sets of three sentences were presented, followed by three sets of four sentences, three sets of five sentences, and three sets of six sen- tences. Immediately after each sentence, participants verbally indicated whether the sentence made sense. After each set of sentences, participants were prompted to recall, in serial order, either the first or the last word of each sentence. The experimenter recorded the number of words correctly recalled, regardless of order.

LSpan test. The LSpan test is an auditory version of the reading span test (Besser, Koelewijn, et al, in press); a list of different but equivalent sentences were auditorily pre- sented. Sentences were spoken by a female speaker and pre- sented in silence, binaurally over headphones at 70 dB SPL. Participants performed the same task as in the RSpan test. In contrast to our procedures for the RSpan test data, we acquired pupillometric data during the LSpan test for purposes that surpass the scope of this article. These data are not included in the analyses of the current study.

Surprise cued recall test. Of those sentences that were completely correctly reproduced by the participant in the SRT29%, SRT71o/o, TRT29 ;,- and TRT71% tests, 40 sentences (10 sentences per test) were randomly selected. The first half of the sentence (e.g., the first three words of a six-word sentence or the first four words of a seven-word sentence) was presented visually. For example, for the sentence, De stad telt twee miljoen

inwoners (The city has two million inhabitants), the cue would be, De stad telt (The city has). Participants were asked to complete the sentences from memory. In most cases, the cue did not contain a clause or a semantically or syntactically meaningful unit. Sentences selected from the four tests were shown in random order. Participants were not forewarned of the memory test and were instructed to complete the sentence even if they were not able to recall the sentence from memory. Both the percentage of correctly added words and the percentage of entirely correctly completed sentences were scored. The rationale for obtaining both scores was that they may reflect partly different abilities: Whereas entirely correctly com- pleting a sentence is based on correct recall from memory, the word scores (the number of single words correctly added) likely depend, to a higher extent, on the participant's ability to use the first half of the sentence as linguistic context in which to infer the probable sentence ending. The two types of scores may relate differently to the other variables col- lected in the current study.

Pupillometry. The pupil size and location of the left eye were measured with a SensoMotoric Instruments pupillometer (2D Video-Oculography, Version 4; Berlin, Germany). The system uses infrared video-based technology, and data were sampled at 50 Hz. The spatial resolution of the pupillometer was 0.03 mm.

For details of the pupil data selection, cleaning, and data reduction, see Zekveld et al. (2010). In the SRT and TRT tests, the baseline pupil size was determined for each sentence by averaging the pupil size in the 1.0 s preceding speech or text onset. The procedure applied to remove eye- blink artifacts from the pupil data started with the calcu- lation of the average pupil diameter between the start of the baseline and the answer prompt, separately for each trial. Pupil diameter values below 3 SDs of this average diameter were classified as blinks. Eye blinks were replaced by linear interpolation starting four samples before and ending eight samples after a blink. We excluded those traces in which more than 15% of the data were missing due to eye blinks and those traces containing artifacts due to eye movements.

The data of the deblinked traces were smoothed by a 5-point moving average filter and then were averaged over trials, for each condition and participant. The maximum number of traces per SRT and TRT condition was 32 be- cause we did not analyze the data of the first four sentences of each test. On average, 29 traces were included in each condition. Then, we determined (a) the peak pupil dilation (peak dilation amplitude) relative to the baseline pupil size, (b) the peak latency relative to sentence onset, and (c) the mean dilation (relative to baseline) between the start of the sentence and the response prompt. See Zekveld et al. (2010, Figure 1) for a graphical presentation of these measures.

Procedure and Equipment

Test administration took place in a sound-treated room. Auditory stimuli were presented via Sony MDR V900 headphones. During the SRT tests, participants maintained focus at a fixation dot positioned 4 m away on a white wall. The test session started with the acquisition of the pure- tone audiogram and near vision screening. Then, either the LSpan test (for half the participants) or the RSpan test (for the other half) was presented. Next, half the participants started with the TRT tests and subsequently performed the SRT tests, and the other half started with the SRT tests and subsequently performed the TRT tests. The order of the 29% and 71% correct conditions was additionally balanced over participants. Both the TRT and SRT tests started with a practice test of 13 sentences. Subsequently, participants performed the RSpan or the LSpan task (i.e., the one they had not yet performed at the start of the test session), and the test session was finished after the surprise cued recall test. The cued recall test was always performed at least 15 min after completing the last TRT or SRT test. Sentences were presented only once to each participant. The assignment of sentence lists to conditions was balanced across participants. The duration of the test session was 2 hr with a 5-min break halfway through the session.

Before starting the first test in which pupil data were collected, and before participants were seated behind their respective PC monitors, we positioned the pupillometric equipment, and we measured pupil size in maximum illu- mination (230 lux [lx]) and in complete darkness. The room illumination was adapted individually such that

the pupil size was around the middle of its dynamic range at the start of the experiment. This prevents floor-and-ceiling effects in the pupil response and makes the response independent of the baseline pupil size (Beatty &Lucero-Wagoner, 2000; Hyönä, Tommola, &Alaja, 1995; Janisse, 1977). The mean room illumination was 84 lx (SD = 35 lx).

Analyses

For the behavioral data, descriptive statistics of the test results were calculated. We performed a within-subjects analysis of variance (ANOVA) to test the effects of test (SRT or TRT) and percent correct condition (29% or 71%) on the pupil response data and cued recall. We performed a correlation analysis to assess the associations between the RSpan and LSpan performances, the pupil response during the TRT and SRT tests, and cued recall.

Results

Behavioral Data

All participants had normal hearing; the mean pure- tone hearing thresholds at 125, 500, 1000, 2000, 4000, and 8000 Hz were <20 dB HL for both ears (M = 6.6 dB HL, SD = 3.5 dB HL).

The mean SRT29% was -15.8 dB SNR (SD = 1.9 dB SNR), and the mean SRT71»,0 was -9.5 dB SNR (SD = 2.2 dB SNR). The mean TRT29% was 63.2% unmasked text (SD = 7.8%), and the mean TRT71% was 80.8% unmasked text (SD = 13%). The mean RSpan was 22.0 (SD = 4.5), and the mean LSpan was 26.4 (SD = 3.6). The mean number of correctly reported sentences was 9.7 (SD = 1.4) in the 29% conditions, out of the total 32 sen- tences included in the analyses, which corresponds to an average performance level of 30% of the sentences. This number equaled 22.1 (SD = 1.4) in the 71%> conditions, corresponding to 69%. of the sentences. The SRT, RSpan, and LSpan performances were similar to those observed in other studies that examined comparable groups of partici- pants (see, e.g., Besser, Koelewijn, et al, in press; Koelewijn et al., 2012).

Pupil Data

Figure 1, Panel A shows the peak and mean pupil dilation, and Panel ? shows the latency of the peak dilation in the SRT and TRT tests, separately for the 29% and 71% correct conditions. Panel A indicates that the pupil response was larger in the 29% correct conditions and larger in the SRT tests than in the TRT tests.

For both the peak and mean pupil dilation data, the ANOVA showed main effects of test as follows: peak dilation, i*U, 23) = 34.7, ρ <.001, partial η2 = .60; mean dilation, i^l, 23) = 29.7,ρ <.001, partial η2 = .56. Also, the ANOVA showed main effects of the percent correct condition as follows: peak dilation, i^l, 23) = 4.9,ρ <.05, η2 = .18; mean dilation, i^ l, 23) = 6.5,ρ <.05, partial η2 = .22. For both dependent variables, the Test χ Percent Correct Condition interaction effect was not statistically significant. No signif- icant effects of the two factors on the latency of the peak dilation were found.

The baseline pupil diameter was determined while participants listened to the interfering talker (SRT test) or watched the bar pattern mask (TRT test). Table 1 shows the mean baseline pupil size for the two tests separately for the two performance levels; the baseline pupil size was larger in the SRT test than in the TRT test. An ANOVA with independent factors test (TRT vs. SRT) and percent correct condition (29% vs. 71%) showed a main effect of test on the baseline pupil size, i*U, 23) = 200.3, ρ <.001, η2 = .90.

Cued Recall Test

Figure 2 shows the percentage of words and sentences that were correctly completed in the cued recall test. Cued recall performance was higher for the sentences that were presented in the more difficult SRT and TRT conditions (29% performance level). The results of the ANOVA on the word scores did not show statistically significant effects of test and percent correct, although a trend was observed for the effect of percent correct condition, F(1,23) = 3.36, ρ = .08, partial η2 = .13. The results of the ANOVA on the sentence scores indicated a main effect of percent correct condition (29% vs. 71%), i*(l, 23) = 5.8,ρ <.05, partial η2 = .20, but no statistically significant effect of test (SRT vs. TRT) and no Test x Percent Correct Condition interaction.

Post Hoc Experiment: Effect of Test Setup on Pupil Response

Figure 1 (Panel A) and Table 1 show that the pupil response and the baseline diameter were larger in the SRT test than in the TRT test. The SRT and TRT tests differ in various aspects, among which the modality (auditory vs. visual stimuli) and the equipment/test setup (i.e., in the TRT test, watching the stimuli presented on a PC screen; in the SRT test, focusing at a fixation dot on the wall) are important factors. To interpret the differences in the pupil response between the two tests, it is important to distinguish between the potential effects of those differences by assessing the sole effect of focusing on a PC screen (TRT test) versus focusing on a fixation positioned on a wall (SRT test) with- out the confounding influence of modality differences be- tween the tests. Therefore, we assessed the pupil response during the SRT test in a different group of participants while they were focusing either (a) on a fixation dot presented on a PC screen or (b) on the wall.

Method

Twenty-four participants (18 female and six male; Magc = 22.0 years, SD = 2.7 years) twice performed the SRT test, estimating the SNR required for completely correctly perceiving 50% of the sentences (1-up-l-down procedure). This post hoc experiment was part of a larger study that re- quired estimation of the SNR required for 50% sentence intelligibility. In one test, the setup was similar to that applied in the SRT test described in the Method subsection of the Main Experiment section, with participants focusing on a fixation dot positioned on a wall at 4 m distance. In the other test, participants were seated 40 cm behind a PC screen and focused on a fixation dot displayed in the middle of the screen. The order of the two conditions was balanced across participants. The other test characteristics (e.g., the stimuli) and the measurement of the pupil response were the same as those described for the Main Experiment.

Results

Figure 3, Panel A shows the peak and mean pupil response for both test setups (participants focusing on a fixation dot on the wall vs. a fixation dot on the PC screen), and Panel ? shows the latency of the peak dilation for the two settings. Panel A suggests that the peak of the pupil response was smaller when participants focused at a fixation dot positioned on the PC screen as compared to the peak dilation while focusing on a fixation dot on the wall.

We performed three paired-samples t tests to assess the effect of test setting on the peak pupil dilation, the mean dilation, and the latency of the peak dilation. The difference in the peak dilation amplitude between the two settings was statistically significant, $r(23) = -2.6$, Bonferroni cor- rected $\rho < .05$. Effects of test setup on the mean dilation and peak latency were not statistically significant.

The mean baseline pupil size in the SRT test that was performed while participants focused on the fixation dot on the wall was 4.4 mm (SD = 0.8 mm). It was 3.3 mm (SD = 0.5 mm) while participants focused on the fixation dot pre- sented on the PC screen. A paired-samples t test indicated that the baseline pupil size was significantly larger when partici- pants focused on the fixation dot on the wall, $t(23) = -10.2$, $\rho < .001$.

The results of the post hoc experiment indicate that the relatively large pupil responses in the SRT test, as com- pared with those in the TRT test, are likely partially ex- plained by differences in test setup between the two test types. Furthermore, the baseline pupil size was substantially smaller when participants focused on the screen than when they focused on the wall, thereby suggesting that the dif- ferences in the baseline pupil size between the SRT and TRT tests were likely the result of the different test setups.

Correlation Analyses Main Experiment

We assessed the Pearson correlation coefficients among SRT, TRT, LSpan, RSpan, cued recall, and the pupil response (peak dilation amplitude in the SRT and TRT tests). To restrict the number of statistical tests, we used the average TRT (averaged over the 29% and 71% correct conditions) and did not include the mean pupil dilation in the analysis because the peak and mean pupil dilation were highly associated in all conditions (Pearson correlation coefficients between .84 and .91). Also, we did not include the latency of the peak dilation because this variable did not show the expected effect of task difficulty. Further, we averaged the cued recall

data over tests and conditions, separately for the word and sentence scores. The results are presented in Table 2. Note that the results of the statistical tests performed on the correlation coefficients should be interpreted cau- tiously because we did not correct the significance level of the statistical tests for the total number of tests (i.e., 30) performed.

No statistically significant correlations were observed among the TRT, SRT, LSpan, RSpan, and cued recall data on the one hand, and the peak pupil dilation on the other hand. The peak dilation amplitude in some of the conditions were positively associated with one another (see Table 2), indicating that participants who had a large pupil response in one condition also had relatively large responses in other conditions.

Discussion

The main result of the current study was that manip- ulation of the performance level in the SRT and TRT tests (29% vs. 71% correct sentence perception) affected the pupil response such that for both the TRT and SRT tests, the peak and mean dilation were smaller (i.e., less processing load) in the 71% correct conditions (see Figure 2). In several previous studies (Koelewijn et al., 2012; Kramer et al., 1997, 2013; Zekveld, Kramer, &Festen, 2010, 2011), we ob- served similar intelligibility effects on the pupil response in the SRT test. Also, it is interesting to observe this effect for the TRT test. As expected, we did not observe an inter- action effect between test modality (TRT vs. SRT) and percent correct. Thus, similar difficulty differences (29% vs. 71% correct) in both tests equally affected the pupil response, which supports the validity of the pupil response as a measure of cognitive processing load.

In addition, we hypothesized that the processing load as reflected by the pupil response would be larger for participants with good TRT performances and smaller for those with good RSpan and LSpan performances. Although researchers have found that RSpan and TRT are important predictors of speech perception (see, e.g., Akeroyd, 2008; Besser, Zekveld, Kramer, Rönnberg, &Festen, 2012; Rönnberg et al., 2008; Rönnberg, Rudner, Lunner, &Zekveld, 2010), the present data do not indicate associations among TRT, RSpan, LSpan, and the peak pupil responses in the SRT and TRT tests. The absence of any significant associations among these variables may be influenced by the relatively small and homogenous sample included in the study. Because con- trasting findings regarding the relation between cognitive abilities and processing load have been found in 1MRI studies (see, e.g., Osaka et al., 2003; Prat &Just, 2011), more research into this relation with a larger group of participants would be valuable.

Further, in line with Pichora-Fuller et al. (1995), Heinrich et al. (2008), McCoy et al. (2005), and Piquado, Cousins, et al. (2010), we expected cued recall performance to be lower in the conditions in which sentence perception performance was lower and cognitive processing load was higher. In contrast, the current findings indicate that par- ticipants were better able to recall sentences that were pre- sented in the more difficult TRT and SRT tests (i.e., the conditions targeting 29% correct sentence perception; see Figure 2). In the current study, all sentences presented in the cued recall test were completely correctly perceived in the TRT or SRT test. By definition, in the SRT and TRT tests targeting 29% correct sentence perception, fewer sentences were perceived correctly than in the 71% correct conditions, which may have enhanced the ability to encode the sentences in the 29% correct condition (cf. the list-length effect; Strong, 1912). However, it is currently unknown whether the list- length effect also applies to sentence lists (Kinnell &Dennis, 2011). In some previous studies (Heinrich et al., 2008; Murphy et al., 2000; Pichora-Fuller et al., 1995; Piquado, Cousins, et al., 2010; Schneider, Daneman, Murphy, &Kwong See, 2000; Surprenant, 1999, 2007), stimulus per- ception was not correct, may have been imperfect in all conditions, or was not directly assessed and thus not con- trolled for, which could have impaired stimulus recall. Furthermore, in most previous studies, the authors used different types of stimuli, such as discourse passages (Schneider et al., 2000) or words (Heinrich et al., 2008; McCoy et al., 2005; Murphy et al., 2000). Additional differ- ences between the current and previous studies include the type of masker used to distort the speech, cued recall versus free recall (used in previous studies), the lower overall performance levels (in the current study), and the fact that participants performed an incidental (in the

current study) instead of intentional recall test. In other fields of research, such as the reading of texts (Gao, Stine-Morrow, Rim Noh, &Eskew, 2011; Walker, Jones, &Mar, 1983), similar findings have been reported, with more difficult (but successful) perception- enhancing recall. However, researchers who have addressed the "levels of processing" approach (Craik &Lockhart, 1972) have found inconsistent effects of noise on recall (see, e.g., Smith &Broadbent, 1981). Thus, in the current study, stim- ulus recall was better for the more difficult listening and reading conditions. In addition, no correlation between pupil response and recall was observed. Therefore, we suggest that processing load may not directly affect cued recall of sentences-at least, not when applying the specific recall tests that were used in the current study.

The lower recall performances of the sentences presented in the 71% as compared with the 29% correct conditions cannot be explained by differences in sentence characteristics between the conditions because the allocation of sentences to conditions was balanced across listeners. However, both sentence perception and cued recall may have depended more on the internal linguistic context (entropy) of the correctly repeated sentences in the 29% correct con- ditions than in the 71% correct conditions, which may have caused the relatively high recall performances for the sen- tences presented in the 29% conditions. A higher dependence on the linguistic entropy in the 29% correct conditions would be reflected by a relatively low /-factor (see Boothroyd &Nittrouer, 1988) for the sentences perceived correctly in these conditions. To test this hypothesis, we calculated the /-factor of each sentence based on the data collected in the current study, separately for the TRT and SRT tests. Independent t tests performed separately for the TRT and SRT tests showed that the average /-factor of the sentences perceived correctly in the 29% conditions did not differ significantly from those perceived correctly in the 71% correct conditions; thus, it is unlikely that linguistic entropy confounded the present data.

The peak and mean dilation (see Figure 2, Panel A) and the baseline pupil size (see Table 1) were larger in the SRT tests than in the TRT tests. The SRT and TRT tests differ in several respects, including stimulus modality and test setup. The post hoc study showed that both the pupil response (Figure 3, Panel A) and the baseline pupil diameter were smaller when participants looked at a fixation dot presented on the screen instead of on the wall. The relatively small baseline pupil size was probably due to the higher illumination level while the participant was seated behind the screen compared with the overall illumination level in the room. The effect of test setup on the peak dilation in the SRT test was relatively small (i.e., around 0.05 mm) as compared with the difference in pupil response between the TRT and SRT tests (i.e., around 0.15 mm). Furthermore, as described by Janisse (1977) and Beatty and Lucero-Wagoner (2000), the baseline pupil size does not affect the pupil response if it is around the middle of its dynamic range, as was the case in the current study. Therefore, we assume that other factors, such as the act of reading, also affected the relatively small pupil response in the TRT test. In addition, the data may indicate that reading masked text is easier than listening to masked speech. Further, in the SRT test, the speech was masked with meaningful, interfering speech, whereas in the TRT test, a meaningless bar pattern masked the text. The higher pupil response in the SRT test may have been asso- ciated with the higher similarity between the target and the masker as compared with the TRT test. If speech is masked by a meaningless masker such as stationary noise, the pupil response is lower (e.g., around 0.13 mm in 71% correct conditions; Koelewijn et al., 2012; Zekveld et al., 2010) and, therefore, more similar to the pupil response evoked in the TRT test as compared with the response to speech masked by an interfering speaker. The results indicate that researchers must take care to minimize differences in tasks and stimuli if they want to directly compare the responses between tests.

The TRT test performances were relatively low (i.e., a relatively high percentage of unmasked text was required for achieving 29% and 71% readability performance) as compared with previous studies (see, e.g., Besser, Zekveld, et al., 2012; Zekveld et al., 2007). In the current study, we adapted the colors of the TRT stimuli to prevent confound- ing the pupil response with illumination differences between the stimuli presented with different degrees of masking. The resulting nonoptimal colors for reading the text likely caused these relatively

low performances.

In conclusion, both masking level and test modality affected the pupil response: The pupil response was larger in more difficult conditions and in the SRT test as compared with the TRT test. The lack of a Masking Level χ Test Modality interaction effect support the validity of the pupil response as a measure of processing load. One unexpected result of this study was that participants were better able to recall stimuli that were presented in the more difficult conditions, regardless of test modality. Our findings indi- cate that stimulus recall is not directly related to cognitive processing load as reflected by the pupil response. Finally, the pupil response was sensitive to test setup, with smaller pupil responses when participants were seated behind a PC screen than when they were seated in front of a wall.

Abstract: This study examined the effects of envelope dynamic-range mismatch on the intelligibility of Mandarin speech in noise by simulated bilateral electric hearing. Noise-vocoded Mandarin speech, corrupted by speech-shaped noise at 5 and 0 dB signal-to-noise ratios, was presented unilaterally or bilaterally to 10 normal-hearing listeners for recognition. For unilateral conditions, the right ear was presented with the 8-channel noise-vocoded stimuli generated using a 15-dB envelope dynamic range (DR). To simulate the envelope DR mismatch between the 2 ears, the left ear was presented with the 8-channel noise-vocoded stimuli generated using a 5-, 10-, or 15-dB envelope DR, respectively. Significant binaural summation benefits for Mandarin speech recognition were observed only with matched envelope DR between the 2 ears. With reduced DR, the performance of tone identification was more consistent in the steady-state speech-shaped noise than that of sentence recognition. Consistent with previous findings, the present results suggest that Mandarin speech-perception performance of bilateral electric listening in noise is affected by the difference of envelope DR between the 2 implanted ears, and the binaural summation benefits are maximized when DR mismatch is minimized between the 2 implanted ears.

Full text: Headnote

Purpose: This study examined the effects of envelope dynamic-range mismatch on the intelligibility of Mandarin

speech in noise by simulated bilateral electric hearing.
Method: Noise-vocoded Mandarin speech, corrupted by speech-shaped noise at 5 and 0 dB signal-to-noise ratios, was presented unilaterally or bilaterally to 10 normal-hearing listeners for recognition. For unilateral conditions, the right ear was presented with the 8-channel noise-vocoded stimuli generated using a 15-dB envelope dynamic range (DR). To simulate the envelope DR mismatch between the 2 ears, the left ear was presented with the 8-channel noise-vocoded stimuli generated using a 5-, 10-, or 15-dB envelope DR, respectively.
Results: Significant binaural summation benefits for Mandarin speech recognition were observed only with matched envelope DR between the 2 ears. With reduced DR, the performance of tone identification was more consistent in the steady-state speech-shaped noise than that of sentence recognition.
Conclusions: Consistent with previous findings, the present results suggest that Mandarin speech-perception performance of bilateral electric listening in noise is affected by the difference of envelope DR between the 2 implanted ears, and the binaural summation benefits are maximized when DR mismatch is minimized between the 2 implanted ears.
Key Words: bilateral electric hearing, electric hearing, dynamic range, binaural benefits
(ProQuest: ... denotes formulae omitted.)
A substantial amount of evidence exists supporting the hearing benefits of binaural cochlear implants (CIs) in terms of better speech recognition in challenging environments (see, e.g., Buss et al, 2008; Gantz et al., 2002; Litovsky, Parkinson, Arcaroli, &Sammeth, 2006; Loizou et al., 2009; Schleich, Nopp, &D'Haese, 2004), sound localization (see, e.g., Litovsky, Johnstone, et al., 2006; Neuman, Haravon, Sislian, &Waltzman, 2007; Schoen, Mueller, Helms, &Nopp, 2005), language acquisition and learning (see, e.g., Caselli, Rinaldi, Varuzza, Giuliani, &Burdo, 2012), and quality of life (see, e.g., Litovsky, Parkinson, et al., 2006; Summerñeld et al., 2006). The binaural benefits for CI speech perception in noise have been receiving an increased level of interest, with researchers examining the head-shadow effect, the binaural summation effect, and the binaural squelch effect (see reviews in Brown &Balkany, 2007; Tyler, Dunn, Witt, &Preece, 2003). The head-shadow effect has probably the largest impact on binaural CI hearing, and the difference in speech recognition thresholds (SRTs) for the two monaural listening conditions (i.e., one condition with the CI closer to the noise sources and the other condition with the CI on the shadowed side) ranges between 4 and 7 dB (see, e.g., Gantz et al., 2002; Tyler et al., 2003). The benefit of the binaural summation effect (i.e., presenting the identical stimulus bilaterally) is mainly attributed to the redundancy of information in the stimuli presented at the two ears. The summation benefits observed from listeners with bilateral CIs are relatively larger (e.g., 1.5-2.9 dB in SRTs; Schleich et al., 2004) than those observed from normal- hearing (NH) listeners (it was suggested to be approximately 1 dB in Bronkhorst &Plomp, 1989). Although the benefit of the binaural squelch effect is rarer and is sensitive to the test conditions, a few studies suggested that some bilateral CI users obtained this benefit (see, e.g., Gantz et al., 2002).
More recently, several studies in which experimenters focused on how the unilateral performance affected binaural benefits (e.g., Litovsky, Parkinson, et al., 2006; Yoon, Li, Kang, &Fu, 2011; Yoon, Liu, &Fu, 2011) showed that significant binaural benefits in bilateral CIs depend on com- parable performance across the two implanted ears. In general, subjects having very dissimilar unilateral speech- understanding performance gain little in terms of binaural advantages. However, only a small number of studies exam- ined the possible origins of the performance mismatch between ears. Garadat, Litovsky, Yu, and Zeng (2010) studied the effects of "dead regions'" for the performance difference be- tween the two implanted ears and suggested that customized programming for bilateral CI processors based on knowledge about dead regions could enhance performance in adverse listening situations. Yoon, Liu, andFu (2011) showed that the CI insertion-depth difference between ears might contribute to mismatched unilateral performance, thereby decreasing binaural benefits. Chen, Wong, Tahmina, Azimi, and Hu (2012) investigated the impact of mismatched spectral resolu- tion between implanted

ears on the recognition of Mandarin tones and sentences and concluded that matched spectral resolution maximized binaural summation benefits for Mandarin speech perception by simulated bilateral electric hearing. In the present study, we examined another likely source of unilateral performance discrepancy-the dynamic range (DR) of the temporal envelope-in the context of Mandarin speech perception in noise by simulated bilateral electric hearing. Our rationale for the present work was that, because of the two different maps used to convert acoustic signal units to electric current units, electric current signals have different DRs across the two implanted ears, which may contribute to the unilateral CI performance discrepancy.

Researchers have extensively used acoustic simulations (Dormán, Loizou, &Rainey, 1997; Shannon, Zeng, Kamath, Wygonski, &Ekelid, 1995) involving NH subjects in CI re- search to study the effects of various factors on speech per- ception by unilateral and bilateral CIs; they have done so because it is advantageous to avoid the impact of patient- specific confounding factors (e.g., insertion depth, neural surviving pattern, etc.) that exist in clinical populations. In general, the vocoding processing used in the CI simulations mimics the way sound is processed in CI devices, with the exception that the final mapping stage is usually ignored. In consequence, without the logarithmic compression, the DRs of the temporal envelopes in acoustic simulations could be much larger than those generated by the clinical devices. In several studies (see, e.g., Fu &Shannon, 1999; Loizou, Dormán, &Fitzke, 2000; van Hoesel, Böhm, Battmer, Beckschebe, &Lenarz, 2005; Zeng &Galvin, 1999; Zeng et al., 2002), researchers examined how DR compression could affect the performances of the vocoding processing in CI simulations and of real CI listening. Fu and Shannon (1999) used peak or center clipping to reduce the DR of the input speech signals, and they measured the effects of reduced DR on phoneme recognition by CI users in quiet and in noise. Zeng and Galvin (1999) showed that, in quiet, reduced DR had little impact on phoneme recognition; however, in noise, phoneme recognition was significantly degraded by the re- duction of the DR. Zeng et al. (2002) examined how to best convert the acoustic signals to optimize the DR of electric currents in CI listeners. Van Hoesel et al. (2005) assessed the effects of amplitude-mapping adjustment on speech intelli- gibility with unilateral and bilateral CI patients by reducing the stimulation level (also referred to as the "DR") of standard monaural amplitude-mapping function when used bilater- ally. They found a modest but statistically significant decrease in performance when stimulation level was lowered in quiet and in noise. In their CI simulation study, Loizou et al. (2000) used a six-channel sinusoid vocoder and compressed the amplitudes of the sine waves in a systematic fashion to sim- ulate the effects of a reduced DR between 6 and 24 dB on speech understanding. The major drawback of their approach is that the minimum envelope amplitude both before and after compression across all spectral channels was always set to the quantization noise floor value (i.e., the value of 1 in the pulse- code modulation wave file format often used in CI simula- tions). As a result, (a) in most cases, the DR of the input acoustic signals was clearly overestimated and (b) the arbi- trarily set minimum value of the output envelope amplitude was not accurate and could lead to undesirable signal distor- tions. To address these issues, in our present study, we used an approach that dynamically set the minimum envelope ampli- tude both before and after compression across all spectral channels.

Among the three types of binaural benefits (i.e., head shadow, binaural summation, and binaural squelch), the head-shadow effect is mainly from the physical phenomenon that the head would attenuate some frequency components of the interfering noise signals and prevent these components from reaching the other side of the head. In other words, the head would produce a shadow; for this reason, the head- shadow effect does not involve central auditory processing. Yoon, Shin, and Fu (2012) showed that binaural spectral mismatch did not appear to have a negative impact on the head-shadow effect, and Garadat et al. (2010) showed that spectral holes in the higher frequency range would have a negative impact on the head-shadow effect because these holes undermine the spectral cues underlying the head- shadow effect. The hypothesized result of the envelope DR mismatch is that the mismatch might have a negative impact on the head-shadow effect. For instance, in the lis- tening scenario where speech is presented from the front of the head and noise from the right, usually

the left ear will have a signal-to-noise ratio (SNR) advantage over the right ear because the head shadow attenuates the low-frequency sound by 3-6 dB and attenuates the high-frequency sound by about 20 dB (Tyler et al, 2003). There are three scenarios for the envelope DR between the two ears: The left is better than the right, the left is similar to the right, or the left is worse than the right. For the left ear to take advantage of the improved SNR, the envelope DR of the left ear cannot be significantly worse than that of the right ear because the reduced DR undermines the spectral contrast, which needs to meet a certain threshold for phoneme recognition (see, e.g., Loizou et al., 2000). In other words, if the DR of the left ear is considerably worse than that of the right ear, the head-shadow effect would be seriously reduced. The binaural summation and squelch effects rely on the redundancy and integration of the speech information from the two ears and involve central processing. The binaural summation effect occurs when both ears are presented with similar speech information (i.e., diotic listening), leading to the increment of the perceived loudness. The hypothesized impact of the envelope DR mismatch on the summation effect is that the mismatch would have a negative impact on the summa- tion effect because the summation effect requires similar speech information from the two ears for the central process- ing. The binaural squelch effect refers to the advantage asso- ciated with bilateral listening when compared to monaural listening with the shadowed ear. On the basis of the results from Yoon et al. (2012), the hypothesized impact of the en- velope DR mismatch on the squelch effect is that the mis- match would have a negative impact on the squelch effect because the squelch effect might require similar speech in- formation from the two ears for central processing. To ac- curately measure the effects of the envelope DR mismatch on the head-shadow and squelch effects, researchers need to conduct spatial-hearing experiments such as those involving head-related transfer functions (HRTFs; e.g., Garadat et al., 2010; Yoon et al., 2012). In the present study, we focused on the binaural summation benefits.

We assessed the effects of envelope DR mismatch in the present study by using vocoded Mandarin speech to simulate unilateral and bilateral CIs. The binaural listening experi- ments were designed to answer the question of how envelope DR mismatch would affect the intelligibility of Mandarin speech in steady-state noise by bilateral electric hearing. From the results of previous studies in which the authors used English speech materials (see, e.g., Litovsky, Parkinson, et al, 2006; Yoon, Li, et al., 2011; Yoon, Liu, &Fu, 2011), we hypothesized that, compared to the conditions with un- matched DR across the two implanted ears, those conditions with matched DR would yield more pronounced binaural summation benefits for Mandarin speech perception in noise. As to the binaural Mandarin tone identification and its re- lationship with sentence recognition, on the basis of our earlier studies on spectral-resolution mismatch in Chen et al. (2012) as well as those results on tone recognition in quiet by Fu, Zeng, Shannon, and Soli (1998), we hypothesized that (a) DR mismatch may have less effect on tone identification than on sentence recognition and (b) factors other than tone identification might account more for the variance of Mandarin sentence recognition performance in noise.

Method

Subjects and Materials

Ten (five male and five female) NH native Mandarin- Chinese listeners participated in the experiments. The subjects' ages ranged from 18 to 28 years, and the majority of subjects were graduate students at The University of Hong Kong. Subjects were compensated for their participation in the study.

The Mandarin tone materials included six single-vowel syllables (/a/, loi, Id, Ii I, lui, and /ü/) in each of the four Mandarin tones (1: flat and high, 2: rising, 3: falling and rising, and 4: falling) produced by two adult native Mandarin- Chinese (one male and one female) speakers in a sound- treated booth, resulting in a total of 48 vowel tokens (i.e., two speakers x six vowels x four tones) for Mandarin tone identification. The Mandarin sentence materials included sentence lists taken from the database of Mandarin Hearing in Noise Test (MHINT; see Wong, Soli, Liu, Han, &Huang, 2007, for more details). All sentences were produced by a native Mandarin-Chinese male speaker, with fundamental frequency (F0) ranging from 75 to 180 Hz. Both Mandarin sentences and vowels were recorded at a sampling rate of 16 kHz, and their waveforms were then adjusted to have the

same root-mean-square (rms) values. The duration of the vowel tokens was normalized (Fu &Zeng, 2000). We used steady-state, speech-shaped noise (SSN) to corrupt the target speech materials at 5 and 0 dB SNR levels before the vocoding processing, and we chose the SNR levels to avoid the ceiling effect.

Amplitude Envelope Dynamic-Range Compression

The amplitude values of the temporal envelopes were extracted in the vocoding processing (see the Signal Processing section, below) and then were linearly compressed within a predetermined DR. The basic mechanism for ampli- tude envelope DR compression in the present study is similar to that developed in Loizou et al. (2000)-that is, experi- menters use a linear transform to convert the range of the input amplitude envelope to a smaller range of the output amplitude envelope. However, the main differences lie in (a) how the minimum envelope amplitude of the input signal is determined and (b) how the linear transform is designed.

To determine the minimum and maximum amplitude values of the temporal envelopes in the spectral channels (denoted as X,,,,·,, and Xmax, respectively), we computed the histograms for the amplitudes of the temporal envelopes using the 240 sentences in the MHINT database. Xmax was selected to include 99% of all sorted amplitude counts, and Xmin was selected to include 1% of all sorted amplitude counts in ascending order. The amplitude envelope compression was conducted as follows: Let x and v denote the input and output amplitude envelopes, respectively. The compressed output amplitude envelope v was computed as

... (1)

where χ is the mean of the input amplitude envelope x, and ? is a constant (i.e., the compression factor) chosen in order for the output amplitude envelope to fall within a certain DR-that is,

... (2)

where Ymax and Ymill indicate the maximum and minimum output amplitude values, respectively. It is clear that the mean value of the output amplitude envelope equals the mean value of the input amplitude envelope (i.e., v = χ), regard- less of the value of DR selected; in contrast, the approach in Loizou et al. (2000) yielded different vs for different DR values. Combining Equations (1) and (2), the compression factor ? can be obtained as

... (3)

To summarize, we performed the compression of the amplitude envelope by first computing the ? value given the DR value using Equation (3), and then ? was used in Equa- tion (1) to map the input amplitude envelope x to the output amplitude envelope v. Figure 1 shows the relationship be- tween the values of the averaged targeted DR and the values of the compression factor a, computed from the 240 sentences taken from the MHINT database. It is noted that when a equals 0 in Equation (1), the compressed amplitude envelope becomes a direct current signal with a constant value of χ (i.e., v = x), and the DR is 0 dB; alternatively, when ? equals 1 in Equation (1), the output amplitude envelope keeps the original DR of the input amplitude envelope. Figure 2 shows the histograms for the DR values of the amplitude envelopes of the eight spectral channels computed from the 240 vocoded MHINT sentences for different values of a, which takes the value of 1/13, 1/5, and 1/3 in Figures 2A, 2B, 2C, and 2D, respectively. Figure 2D shows that the input amplitude envelopes across the eight spectral channels have a DR be- tween around 40 to 80 dB, showing a nearly normal distri- bution with a mean value around 60 dB; similarly, the output amplitude envelopes have a mean DR value of around 5,10, and 15 dB in Figures 2A, 2B, and 2C, respectively. Figure 2 also shows the plots (i.e., dotted lines) of fitting the histograms of the envelope DR values using normal-distribution functions with parameter values of mean (μ) and standard deviation (σ).

Signal Processing

An eight-channel noise vocoder was used in the vocod- ing processing in this study. We did this because Friesen, Shannon, Baskent, and Wang (2001) showed that, despite the relatively large number (16-22) of electrodes available, most CI users receive only a limited number (i.e., up to eight) of channels of spectral information. In implementing the eight- channel noise vocoder, the corrupted Mandarin speech materials were first processed through a pre-emphasis high- pass filter (2000-Hz cutoff) with a 3-dB/octave rolloff and then

were band-pass filtered into eight frequency bands be- tween 80 and 6000 Hz using sixth-order Butterworth filters. We used the equivalent rectangular bandwidth scale (Glasberg &Moore, 1990) to allocate the eight channels with the specific bandwidth (see Table 1). The temporal envelope of each spectral channel was extracted by full-wave rectification fol- lowed by low-pass filtering using a second-order Butterworth filter with a cutoff frequency of 160 Hz. The envelope of each frequency band was then compressed to the pre-set DR (e.g., a = 1/5 for compressing the envelope DR to 10 dB; see Figure 2B) and was used to modulate a white-noise signal, followed by band-limiting using the same Butter- worth band-pass filters. The envelope-modulated noises of each band were finally summed up, and the level of the syn- thesized speech was adjusted to yield the same rms value as that of the original speech.

To simulate DR mismatch across the two implanted ears, the right ear was presented with the eight-channel noise-vocoded stimuli that were compressed into 15-dB DR, whereas the left ear was presented with the eight-channel noise-vocoded stimuli that were compressed into 5-, 10-, and 15-dB DR, respectively. Note that the 15-dB DR was used because researchers have found that the electrical DR was about 15 dB for CI listeners (Zeng et al., 2002). The three processing conditions described above are referred to as R15_L5, R15_L10, and R15_L15, respectively, where R and L denote the right and left ears, respectively. As the control condition, we implemented the condition R15_L0, which presented only to the right ear the eight-channel noise- vocoded stimuli that were compressed into 15-dB DR.

Note that, because the amplitude of the white noise was not constant, using white noise as the carrier signal might introduce undesirable change to the DR of the envelope- modulated noise in each frequency band, although the en- velope DR prior to modulating the white-noise signal (i.e., the DR of envelope .!') was controlled following Equations (1) and (3). However, we did not expect the simulations in this study to accurately predict CI listeners' speech perception perfor- mance with various DRs; rather, we wanted to explore the effects of DR mismatch on binaural summation benefits of speech intelligibility in simulated bilateral electric hearing. In contrast, because of the constant amplitude of the sinu- soidal carrier signal, a sinusoid vocoder may be selected in future studies. Further investigation is warranted, in which researchers compare the effects of envelope DRs on speech intelligibility between noise-vocoded and sinusoid-vocoded speech.

Procedure

The experiment was performed in a soundproof booth, and stimuli were played to listeners through a set of Sennheiser HD 250 Linear II circumaural headphones at a comfort- able listening level. Prior to the test, in order to become familiar with the vocoded stimuli and the testing procedure and conditions, each subject participated in a 20-min practice session and listened to the noise-vocoded speech with both matched and unmatched DRs in the temporal envelopes across the two ears. Each subject participated in eight testing conditions (i.e., two SNR levels x four processing conditions) in both Mandarin sentence recognition and tone identifica- tion tests. The order of the eight testing conditions was ran- domized across subjects. For the Mandarin sentence test, a total of 20 Mandarin sentences were used per condition, and none of the sentences were repeated across various testing conditions. The subjects were instructed to write what they heard on the response sheets, and they were allowed to repeat the stimuli only once. The subjects were also instructed to guess when they were unsure about what they heard. For the Mandarin tone test, each condition consisted of two presentations of each vowel stimulus spoken by a male talker and a female talker, and each subject listened to a total of 96 randomized vowel stimuli (i.e., two repetitions x two speakers χ six vowels χ four tones) per condition. The Mandarin tone responses were collected with custom soft- ware through the use of a computer display of response alternatives and a mouse as a response key. The subjects were allowed to use a repeat key as many times as they wished to repeat the presentations of the test stimuli during the tone test. We calculated the percent correct score for each condition by dividing the number of words or tones correctly identified by the total number of words or vowel stimuli presented, respectively. Subjects were given a 5-min break every 30 min during the test.

Results

Figure 3A shows the mean percent correct scores of Mandarin sentence recognition for all conditions at different SNRs. We determined statistical significance by using the percent correct score as the dependent variable and using SNR levels and processing conditions as the two within- subjects factors. Two-way analysis of variance (ANOVA) with repeated measures indicated a significant effect of SNR level, i*U, 9) = 601.7, ρ <.0005; a significant effect of DR, F(3, 27) = 12.0, ρ <.0005; and a nonsignificant SNR Level x Dynamic Range interaction, F(3, 27) = 1.63,;; = .206. Sig- nificant improvement in intelligibility was observed when lis- teners had access to the binaural vocoded stimuli with the same envelope DR (i.e., condition R15_L15) across the two ears, compared with the binaural stimulation with unmatched en- velope DR (i.e., conditions R15_L10 and R15_L5). For in- stance, the improvement with the R15_L15 stimuli relative to the R15_L5 stimuli ranged from 15 percentage points at 5 dB SNR to 9 percentage points at 0 dB SNR. Furthermore, post hoc pairwise comparisons revealed a significant binaural benefit only for the condition R15_L15 (ρ <.05), compared with the condition R15_L0, in which the vocoded stimuli were presented unilaterally to the right ear. When the enve- lope DRs were not matched between the ears (i.e., conditions R15_L10 and R15_L5), there was no performance improve- ment with bilateral stimulation over condition R15_L0.

The results from the tone identification are shown in Figure 3 ? and are not quite similar to those observed from sentence recognition in Figure 3A. A two-way ANOVA with repeated measures indicated a nonsignificant effect of SNR level, i*U, 9) = 1.51, = .255; a (weakly) significant effect of envelope DR, F(3, 27) = 6.04, ρ = .04; and a nonsignifi- cant SNR Level x Envelope Dynamic Range interaction, F(3, 27) = 0.50, ρ = .685. Furthermore, post hoc pairwise comparisons revealed a significant binaural benefit only for the condition R15_L15 (ρ <.05) at 0 dB SNR, compared with the condition R15_L0, in which the vocoded stimuli were presented unilaterally to the right ear. Again, when the envelope DRs were not matched across ears (i.e., conditions R15_L10 and R15_L5), there were no significant binaural benefits over unilateral hearing (i.e., condition R15_L0) at both 5 and 0 dB SNR.

Discussion and Conclusions

A prominent feature of the proposed compression scheme is that the probability distribution of the input-amplitude DR is more or less retained in the output-amplitude DR. As can be seen in Figure 2, the nearly normal distribution shown in subplot D for the original DR is mostly kept intact in subplots ? and C (for the compressed DRs of 10 and 15 dB, respectively), except that the mean and standard deviation values are reduced accordingly due to the compression; sub- plot A shows that the DR distribution for the compressed DR of 5 dB is skewed toward lower values and slightly deviates from the normal distribution. In contrast, the compression scheme in Loizou et al. (2000) used arbitrarily set minimum values of input and output amplitudes; as a consequence, as shown in Figure 3 of that article, the DR values of the com- pressed envelope amplitudes heavily tilted toward lower numbers, which might lead to artificially introduced distor- tion in the test stimuli, thereby underestimating the speech recognition performance. It is worthwhile to point out that both compression schemes used in the present study and Loizou et al. (2000) are based on linear transforms, which differ from the logarithmic compression typically used in CIs. In order to match the loudness growth between electric stim- ulation and acoustic stimulation (Zeng &Shannon, 1992), CI processing typically uses logarithmic compression, as the loudness growth in acoustic stimulation of the auditory sys- tem features a power function of physical intensity of the sound. Because our simulation study used acoustic stimula- tions involving the typical peripheral auditory system, the perceived loudness of the stimuli by NH listeners had a loga- rithmic relationship with the rms values of the stimuli. In other words, a linear transform would be more appropriate for our acoustic simulation study, although there would be differences between the loudness growth in our study and that in electric hearing. To our understanding, a logarith- mic transformation would skew the DR distribution toward higher values, and as a consequence, the DR distribution would deviate away from the nearly normal distribution in the original envelopes. In the acute-testing setup, a loga- rithmic transform might lead to more practice time, but with that exception, we would expect results to be similar to those using a linear transform.

Certainly in future studies, nonlinear compression schemes warrant further investigation.

The findings of this study suggest that Mandarin tone identification may be robust to noise interference (i.e., at least for steady-state noise (SSN) maskers of 5- to 0-dB SNR levels) when the amplitude envelopes are compressed to a smaller DR (e.g., DR =15 dB). Outcomes from other studies have reported the relatively small effect of spectral manipula- tions on Mandarin tone identification performance. For in- stance, Fu et al. (1998) found that when the spectral resolution in the noise-vocoder simulation was altered from η = 1 to η = 4, the identification of Mandarin tones was almost con- sistent-that is, around 60% and 80% with envelope filter cutoff frequencies of 50 and 500 Hz, respectively. Zhou and Xu (2008) simulated the effect of mismatched spectral dis- tribution of envelopes on Mandarin tone recognition using a noise vocoder; they found that spectral shift might not pose a severe problem for tone recognition when the carrier bands are shifted basally relative to the analysis bands by 1-7 mm in the cochlea. To some extent, the present result is consistent with previous findings on the relative robustness of Mandarin tone recognition when compared to performances recogniz- ing other speech components (e.g., phonemes and sentences). Chen et al. (2012) suggested that the smaller effects of noise on Mandarin tone recognition than on speech recognition might be partially due to (a) the favorable local SNRs of vowel segments where lexical tones were located and (b) a higher chance level for tone identification (i.e., 25%) than for con- sonant or vowel recognition. In addition to these factors, we believe that another factor for the relatively unchanged per- formance of Mandarin tone recognition across the three DR conditions may be the severe degradation of the temporal amplitude contour cues used for tone recognition, such that there was very little difference in the availability of this cue across the three reduced DRs tested. Many studies suggested that CI listeners used temporal amplitude contour and peri- odicity cues for tone identification (Fu &Zeng, 2000; Fu et al, 1998; Yuan et al., 2009). The envelope filter cutoff frequency was set to 160 Hz in the present study because researchers have used this setting in other acoustic simulation studies to inves- tigate the performance of Mandarin tone identification (see, e.g., Chen et al., 2012; Zhou &Xu, 2008). Nevertheless, using a relatively low cutoff frequency to extract temporal amplitude envelope means that listeners relied primarily on the limited temporal cues (e.g., tonal amplitude envelope/contour; Fu et al., 1998) for tone identification. Further analysis revealed that when the amplitude envelope was compressed to a smaller DR (e.g., 15 dB), the distinction among the amplitude contours of four Mandarin tones was reduced, which made it difficult for listeners to obtain sufficient amplitude contour information for reliable tone identification. Figure 4 illustrates the am- plitude contours of a recording of the Mandarin Chinese vowel /a/ in quiet and at three DRs: the original range, 15 dB, and 10 dB. It is seen in Figure 4A that the amplitude contours of four lexical tones are notably different, with each repre- senting the F0 contours of four Mandarin tones accordingly. However, when the DR of amplitude envelope was com- pressed to 15 dB and 10 dB in Figures 4B and 4C, respectively, it is clear that the difference among the four amplitude con- tours is not as salient as that observed in Figure 4A (i.e., with the original DR). This diminished distinction among ampli- tude contours at a smaller DR might also partially account for the lower and relatively consistent recognition scores of Mandarin tones in Figure 3B. Note that further study is needed, in which researchers investigate how the periodicity cues and DR would interact with one another to influence the performance of tone recognition.

Furthermore, the reduced DR might also damage the formant representation in vowels and other temporal enve- lope cues beneficial for phoneme recognition (Fu &Zeng, 2000; Fu et al., 1998; Loizou et al., 2000). Hence, comparing the recognition scores in Figure 3 of the current article with those in Figure 1 of Chen et al. (2012), it is not surprising to see that, for the same eight-channel noise-vocoding processing and the same testing materials, the proposed compression scheme reduced the unilateral sentence and tone recognition perfor- mance by about 27%-36% and 14%-24%, respectively, when the amplitude envelope DR was compressed from (the origi- nal) 60 dB to 15 dB.

In conclusion, in the present study we assessed the effects of envelope DR mismatch on the binaural summation benefits for Mandarin speech intelligibility in simulated bi- lateral electric hearing with an improved

DR compression scheme. It is important to note that because this is an NH- based acoustic simulation study that involved "ideal" as- sumptions unlikely to hold in actual patients with bilateral CIs, caution should be used in interpreting the present findings, and a follow-up study with bilateral CI users is needed to verify these results (e.g., the testing conducted was acute and was not performed after long-term experience with the mis- matched DRs, and we do not yet understand how CI users adapt their DR mapping after long-term use; in addition, there are many confounding factors in electric hearing such as the depth of electrode insertion, neuron survival patterns, and current spread). With this in mind, in this article we examine the implications of the present study. Consistent with previ- ous findings on the binaural summation benefits for English materials (see, e.g., Litovsky, Parkinson, 2006; Yoon et al., 2011; Yoon, Liu, &Fu, 2011), as well as those on the effects of spectral resolution mismatch for Mandarin speech materials (Chen et al., 2012), the present results suggest that the sentence perception performance of binaural CI listening in noise is affected by the difference of envelope DRs between the two ears, and binaural summation benefits are maximized with matched DRs in the two implanted ears. In addition, the present study shows that in the context of compressed envelope amplitudes, tone identification in steady-state SSN is steadier than sentence recognition, suggesting that tone identification performance in noise might not predict sentence recognition performance in unilateral and bilateral CIs.

Abstract: [...]a digital signal resulting from the AD conversion is first split into a multiple frequency bands by bandpass filters, and then at each frequency band the signal is processed via a digital filter with a gain being increased or decreased according to the auditory characteristics of a hard-of-hearing person.

Full text: 2013 JUL 30 (VerticalNews) -- By a News Reporter-Staff News Editor at China Weekly News -- From Alexandria, Virginia, VerticalNews journalists report that a patent by the inventors Yamamoto, Yutaka (Kyoto, JP); Nagahara, Masaaki (Kyoto, JP), filed on August 3, 2009, was published online on July 16, 2013.
The patent's assignee for patent number 8488823 is Kyoto University (Kyoto, JP).
News editors obtained the following quote from the background information supplied by the inventors: "When viewed worldwide, the number of hard-of-hearing persons is supposed to be increasing. Hearing loss is categorized into conductive hearing loss, sensorineural hearing loss and mixed hearing loss that includes both thereof, depending on a part of disorder in the auditory system. A character given as common to these categories of hearing loss is incapability of or difficulty in sensing a certain frequency band of sounds that a hard-of-hearing person wants to hear.
"The miniaturization and speed-up of digital signal processing processors (DSP) in recent years have enhanced freedom in designing hearing aids, and thus have caused the mainstream of the hearing aids to shift from analog to digital.
"Currently, a method commonly used in audio signal processing for digital hearing aids is a multi-channel method using the conventional signal processing theory. In this method, first, an analog audio signal that comes

in from a microphone is passed through a microphone amplifier, and then is subjected to an AD-conversion process.
"Secondly, a digital signal resulting from the AD conversion is first split into a multiple frequency bands by bandpass filters, and then at each frequency band the signal is processed via a digital filter with a gain being increased or decreased according to the auditory characteristics of a hard-of-hearing person.
"The divided frequency bands are then resynthesized.
"And finally, the signal undergoes a DA-conversion process and then is outputted as an analog audio signal from a speaker by way of a speaker amplifier.
"In relation to this, references related to the present invention include patent literature 1, 2 as cited below. The patent literature 1, 2 below are attributable to the present inventor(s), where the patent literature 1 discloses a method for designing a digital filter according to sampled-data H.infin. control theory, whereas the patent literature 2 discloses a sampling rate conversion device designed according to sampled-data H.infin. control theory.
"[Citation List]
"[Patent Literature]
"Patent Literature 1 Japanese Patent Gazette No. 3,820,331
"Patent Literature 2 Japanese Patent Gazette No. 3,851,757"
As a supplement to the background information on this patent, VerticalNews correspondents also obtained the inventors' summary information for this patent: "The multi-channel method described as above requires an adjustment by which frequency characteristics of the digital filter is tailored to each hard-of-hearing person so as to carry out an audiometry to the hard-of-hearing person and then to increase or decrease the gain on each of the divided frequency bands.
"Adjusting and optimizing a hearing aid to its user with hearing loss involve trial and error, and therefore troublesome.
"An objective of the present invention is to provide a novel technology for designing a hearing aid that is more appropriate to a hard-of-hearing person, an audio signal processing system therefor and a hearing aid therewith.
"The present invention is a method for designing an audio signal processing system for a hearing aid,
"wherein the system comprises
"an AD converter for converting an analog audio input signal (y.sub.c) inputted to the hearing aid into a digital audio input signal;
"a hearing aid digital filter (K(z)) for performing a signal processing on the digital audio input signal outputted from the AD converter; and
"a DA converter for converting a digital signal outputted from the hearing aid digital filter into an analog audio output signal (u.sub.c) to be outputted to a hard-of-hearing person; and
"wherein the hearing aid digital filter (K(z)) is designed according to sampled-data control theory so as to reduce an error (e.sub.c) occurring between a restored analog signal (z.sub.c) obtained by filtering the analog audio output signal (u.sub.c) outputted from the DA converter through an analog filter (P(s)) that has characteristics corresponding to auditory characteristics of the hard-of-hearing person and
"the analog audio input signal (y.sub.c) inputted to the hearing aid.
"In conventional digital hearing aids, as set forth above, the audio signal processing has been performed within the framework of the multi-channel method or methods based on other signal processing theories.
"In contrast, the present inventors have conceived a new idea to contemplate an audio signal processing for a digital hearing aid within the framework of control theory, the idea being completely different from the conventional methods for designing digital hearing aids.
"Here, in the field of control theory, sampled-data control theory has been established for digitally controlling an

analog control object.
"In this context, the present inventors arrived at the conception that a technique of sampled-data control can apply to design of a hearing aid when a sound input/output system including an auditory analog characteristics of a hard-of-hearing person is assumed as an analog control object.
"In other words, it may be said that a hearing aid is a device to recover the auditory perception of a hard-of-hearing person by adjusting a certain frequency band in a sound to the auditory characteristics of the hard-of-hearing person.
"Stated differently, when assuming a signal system in which a hearing aid and auditory characteristics of a hard-of-hearing person are combined, it can be said that the function of a hearing aid is to match a sound that the hard-of-hearing person can recognize through his or her auditory perception with the sound that is inputted to the hearing aid as much as possible, and thus to reduce the error lying between them.
"Therefore, it may be said that an appropriate design of a hearing aid is identical with designing of a digital filter with which a difference (an error) between the sound that is inputted to the hearing aid and the sound that a hard-of-hearing person can recognize through his or her auditory perception is diminished in the sound input/output system that includes the auditory characteristics of the hard-of-hearing person.
"The present invention was achieved based on the above-mentioned conception. According to the present invention, by assuming a signal restoration system by which a restored analog signal is generated by filtering an analog audio output signal outputted from the DA converter through an analog filter having characteristics corresponding to auditory characteristics of a hard-of-hearing person, an appropriate digital filter can theoretically be designed based on existing sampled-data control theory.
"Here, for auditory characteristics of a hard-of-hearing person, either auditory characteristics obtained from a measurement on an individual hard-of-hearing person or auditory perception characteristics that are generally assumable may be used.
"For the aforesaid existing sampled-data control theory, sampled-data H.infin. control theory is preferable. However, it may be other design methods in sampled-data control theory, for example, sampled-data H.sup.2 control theory.
"Moreover, it is preferred that the audio signal processing system further comprises
"an anti-aliasing filter for performing anti-aliasing on a digital audio input signal outputted from the AD converter,

"a downsampler for performing a downsampling on an output from the anti-aliasing filter, and
"an upsampler for restoring a sampling rate that was lowered by the downsampler, wherein
"the hearing aid digital filter is for performing the signal processing on a digital audio input signal outputted from the upsampler.
"By employing the configuration as described above, high frequency sound which is a problem for the conventional hearing aids can be eliminated. That is, a 'high frequency noise having peak property such as the one occurring when hard substances clash' has been a harsh sound in the conventional hearing aids. However, with the above described configuration, after removing the high frequency noise having peak property that causes harsh sounds and then by means of the hearing aid digital filter, an appropriate signal processing can be performed based on the auditory characteristics of the hard-of-hearing person, to give a hearing aid that generates a more natural sound.
"From another viewpoint, the present invention is an audio signal processing system for a hearing aid, the system comprising
"an AD converter for converting an analog audio input signal inputted to the hearing aid into a digital audio input signal,
"a hearing aid digital filter for performing a signal processing of the digital audio input signal outputted from the AD converter,

"a DA converter for converting the digital signal outputted from the hearing aid digital filter into an analog audio output signal to be outputted to a hard-of-hearing person,
"wherein the hearing aid digital filter is designed according to sampled-data control theory so as to reduce the error between
"a restored analog signal obtained by filtering an analog audio output signal outputted from the DA converter through an analog filter that has characteristics corresponding to auditory characteristics of the hard-of-hearing person, and
"the analog audio input signal to the hearing aid.
"From yet another viewpoint, the present invention is a hearing aid including the audio signal processing system.
"According to the present invention, a hearing aid digital filter can be theoretically designed."

Gn Resound A/s; Agency Reviews Patent Application Approval Request for "Hearing Aid with Signal Enhancement"

Publication info: Electronics Newsweekly (Jul 24, 2013): 3893.
ProQuest document link

Abstract: From the background information supplied by the inventors, news correspondents obtained the following quote: "Hearing impaired individuals often experience at least two distinct problems: a hearing loss, which is an increase in hearing threshold level, and a loss of ability to understand high level speech in noise in comparison with normal hearing individuals.

Full text: 2013 JUL 24 (VerticalNews) -- By a News Reporter-Staff News Editor at Electronics Newsweekly -- Gn Resound A/s has been issued patent application serial number 343428, according to news reporting originating out of Washington, D.C., by VerticalNews editors.
The patent's inventors are Gran, Karl-Fredrik Johan (Malmo, SE); Dittberner, Andrew Burke (Antioch, IL).
This patent application was filed on January 4, 2012 and was made available online on July 11, 2013.
From the background information supplied by the inventors, news correspondents obtained the following quote: "Hearing impaired individuals often experience at least two distinct problems: a hearing loss, which is an increase in hearing threshold level, and a loss of ability to understand high level speech in noise in comparison with normal hearing individuals. For most hearing impaired patients, the performance in speech-in-noise intelligibility tests is worse than for normal hearing people, even if the audibility of the incoming sounds is restored by amplification. An individual's speech reception threshold (SRT) is the signal-to-noise ratio required

in a presented signal to achieve 50 percent correct word recognition in a hearing in noise test.
"Today's digital hearing aids that use multi-channel amplification and compression signal processing can readily restore audibility of amplified sound for a hearing impaired individual. The patient's hearing ability can thus be improved by making previously inaudible speech cues audible.
"Loss of capability to understand speech in noise is accordingly the most significant problem of most hearing aid users today. The traditional way of increasing SRT in hearing instruments, is to apply either beamforming or spectral subtraction techniques.
"In the first case, at least one microphone in combination with a number of filters, fixed or adaptive, is used to enhance a signal from the presumed target direction and at the same time suppress all other signals.
"In spectral subtraction techniques, the goal is to create an estimate of the long term noise spectrum and turn down gain in frequency bands where the instantaneous target signal power is lower than the long term noise power. Even though the methods are very different from a technological standpoint, they still have the common goal; enhance the target signal and remove the noise disturbance.
"The methods cannot take listener intent into account and they may remove parts of the audio signal which the listener is trying to focus on."
Supplementing the background information on this patent application, VerticalNews reporters also obtained the inventors' summary information for this patent application: "Below, a new method of enhancement of a desired signal is disclosed. The new method makes use of the human auditory system's capability of concentrating on a desired signal. A new binaural hearing aid system using the new method is also disclosed.
"Listening in complex sound fields is to a large extent facilitated by binaural processing in the auditory system. Due to diffraction effects by the pinna, concha, head and torso and due to reflection effects in reverberant environments, cues are imparted to the sound field, which are highly individual for the given subject.
"The most important cues in binaural processing are the interaural time differences (ITD) and the interaural level differences (ILD). The ITD results from the difference in distance from the source to the two ears. This cue is primarily useful up till approximately 1.5 kHz and above this frequency the auditory system can no longer resolve the ITD cue.
"The level difference is a result of diffraction and is determined by the relative position of the ears compared to the source. This cue is dominant above 2 kHz but the auditory system is equally sensitive to changes in ILD over the entire spectrum.
"It has been argued that hearing impaired subjects benefit the most from the ITD cue as the hearing loss tends to be less severe in the lower frequencies.
"It has been shown that manipulating the relative interaural phase and level of a target signal, i.e. a signal a listener desires to listen to, and of a noise signal, i.e. a signal the listener perceives as disturbing, can improve speech intelligibility significantly. It seems as if the auditory system is indeed adapted to separate signals with different ITD and ILD encoding to perform a natural type of noise reduction to facilitate focusing on the target signal.
"It has been found that if the target signal is presented in anti-phase, i.e. phase shifted 180.degree., and the noise in-phase in the two ears, an increase of the Binaural Masking Level Difference (BMLD) of 13 dB can be achieved compared to when both signals are presented in-phase in the two ears. Depending on the type of noise, an improvement of 20 dB of the BMLD is achievable.
"The reverse situation where noise is presented out of phase and the target is presented in phase yields a slightly lower performance.
"In the new method, at least one of the target signal and the noise signal is estimated, and the at least one estimate is presented to the user of the binaural hearing aid system in such a way that a user's capability of understanding speech in noise is improved.
"For example, a listener may listen to sound with a signal S that the listener desires to listen to and noise N that

the listener finds disturbing, i.e. the sound signal is S+N.

"Based on the sound signal S+N, the desired signal S may be estimated. The estimate is denoted ES. Subtracting two times the estimate ES from the sound signal S+N results in a modified signal: S+N-ES-ES, and since ES is approximately equal to S, modified signal is: N-ES which is approximately equal to -S+N, i.e. the original sound signal wherein the desired signal S has been substantially substituted with signal S phase shifted by 180.degree.. Now, the original signal S+N may be presented to one ear of a user, and the phase shifted signal N-ES, or more accurately S+N-2ES, may be presented to the other ear for improved BMLD and SRT.

"Alternatively, both the desired signal S and the noise N may be estimated and the sum of the estimates ES+EN may be presented to one ear of the user, and the phase shifted sum -ES+EN may be presented to the other ear for improved BMLD and SRT.

"The desired signal S and the noise may be swapped so that the noise estimated is phase shifted instead of the desired signal for improved BMLD and SRT; however with decreased performance compared to phase shifting the desired signal S.

"Noise can be background speech, restaurant clatter, music (when speech is the desired signal), traffic noise, etc.

"The purpose for the method is not to remove any part of the signal but instead present the signals so that the auditory system can perform natural noise reduction and separate the target signal from the noise signal.

"In this way, if for some reason (e.g. the presumed target direction is wrong, or the unit is not able to achieve sufficient target/noise separation, the target signal and the noise signal are swapped; enhancement of the target signal is still obtained, although with slightly decreased performance.

"This would not be possible with traditional noise reduction techniques, since the target signal, which in this case would be assumed to be the noise would be suppressed.

"Thus, a new binaural hearing aid system is provided, comprising

"at least one microphone for provision of respective at least one microphone audio signal in response to sound received at the at least one microphone, a signal separation unit configured to provide an estimate of one of a target signal and a noise signal based on the at least one microphone audio signal, a phase shift circuit configured to phase shift the estimate of one of the target signal and the noise signal, and a phase shift adder connected to provide a phase shifted signal representing sound received at the at least one microphone in which the estimate of one of the target signal and the noise signal has substantially substituted the respective original one of the target signal and the noise signal, and a first receiver for conversion of a receiver input signal into an acoustic signal for transmission towards one of the eardrums of a user of the binaural hearing aid system, and a second receiver for conversion of a receiver input signal into an acoustic signal for transmission towards the other one of the eardrums of the user, and wherein the receiver input of one of the first and second receivers is connected to a signal representing the phase shifted signal, and the receiver input of the other one of the first and second receivers is connected to a signal representing sound received at the at least one microphone.

"Further, a new method is provided of binaural signal enhancement in a binaural hearing aid system, the method comprising the steps of

"providing at least one microphone audio signal in response to sound, and providing an estimate of one of a target signal and a noise signal based on the at least one audio signal, phase shifting the estimate of one of the target signal and the noise signal, and providing a phase shifted signal representing the at least one microphone audio signal in which the phase shifted estimate of one of the target signal and the noise signal has substantially substituted the respective original one of the target signal and the noise signal, and transmitting a signal representing the phase shifted signal towards one of the eardrums of a user of the binaural hearing aid system, and transmitting a signal representing the at least one microphone audio signal towards the other one of the eardrums of the user.

"In the event that the estimate of one of the target signal and the noise signal is equal to the corresponding original one of the target signal and the noise signal, the phase shifted estimate can exactly substitute the respective original signal; however typically, the estimate of a signal will deviate from the original signal and substitution of the original signal with its estimate will typically not lead to substitution of the deviation, and thus the estimate is said to substantially substitute the original signal.

"Throughout the present disclosure, one signal is said to represent another signal when the one signal is a function of the other signal, for example the one signal may be formed by analogue-to-digital conversion, or digital-to analogue conversion of the other signal; or, the one signal may be formed by conversion from another acoustic signal to an electronic signal or vice versa; or the one signal may be formed by analogue or digital filtering or mixing of the other signal; or the one signal may be formed by transformation, such as frequency transformation, etc, of the other signal; etc.

"Further, signals that are processed by specific circuitry, e.g. in a signal processor, may be identified by a name that may be used to identify any analogue or digital signal forming part of the signal path from the source of the signal in question to an input of the circuitry, e.g. signal processor, in question. For example an output signal of a microphone, i.e. the microphone audio signal, may be used to identify any analogue or digital signal forming part of the signal path from the output of the microphone to its input to the signal processor, including pre-processed microphone audio signals.

"The at least one microphone may contain a single microphone; however preferably, the at least one microphone has two microphones. Further, the at least one microphone may have more than two microphones for improved separation of the target signal and the noise signal.

"For improved signal enhancement, the second hearing aid may also comprise at least one microphone for provision of microphone audio signals in response to sound received at the respective microphones. In this case, the transceiver of the first hearing aid is connected for reception of signals representing the microphone audio signals of the second hearing aid, and the signal separation unit is configured to provide the estimate of the target signal and the estimate of the noise signal based on the audio signals of the first and second hearing aids.

"Preferably, the phase shift circuit phase shifts the estimate of the target signal, and preferably, the phase shift ranges from 150.degree. to 210.degree., more preferred the phase shift is approximately equal to 180.degree., and most preferred equal to 180.degree.

"The signal separation unit may be configured to provide the estimates based on spectral characteristics of the audio signals as is well-known in the art of noise reduction. However, according to the new method, the noise estimate is not suppressed in the output presented to the user; rather the target estimate and the noise estimate is presented to the user in a way that improves the user's SRT.

"The signal separation unit may be configured to provide the estimates based on statistical characteristics of the audio signals as is well-known in the art of noise reduction. However, according to the new method, the noise estimate is not suppressed in the output presented to the user; rather the target estimate and the noise estimate is presented to the user in a way that improves the user's SRT.

"The signal separation unit may comprise a beamformer, and the beam former may be configured to provide the estimates based on microphone audio signals of the first and second hearing aids. The beamformer of the signal separation unit is different from conventional beamformers in that the noise estimate is not suppressed in the output presented to the user; rather the target estimate and the noise estimate is presented to the user in a way that improves the user's SRT.

"The beamformer combines the microphone audio signals output by a plurality of microphones of the at least one microphone into a target signal with varying sensitivity to sound sources in different directions in relation to the plurality of microphones. Throughout the present disclosure, a plot of the varying sensitivity as a function of the direction is denoted the directivity pattern. Typically, a directivity pattern has at least one direction wherein

the microphone signals substantially cancel each other. Throughout the present disclosure, such a direction is denoted a null direction. A directivity pattern may comprise several null directions depending on the number of microphones in the plurality of microphones and depending on the signal processing.

"The beamformer may be a fixed beamformer with a directional pattern that is fixed with relation to the head of the user. The beamformer may for example be based on at least two microphones, with a directional pattern that has a maximum in the front direction of the user, i.e. the forward looking direction of the user, and a null in the opposite direction, i.e. the rear direction of the user.

"The beamformer may be based on more than two microphones, and may include microphones of both hearing aids using wireless or wired communication techniques. The increased distance between the microphones may be utilized to form a directional pattern with a narrow beam providing improved spatial separation of the target estimate from the noise estimate. The conventional output of the beamformer may be used as the target estimate, and the noise estimate may be provided by subtraction of the target estimate from the microphone audio signal of one of the microphones of the plurality of microphones.

"When microphones of both hearing aids of the binaural hearing aid system cooperate with the beamformer, the respective microphone signals must be sampled substantially synchronously. Time shifts as small as 20-30 .mu.S between sampling instants of the respective microphone signals in the two hearing aids may lead to a perceivable shift in the beam direction. Furthermore, a slowly time varying time shift between the sampling instants of the respective microphone signals, which inevitably will occur if the hearing aids are operated asynchronously, will result in an acoustic beam that appears to drift and focus in alternating directions.

"Thus, the hearing aids of the binaural hearing aid system may be synchronized as for example discloses in more detail in WO 02/07479.

"The beamformer may comprise adaptive filters configured to filter respective microphone audio signals and to adapt the respective filter coefficients for adaptive beamforming towards a sound source. For example, the beamformer may adapt to optimize the signal to noise ratio.

"An adaptable beamformer makes it possible to focus on a moving sound source or to focus on a non-moving sound source, while the user of the hearing aid system is moving. Furthermore, the adaptable beamformer is capable of adapting to changes in the sound environment, such as appearance of a new sound source, disappearance of a noise source or movement of noise sources relative to the user of the hearing aid system.

"An adaptive beamformer may be designed under the assumption that the signals received at the at least one microphone can be modelled as a combination of a target signal from a pre-determined target direction plus noise:

"y.sub.i(n)=h.sub.i(n)*s(n)+v.sub.i(n)

"where h.sub.i(n) is the impulse response of sound propagation from the source emitting the signal s(n) to the i.sup.th microphone and v.sub.i(n) is the noise signal at the same microphone. The noise can consist of both directional noise and other types of noise such as diffuse noise or babble noise.

"The filter coefficients may adaptively be determined by solving the following optimization problem:

"{ a i (n) } i = 1 4 = arg min { a i (n) } i = 1 4 z (n) 2 ##EQU00001## subject to i = 1 4 a i (n) * h i (n) = h 1 (n) ##EQU00001.2##

"Finding a solution to this optimization could be done adaptively using least mean square, recursive least square, steepest descent or other types of numerical optimization algorithms.

"Once the target and noise estimate has been determined, the signals are presented to the user in such a way that the SRT of the user is improved.

"Preferably, the target estimate is presented in opposite phase, i.e. 180.degree. phase shifted with relation to each other, at the two ears of the user, while the noise estimate is presented in phase at the two ears of the user. Thus, in the first hearing aid, a first adder may be connected to the signal separation unit, and output a sum of the target estimate and the noise estimate provided by the signal separation unit, and the output of the

first adder may be connected to a signal processor for further processing, such as hearing loss compensation, and the output of the signal processor may be connected to an output transducer that outputs a corresponding output to one ear of the user, or the output of the first adder may be connected directly to the output transducer. A second adder may be connected to the signal separation unit, and output a sum of the reverse phases target estimate and the noise estimate provided by the signal separation unit, and the output of the second adder is connected to a transceiver that transmits the output of the second adder to the other hearing aid having a transceiver for reception of the output of the second adder. The output of the transceiver may be connected to a signal processor for further processing, such as hearing loss compensation, and the output of the signal processor may be connected to an output transducer that outputs a corresponding output to another ear of the user, or the output of the transceiver may be connected directly to the output transducer.

"Instead, with somewhat reduced performance in improved SRT of the user, the noise signal may be presented in opposite phase, i.e. 180.degree. phase shifted with relation to each other, at the two ears of the user, while the target estimate is presented in phase at the two ears of the user.

"Preferably, the first hearing aid includes a delay between the adder and the output transducer so that the relative phase of the signals output by the respective output transducers of the first and second hearing aids is maintained.

"The improvement of SRT as a function of the phase shift has a maximum at 180'; however the function is sine-shape with a flat maximum so that the improvement obtained by a phase shift ranging from 150.degree. to 210.degree. is close to the maximum improvement. Thus, the phase shift need not be exactly 180.degree., but preferably has a value within the range from 135.degree. to 225.degree., more preferred from 150.degree. to 210.degree.

"The new binaural hearing aid system may comprise a multi-channel first hearing aid in which the microphone audio signals are divided into a plurality of frequency channels.

"Correspondingly, individual target signal estimates and noise estimates may be provided in each frequency channel of the plurality of frequency channels, or may be provided in one or more selected frequency channels of the plurality of frequency channels, or one or more target signal estimates and noise estimates may be provided for one or more respective groups of selected frequency channels of the plurality of frequency channels, or one target signal estimate and noise estimate may be provided based on all the frequency channels of the plurality of frequency channels.

"The plurality of frequency channels may include warped frequency channels, for example all of the frequency channels may be warped frequency channels.

"The new binaural hearing aid system may additionally provide circuitry used in accordance with other conventional methods of hearing loss compensation so that the new circuitry or other conventional circuitry can be selected for operation as appropriate in different types of sound environment. The different sound environments may include speech, babble speech, restaurant clatter, music, traffic noise, etc.

"The new binaural hearing aid system may for example comprise a Digital Signal Processor (DSP), the processing of which is controlled by selectable signal processing algorithms, each of which having various parameters for adjustment of the actual signal processing performed. The gains in each of the frequency channels of a multi-channel hearing aid are examples of such parameters.

"One of the selectable signal processing algorithms operates in accordance with the new method.

"For example, various algorithms may be provided for conventional noise suppression, i.e. attenuation of undesired signals and amplification of desired signals.

"Microphone audio signals obtained from different sound environments may possess very different characteristics, e.g. average and maximum sound pressure levels (SPLs) and/or frequency content. Therefore, each type of sound environment may be associated with a particular program wherein a particular setting of algorithm parameters of a signal processing algorithm provides processed sound of optimum signal quality in a

specific sound environment. A set of such parameters may typically include parameters related to broadband gain, corner frequencies or slopes of frequency-selective filter algorithms and parameters controlling e.g. knee-points and compression ratios of Automatic Gain Control (AGC) algorithms.

"Signal processing characteristics of each of the algorithms may be determined during an initial fitting session in a dispensers office and programmed into the new binaural hearing aid system in a non-volatile memory area.

"The new binaural hearing aid system may have a user interface, e.g. buttons, toggle switches, etc, of the hearing aid housings, or a remote control, so that the user of the new binaural hearing aid system can select one of the available signal processing algorithms to obtain the desired hearing loss compensation in the sound environment in question.

"The new binaural hearing aid system may be capable of automatically classifying the users sound environment into one of a number of sound environment categories, such as speech, babble speech, restaurant clatter, music, traffic noise, etc, and may automatically select the appropriate signal processing algorithm accordingly as known in the art.

"In accordance with some embodiments, a binaural hearing aid system includes at least one microphone for provision of at least one microphone audio signal in response to sound received at the at least one microphone, a signal separation unit configured to provide an estimate of one of a target signal and a noise signal based on the at least one microphone audio signal, a phase shift circuit configured to phase shift the estimate, a phase shift adder connected to provide a phase shifted signal, wherein in the phase shifted signal, the phase shift of the estimate of one of the target signal and the noise signal substantially substitutes respective one of the target signal and the noise signal, a first receiver for conversion of a first receiver input signal into a first acoustic signal for transmission towards a first eardrum of a user of the binaural hearing aid system, and a second receiver for conversion of a second receiver input signal into a second acoustic signal for transmission towards a second eardrum of the user, wherein a receiver input of one of the first and second receivers is connected to a signal representing the phase shifted signal, and a receiver input of the other one of the first and second receivers is connected to a signal representing the sound received at the at least one microphone.

"In accordance with other embodiments, a method of binaural signal enhancement in a binaural hearing aid system, includes providing at least one microphone audio signal in response to sound, providing an estimate of one of a target signal and a noise signal based on the at least one microphone audio signal, phase shifting the estimate of one of the target signal and the noise signal, providing a phase shifted signal in which the phase shifted estimate of one of the target signal and the noise signal substantially substitutes the respective one of the target signal and the noise signal, transmitting a first signal representing the phase shifted signal towards a first eardrum of a user of the binaural hearing aid system, and transmitting a second signal representing the at least one microphone audio signal towards a second eardrum of the user.

"Other and further aspects and features will be evident from reading the following detailed description of the embodiments. BRIEF DESCRIPTION OF THE DRAWINGS

"The drawings illustrate the design and utility of embodiments, in which similar elements are referred to by common reference numerals. These drawings are not necessarily drawn to scale. In order to better appreciate how the above-recited and other advantages and objects are obtained, a more particular description of the embodiments will be rendered, which are illustrated in the accompanying drawings. These drawings depict only typical embodiments and are not therefore to be considered limiting of its scope.

"FIG. 1 schematically illustrates an exemplary new binaural hearing aid system,

What you can expect from your hearing aids

Publication info: Daily Record [Wooster, Ohio] 23 July 2013: D.8.
ProQuest document link

Abstract: If your hearing loss has progressed to the degree that you need hearing aids, a critical factor in their success is your understanding and acceptance of realistic expectations of their capabilities.

Full text: If your hearing loss has progressed to the degree that you need hearing aids, a critical factor in their success is your understanding and acceptance of realistic expectations of their capabilities. Hearing instruments -- regardless of brand or type of technology -- can never replace normal hearing in all listening situations. Expecting results that cannot be achieved will only lead to frustration and dissatisfaction. If you know what to expect, you'll be free to enjoy the improvements that hearing aids can make in your life. Here are some guidelines which should help you and your provider agree on a set of realistic expectations for you.
-- The extent to which the lost hearing function can be restored through amplification is based on the severity and duration of your hearing loss. The degree and extent of hearing loss is determined by using calibrated equipment called an audiometer.
-- The more severe your hearing loss, the larger the hearing aid must be to provide room for a larger amplifier and components.
-- Crowded social gatherings and restaurants are examples of noisy conditions where even a person with "normal hearing" has trouble hearing conversations. As a person's hearing deteriorates, so also does the ability of a hearing aid to correct for hearing loss in these types of situations. Your provider's goal is to select an appropriate circuit for your hearing aid that will deliver a natural loudness throughout your entire listening range without getting too loud or too quiet.
-- In difficult listening situations normal hearing listeners rely on using speech reading cues and focusing their attention on the speaker. These listening skills are even more important for the hearing aid user when faced with these circumstances.
-- In quiet, many hearing aid users can achieve a performance level equal to normal hearing. But as the difficulty of the listening task increases, the gap between a person with normal hearing and a person with hearing loss widens. The more severe the hearing loss, the wider the gap.
-- With properly fitted hearing aids, you should be able to hear many normal sounds that you may not otherwise be able to hear clearly, such as the voice of your clients or the words of a loved one. You may also begin to

hear sounds you have forgotten were a part of your world, such as the hum of the motor on your refrigerator or the buzz of your fluorescent lights.
-- Hearing aids in the conventional non-linear and digital categories should prevent normally loud sounds from becoming uncomfortable.
-- Depending on the degree and severity of your loss, hearing aids may allow you to hear speech more clearly in some noisy situations.
-- You'll need time to get used to your new hearing aids to learn how to achieve maximum performance from them.
-- Hearing aids will not restore your hearing to normal. Science has not been able to match the human hearing mechanism.
-- Hearing aids will not "filter out" background noise, despite some advertising claims. Some hearing aids have circuitry that will avoid boosting the volume of some types of background noise, but this can also remove some of the speech you want to hear. This is usually a benefit, however, providing a more comfortable listening experience and better sound quality in some types of noise situations.
-- Hearing aids should allow you to understand speech more clearly, with less effort, in a variety of listening situations.
-- Hearing aids should keep others from noticing your hearing loss.
--We have the same goal as you: to find a way to help you reach the best possible hearing improvement. Using the best testing and assessment equipment science has to offer, and the availability of hearing aids from 27 worldwide manufacturers, we pledge to do our best to meet a set of mutually agreed-upon objectives and expectations.

GETTING AN EARFUL

Author: Dimond, Valerie.

Publication info: Sarasota Herald Tribune [Sarasota, Fla] 23 July 2013: E.6.
ProQuest document link

Abstract: Consumers are often unaware that hearing devices work differently for different people, says Ed Ogiba, president the Hearing Loss Association of Sarasota, a consumer education and advocacy group. HOW TO SHOP People often feel dissatisfied with their hearing aids because they were fitted by someone too focused on the sale, instead of the patient's needs, says Bradenton audiologist Victoria Moore of Hearing Aid Systems Inc. Hearing instrument specialists and audiologists are both legally certified to fit patients with hearing aids -- but there are important differences between them, she adds.

Full text: Finding the right hearing device takes time -- and money
Second of two parts.
Venice resident Judi Picha, 73, knows her way around a hearing aid.
She has been using them since she was a teenager, and says keeping a detailed list of what does and doesn't work is key.
"I wrote down everything that I did not like, so when I had my visit I could describe accurately what was wrong, versus saying, 'They don't work for me,'" says Picha. "Also I learned to keep the aids in for several weeks, so my brain could adjust to the new sound. It takes patience."

Today Picha has a cochlear implant that includes a T-coil. She says T-coils are kind of like having your own personal loudspeaker.

"It brings the sound right to one's ear, and I hear just about every single word when I use it," says Picha, who activates hers every Sunday at church. "Often I hear someone my hearing husband cannot hear well, because they are so soft-spoken."

Consumers are often unaware that hearing devices work differently for different people, says Ed Ogiba, president the Hearing Loss Association of Sarasota, a consumer education and advocacy group.

"You have to start by getting the right audiologist," Ogiba says. "We recommend that you look for audiologists that sell the top six: Oticon, Phonak, Resound, Siemens, Starkey, Widex."

These brands, he says, are consistently recommended by leading audiologists who speak at the HLAS monthly meetings.

Joan Mastrandrea of Sarasota learned her lesson through experience, after buying the cheapest pair of hearing aids she could find for a few hundred dollars. Frustrated and disappointed with their performance, she eventually gave up on hearing aids and went without until she found a good pair last year.

"I was too cheap to pay for good ones back then," says Mastrandrea, 82, who was fitted with new aids by Sarasota audiologist Lyndsey Nalu.

"I never knew the difference until I joined the Hearing Loss Association," says Mastrandrea. "I assumed that all people who sold hearing aids have the same education. I was wrong."

HOW TO SHOP

People often feel dissatisfied with their hearing aids because they were fitted by someone too focused on the sale, instead of the patient's needs, says Bradenton audiologist Victoria Moore of Hearing Aid Systems Inc.

Hearing instrument specialists and audiologists are both legally certified to fit patients with hearing aids -- but there are important differences between them, she adds.

"Audiologists have to go through years of university training and 1,450 hours of clinical practice. Hearing aid specialists only need a high school diploma and six months of training," Moore says.

It's also important to make sure you are being seen as an individual, and not a dollar sign.

"A good audiologist will want your lifestyle inputs," says Ogiba. If not, "You're going to end up with what they sell, not what you need."

Ogiba notes that today's aids come with a variety of styles, sizes and programs that can be customized to different needs.

"You want someone who won't just throw out that same brand at every customer that walks in," says audiologist Brad Ingrao, also from Hearing Aid Systems Inc.

And don't be enticed by a certain brand based on someone else's experience.

"Uncle Harry's hearing is different from yours," Ogiba says.

He believes you should follow the audiologist's advice -- many patients don't -- and get the recommended device, which could mean wearing one that's larger than you expected. Ogiba says the social stigma people attach to hearing aids is the most common reason people complain -- because they want the most discreet model on the shelf.

"This is one of the biggest issues for people in the market for an aid," he says. "Performance increases progressively with an aid's size, but so does the first-time wearer's perceived stigma issue."

On the other hand, today's smaller aids can be very good, says Ingrao, modeling a miniature hearing aid that virtually disappears inside his ear. As technology advances, he says, smaller models are performing better all time.

"Hearing devices aren't like your grandparents' hearing aids," says Moore. "They've come a long way."

When you buy your hearing aids, your provider should be scheduling that first follow-up appointment before you leave the office, Ingrao says. And "understand your contract," he adds -- especially

if you live in different places throughout the year.
If you buy hearing aids in Ohio and you need service in Sarasota, you may need to pay an additional service fee to the audiologist you visit here. Find out.
"The other alternative is to mail your hearing aid to the original place where you purchased it," says Moore.
ABOUT THAT PRICE
The bottom line is to find what works, because hearing aids are an investment that doesn't come cheap.
The average cost of a quality hearing aid starts at around $3,000 -- for one ear.
"It can hit you like a thunderbolt. Medicare doesn't cover it. Health insurance plans don't cover it," Ogiba says.
Moore says military veterans,
federal employees and some with
unionized jobs do have hearing aid coverage.
And funding for hearing aids and implants is available to those who can't afford them through a new program, Help Us Hear (HUH), says Jennifer Moss, executive director of the Ear Research Foundation at Silverstein Institute in Sarasota.
The collaborative effort includes support from HLAS, Sarasota Memorial Healthcare Foundation, Audiology Management Group, hearing equipment manufacturers and private donors.
"We were getting calls all the time about cost issues," says Moss, noting that so far 16 people have seen benefits from the program.
In Florida, people who purchase hearing aids are entitled to a refund of the purchase price, minus 5 percent, within 30 days. So once you do get fitted, Ogiba suggests getting acquainted with your new equipment right away. "Wear it every waking hour -- really put it to the test," he says. "If you miss the movies, get your butt to the movies two to three days a week in that 30-day period."
What you get when you get those T-coils
A T-coil is a tiny wireless receiver inside a hearing aid or cochlear implant that vastly improves sound quality wherever a hearing loop system is installed.
"My patients that have T-coils love them," says Sarasota audiologist Lyndsey Nalu at Adept Audiology.
Sound travels through a microphone or a sound board hooked up to an amplifier and connected to an induction loop. The loop runs along the border of the room -- or designated area -- and delivers the sound via magnetic signal directly to the person's T-coil, filtering out ambient or background noise.
"This makes the signal far clearer than that picked up by a hearing device without a T-coil," Nalu says.
Edward Ogiba, president of the Hearing Loss Association Sarasota says hearing loops can now be found in dozens of places around Sarasota, Bradenton and Venice, including the Van Wezel, Players Theater, Sarasota Orchestra, churches, libraries and medical offices.
"This county has more loops in theaters than anywhere else in the country -- 18 playhouses are looped and more houses of worship than anywhere in the country," says Ogiba, a T-coil user who is lobbying to get more places on board.
An audiologist may need to activate your T-coil before it can be used. After that, it turns on and off by flipping a tiny switch or remote control. Some kick in automatically if they detect a hearing loop system.
If you have a hearing aid without a T-coil, Nalu says, you may be able to have one installed for $50 to $250 -- if your device isn't too tiny.
"Most of the very small in-the-ear and behind-the-ear devices cannot accommodate a T-coil," she explains. "I have found that most individuals would prefer hearing devices with a T-coil, even if it means they are slightly larger in size."

GN ReSound A/S; Agency Reviews Patent Application Approval Request for "Hearing Aid with Improved Magnetic Reception during Wireless Communication"

Publication info: Telecommunications Weekly (Jul 10, 2013): 625.
ProQuest document link

Abstract: [...]this way of solving the problem prevents the user of the hearing aid from using a remote control to adjust the hearing aid and also prevents transmission of signals to the other hearing aid in a binaural hearing aid system. [...]there is a need for a hearing aid that allows use of the telecoil, or another magnetically sensitive transducer, as an input source of the hearing aid and simultaneous RF-transmission without the RF-transmission causing interference in the signal output by the hearing aid in response to the output signal of the telecoil or another magnetically sensitive transducer.

Full text: 2013 JUL 10 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- GN ReSound A/S has been issued patent application serial number 330524, according to news reporting originating out of Washington, D.C., by VerticalNews editors.

The patent's inventors are Pedersen, Brian Dam (Ringsted, DK); Nijsse, Gerard ('S-GRAVENHAGE, NL).

This patent application was filed on December 19, 2011 and was made available online on June 27, 2013.

From the background information supplied by the inventors, news correspondents obtained the following quote:

"The present application relates to a hearing aid with a telecoil, or another magnetically sensitive transducer, and an RF transceiver for wireless communication, e.g. via a wireless network, such as for wireless interconnection of two hearing aids in a binaural hearing aid system, and wireless interconnection of hearing aids with other devices, such as a remote control for a hearing aid, a fitting instrument, a mobile phone, a headset, a door bell, an alarm system, a broadcast system, etc, etc."

Supplementing the background information on this patent application, VerticalNews reporters also obtained the inventors' summary information for this patent application: "Magnetic pick-up coils, often referred to as telecoils or T-coils (from 'Telephone Coils'), in hearing aids allow audio sources to be electro-magnetically, i.e. non-acoustically, connected to a hearing aid, which is intended to help the wearer filter out background noise. They can be used with telephones, FM systems (with neck loops), and induction loop systems, also called 'hearing loops', that transmit sound to hearing aids from public address systems and TVs. Hearing loops are widely used in churches, shops, railway stations, and other public places.

"A telecoil consists of a metal core (or rod) around which ultra-fine wire is coiled. Telecoils generate an electrical signal in response to a varying magnetic field.

"Although a telecoil constitutes a wide-band receiver, interference is unusual in most hearing loop situations. Interference can manifest as a buzzing sound, which varies in volume depending on the distance between the wearer and the source. Sources are electromagnetic fields, such as CRT computer monitors, older fluorescent lighting, some dimmer switches, many household electrical appliances and airplanes.

"In addition, an RF-transceiver of the hearing aid may also generate interference. During normal operation, power consumption of hearing aid circuitry is very low. In an example, a hearing aid has a current consumption

of 1 mA during normal operation.

"Typically, an RF transceiver in a hearing aid consumes a comparatively large amount of power during transmission or reception. For example, the current consumption of the RF transceiver circuitry may increase from 50 .mu.A to 30 mA during transmission or reception by the RF transceiver. Therefore, turning the RF transceiver on or off generates a large current transient in the hearing aid circuitry, and during the duration of the current transient, a varying magnetic field with large magnetic field gradients is generated.

"The magnetic field gradients are picked up by the telecoil and induce a disturbing signal in the electronic telecoil signal output by the telecoil, e.g. residing in a hearing loop. The disturbing signal interferes with the desired signal in a disturbing and bothering way for the wearer of the hearing aid.

"The characteristics of the current transients generated in the hearing aid changes over time, e.g. as a function of the degree of depletion of the hearing aid battery, the number of previous charging cycles having been applied to the battery, the type of battery currently in use, etc.

"Conventionally, this interference problem has been solved by turning the RF transceiver off whenever the telecoil is selected as an input source for inputting the electronic telecoil signal to the processor of the hearing aid, for example when the user desires to listen to signals of a hearing loop. However, this way of solving the problem prevents the user of the hearing aid from using a remote control to adjust the hearing aid and also prevents transmission of signals to the other hearing aid in a binaural hearing aid system.

"Thus, there is a need for a hearing aid that allows use of the telecoil, or another magnetically sensitive transducer, as an input source of the hearing aid and simultaneous RF-transmission without the RF-transmission causing interference in the signal output by the hearing aid in response to the output signal of the telecoil or another magnetically sensitive transducer.

"In the new hearing aid, interference from the RF-transceiver of the hearing aid is prevented by substitution of the output signal of the magnetically sensitive transducer disturbed by current transients generated when the RF-transceiver is turned on or off with an estimated output signal, wherein the estimate is based on parts of the output signal that have not been disturbed by turning the RF-transceiver on or off.

"Thus, a new method of removing interference from a hearing aid audio signal is provided, comprising the steps of:

"converting a varying magnetic field into an audio signal,

"generating a hearing loss compensated output signal based on the audio signal,

"converting the hearing loss compensated output signal to an auditory output signal that can be received by the human auditory system,

"controlling turn-on and turn-off of an RF transceiver of the hearing aid,

"forming an estimate of the audio signal that is within a time period comprising an event that the RF transceiver changes state between on and off, wherein the estimate is formed based on the audio signal obtained outside the time period, and

"generating the hearing loss compensated output signal based on the estimate of the audio signal that is within the time period.

"The method may further comprise at least one of the following steps:

"(a) forming an estimate of the audio signal before the time period, the estimate of the audio signal before the time period being based on a part of the audio signal input to the processor after the time period, and wherein the hearing loss compensated output signal is also based on the estimate of the audio signal before the time period, and

"(b) forming an estimate of the audio signal after the time period, the estimate of the audio signal after the time period being based on a part of the audio signal input to the processor before the time period, and wherein the hearing loss compensated output signal is also based on the estimate of the audio signal after the time period.

"Further, a new hearing aid is provided, comprising

"a magnetically sensitive transducer for conversion of a varying magnetic field into an audio signal,
"a processor configured to generate a hearing loss compensated output signal based on the audio signal,
"an output transducer for conversion of the hearing loss compensated output signal to an auditory output signal that can be received by the human auditory system, e.g. an acoustic output signal,
"an RF transceiver for wireless communication, and
"a communication controller that is configured to turn the RF transceiver on and off, and wherein,
"the processor is further configured to generate the hearing loss compensated output signal based on an estimate of the audio signal within a time period comprising an event that the RF transceiver changes state between on and off, and wherein the estimate is based on a part of the audio signal input to the processor outside the time period.
"The processor may also be configured to generate the hearing loss compensated output signal based on an estimate of the audio signal before the time period, the estimate of the audio signal before the time period being based on the audio signal that is input to the processor after the time period.
"The processor may also be configured to generate the hearing loss compensated output signal based on an estimate of the audio signal after the time period, the estimate of the audio signal after the time period being based on the audio signal that is input to the processor before the time period.
"When the communication controller turns the RF transceiver on or off, the processor receives information that the RF transceiver is turned on or off so that the processor can substitute the audio signal with an estimated signal within an appropriate time interval.
"Typically, the auditory output signal is an acoustic signal that is transmitted towards the ear drum of the wearer of the hearing aid; however, the auditory output signal may also be an electronic signal for electronic stimulation of the auditory system of the user, for example using a cochlear implant.
"Throughout the present disclosure, the term 'audio signal' may be used to identify any analogue or digital signal forming part of the signal path from the output of the magnetically sensitive transducer to an input of the signal processor.
"The magnetically sensitive transducer may be any transducer capable of converting a varying magnetic field into an audio signal, such as a telecoil, GMR sensor (Giant MagnetoResistance sensor), Hall sensor, etc.
"The hearing aid may also include an input transducer, preferably a microphone, or an array of microphones, for conversion of an acoustic sound signal into an electronic transducer signal.
"In a digital hearing aid, the electronic transducer signal and the audio signal are digitized by respective AD-converters.
"The signal processor, such as a digital signal processor or DSP, may be configured to process a selected one of, or a selected combination of, the audio signal and the electronic transducer signal in accordance with a selected signal processing algorithm into a processed output signal for compensation of hearing loss, for example including a compressor for compensation of dynamic range hearing loss.
"The time period includes the time during which the current transient disturbs or distorts the audio signal, and typically, the time period starts at turn-on or turn-off of the RF-transceiver. Within the time period, the audio signal is substituted by an estimated signal calculated from the audio signal outside the time period, e.g. preceding the time period, or succeeding the time period, or a combination. In a digital hearing aid, the samples of the audio signal are substituted by estimated samples calculated from samples of the audio signal outside the time period, such as samples preceding the time period, or samples succeeding the time period, or a combination of samples preceding and samples succeeding the time period.
"Thus, the estimate may be based on extrapolation of the audio signal input to the processor outside the time period, e.g. the estimate may be based on extrapolation of the audio signal input to the processor before the time period, i.e. forward prediction; or, the estimate may be based on extrapolation of the audio signal input to the processor after the time period, i.e. backward prediction; or, the estimate may be based on a combination of

extrapolation of the audio signal input to the processor before and after the time period, respectively, i.e. both forward and backward prediction.

"Obviously, backward prediction requires delaying the signal, parts of which are to be estimated, in order for the signal after the time period to be available for estimation of the signal within the time period.

"Samples in the time period may be estimated using Linear Predictive Coding based on samples preceding the time period, or samples succeeding the time period, or a combination of samples preceding and samples succeeding the time period.

"The estimates may be weighted with a window, such as a Hanning window. Windowing minimizes formation of artefacts in the auditory output signal of the hearing aid by transition from the audio signal itself to an estimate of the audio signal.

"Other estimates may be calculated using other formulas, such as Warped Linear Predictive Coding, Polynomial extrapolation, etc.

"The estimate may also be calculated in the frequency domain, for example based on calculation of the Fast Fourier Transform of the audio signal input to the processor before the time period, i.e. forward prediction in the frequency domain; or, the estimate may be based on calculation of the Fast Fourier Transform of the audio signal input to the processor after the time period, i.e. backward prediction in the frequency domain; or, the estimate may be based on a combination of calculation of the Fast Fourier Transform of the audio signal input to the processor before and after the time period, respectively, i.e. both forward and backward prediction in the frequency domain.

"In order to further smooth the transition from real samples of the audio signal to estimated samples, one or more consecutive samples immediately preceding the time period, or one or more consecutive samples immediately succeeding the time period, or both, may also be substituted with estimated samples, wherein the original undisturbed signal samples are included in the estimates.

"For example, the most recent undisturbed signal sample occurring immediately before turn-on or turn-off of the RF transceiver may be substituted by an estimate calculated from samples occurring after the time period in a weighted combination with the undisturbed audio signal sample itself in order to gradually change from the undisturbed audio signal itself to an estimate of the audio signal.

"Likewise, the first undisturbed signal sample occurring after turn-on or turn-off of the RF transceiver may be substituted by an estimate calculated from samples occurring before the time period in a weighted combination with the undisturbed signal sample itself in order to gradually change from an estimate of the audio signal to the undisturbed audio signal itself.

"The hearing aid including the processor may further be configured to process the signal in a plurality of frequency channels.

"An estimate of the audio signal may be provided in at least one frequency channel of the plurality of frequency channels, such as in one or more selected frequency channels, such as in all of the frequency channels.

"The plurality of frequency channels may include warped frequency channels, for example all of the frequency channels may be warped frequency channels.

"In accordance with some embodiments, a hearing aid includes a magnetically sensitive transducer for conversion of a varying magnetic field into an audio signal, a processor configured to generate a hearing loss compensated output signal based on the audio signal, an output transducer for providing an auditory output signal based on the hearing loss compensated output signal, an RF transceiver for wireless communication, and a communication controller that is configured to turn the RF transceiver on and off, wherein the processor is further configured to generate the hearing loss compensated output signal based on an estimate of the audio signal within a time period comprising an event that the RF transceiver changes state between on and off, and wherein the estimate is based at least on a part of the audio signal input to the processor outside the time period.

"In one or more embodiments, the estimate may be based on extrapolation of the part of the audio signal input to the processor outside the time period.
"In one or more embodiments, the part of the audio signal may be input to the processor before the time period.
"In one or more embodiments, the part of the audio signal may be input to the processor after the time period.
"In one or more embodiments, the part of the audio signal on which the estimate is based may have a duration that is at least twice as long as the time period.
"In one or more embodiments, the estimate may be formed using Linear Predictive Coding.
"In one or more embodiments, the estimate may be formed using Warped Linear Predictive Coding.
"In one or more embodiments, the estimate may be formed using windowing.
"In one or more embodiments, the windowing may comprise a Hanning window.
"In one or more embodiments, the processor may also be configured to generate the hearing loss compensated output signal based on an estimate of the audio signal before the time period, the estimate of the audio signal before the time period being based on a part of the audio signal that is input to the processor after the time period.
"In one or more embodiments, the processor may also be configured to generate the hearing loss compensated output signal based on an estimate of the audio signal after the time period, the estimate of the audio signal after the time period being based on a part of the audio signal that is input to the processor before the time period.
"In one or more embodiments, the processor may further be configured to process the audio signal in a plurality of frequency channels, and wherein the estimate of the audio signal may be provided in at least one of the plurality of frequency channels.
"In accordance with other embodiments, a method of removing interference from a hearing aid audio signal includes converting a varying magnetic field into an audio signal, generating a hearing loss compensated output signal based on the audio signal, providing an auditory output signal based on the hearing loss compensated output signal, controlling turn-on and turn-off of an RF transceiver of the hearing aid, forming an estimate of the audio signal that is within a time period comprising an event that the RF transceiver changes state between on and off, wherein the estimate is formed based at least on the audio signal obtained outside the time period, and generating the hearing loss compensated output signal based on the estimate of the audio signal that is within the time period.
"In one or more embodiments, the estimate may be formed utilizing Linear Prediction Coding.
"In one or more embodiments, the hearing loss compensated output signal may also be based on an estimate of the audio signal before the time period, the estimate of the audio signal before the time period being based on a part of the audio signal input to the processor after the time period.
"In one or more embodiments, the hearing loss compensated output signal may also be based on an estimate of the audio signal after the time period, the estimate of the audio signal after the time period being based on a part of the audio signal input to the processor before the time period.
"Other and further aspects and features will be evident from reading the following detailed description of the embodiments. DESCRIPTION OF THE DRAWING FIGURES
"The drawings illustrate the design and utility of embodiments, in which similar elements are referred to by common reference numerals. These drawings are not necessarily drawn to scale. In order to better appreciate how the above-recited and other advantages and objects are obtained, a more particular description of the embodiments will be rendered, which are illustrated in the accompanying drawings. These drawings depict only typical embodiments and are not therefore to be considered limiting in the scope of the claims. The embodiments will be described in more detail with reference to the drawings, wherein
"FIG. 1 shows a block diagram of a hearing aid with a telecoil and an RF-transceiver,
"FIG. 2 shows a plot of signals in the hearing aid of FIG. 1, and

"FIG. 3 illustrates audio signal estimation."

Mechanized scaling with ultrasonics: Perils and proactive measures

Author: Paramashivaiah, Rashmi; Prabhuji, M. L..

Publication info: Journal of Indian Society of Periodontology 17.4 (Jul-Aug 2013): 423-428.
ProQuest document link

Abstract: Mechanized scaling for plaque removal is a routine procedure in the practice of periodontics. Though it appears innocuous by itself, there are retinues of hazards associated with it on various organ systems in the body. Some of these unwanted effects and measures to avoid or ameliorate the same are elaborated here. Exposure to ultrasonic scaling is inevitable before any other treatment procedure. Aerosol contamination, vibrational hazards, thermal effects on the dental pulp, altered vascular dynamics, disruption in electromagnetic device, diminished hearing and dental unit waterline contamination are some of the probable off-shoots a patient has to bear. Uses of barrier devices, proper attention to usage of equipment, protection for ear and water treatment are few of solutions for the same. Though documented evidence for the existence of all effects is lacking, it is never the less significant for the overall safety of the patient. A conscientious clinician should therefore inculcate the available steps to overcome the hazards of ultrasonic scaling.

Full text: Introduction
The periodic removal of supra and sub-gingival plaque is essential for controlling inflammatory periodontal diseases. [1] Mechanized instruments use the water-cooled instrument tip vibrating at high frequency for eradication of bacterial deposits from teeth and periodontal pockets. The two categories of mechanized instruments are ultrasonic and sonic handpieces. [2] Though they are indispensable tools of periodontics, they are not without their set of perils. Thus, some of the inherent problems associated with the use of ultrasonic scalers and the practical solutions for the same are elaborated here.
Indoor Air Pollution
Health problems related to poor indoor air quality are often related to contaminants, which include bioaerosols, non-viable particulates and volatile organic chemicals. [3] Many routine dental procedures produce aerosol and splatter composed of varying combinations of water, tissue and tooth dust, blood and saliva. At a minimum distance of 50 cm from patient undergoing ultrasonic scaling about 33% of blood borne aerosols were isolated in a recent study. [4]
Micik et al. defined dental aerosols as particles smaller than 50 μm with any particles larger than 50 μm being described as splatter. [5] Aerosol particles of 50 μm or smaller remain airborne for a longer period and enter the

nasal passages with penetration deep into the respiratory tree creating health concern. All aerosol particles may contain blood elements with attached viral particles, such as human immunodeficiency virus and hepatitis B virus. [6] Other diseases known to be spread through airborne route are pneumonic plague, tuberculosis, influenza, legionnaire's disease and severe acute respiratory distress syndrome. [7]

Reduction of Indoor Air Pollution

Recommendations by American Dental Association (ADA) and Prevention and Occupational Safety and Health Administration support the use of a "spray-wipe-spray" technique. Use of a surface disinfectant with documented evidence of bactericidal, tuberculocidal and virocidal activity is recommended. All areas within six feet radius of the operation should be cleaned. [7]

The dental team should not rely on a single precautionary strategy.

In the reduction of dental aerosols, the first layer of defense is personal protection barriers such as masks, gloves and safety glasses. For masks to be protective, they must filter effectively aerosol particles of 50 μm or less with minimal marginal leakage. [8]

The second layer is antiseptic pre-procedural rinse with a mouthwash such as chlorhexidine.

The third layer of protection is the routine use of a high volume evacuator (HVE).

An additional fourth layer would be the use of a device to reduce aerosol contamination that escapes the operating area, such as a high efficiency particulate air filter (HEPA). Extra-oral HVE covered with a towel can filter out blood-borne aerosols. [4]

According to the ADA and centers for disease control a room ceiling equipped with HEPA will be 99.97% efficient in removing all particles 0.3 μm or larger in diameter. [3]

The advantages and disadvantages of commonly used protective measures are given in [Table 1]. [7]{Table 1}

Vibration Hazards

It is well-recognized that the large amplitudes produced by pneumatic drills will cause "white finger" or "acrocyanosis." This is a disruption in the blood flow to the fingers, caused by the vibration that is passed from the drill through to the hand. [9]

A study was undertaken on 120 subjects comprising of 60 dentists and hygienists exposed to vibrations, from high-speed hand pieces and ultrasonic scalers and a control group of 60 dental assistants and medical nurses. [10] They were assessed for manual performance, tactility, strength, etc., In this study, it was found that the vibrations could produce a reduction in strength and tactile sensitivity and performance. It was stated that vibrating tools are used for an average of 75 min a day highlighting the need for the reduction of exposure time.

Reduction of Hazards From Vibration

Prolonged operation of an ultrasonic scaler may cause alteration of blood and nerve supplies to the operator finger. In this respect, adequate standardization of instruments and procedures is essential including:

Adequate training of the clinician in the use of the ultrasonic scalerAvoidance of heavy contact loadsAn indication of the displacement amplitude of the scaling probe tip and the direction of its oscillation. [11]

Research is needed to aid in the development, design and production of an ultrasonic hand piece that will eliminate any vibration hazards to the operator. [9]

Thermal Hazards

If the ultrasonic scaler is perfectly coupled at the probe/enamel interface then about 37% of ultrasonic energy would leave the metal and enter the tooth. However, this does not occur because:

The dimensions of the probe tip are much smaller than the wavelength of sound at these frequenciesThere is usually a thin layer of water imposed between the probe and the tooth.If heavy contact pressures are used the coupling will then be improved, increasing the amount of ultrasound entering the tooth. One of the major sources of damage to the tooth is the result of frictional heating between the probe and the enamel, especially if there is inadequate or no water cooling. However, the presence of water may act as a matching layer allowing uniform ultrasound energy to enter the tooth. [11]

A study has shown that temperature rise in the tooth caused by heating can cause damage to the pulp and dentine. An increase above 11C was shown to invariably destroy the pulp and a 17C increase produced pulp death. [12] However, a recent work suggests that an increase of 11.2C produces no damage on the pulp tissues. [13]

Down-Regulation of Thermal Hazards

Consistent use of the unit on the highest power setting will increase the potential for thermal damage without necessarily increasing the efficiency. [14] Temperature sensitivity can be controlled by slightly reducing the water flow or in the case of units with self-contained lavage warm water can be added to the container. When soft-tissue sensitivity is perceived as a problem and local anesthetics are not viable treatment choice, long acting topical anesthetic solutions have been used successfully for sub-gingival debridement. [2]

A study was designed to compare the temperature rise in dentin during ultrasonic scaling using either ultrasonic handpiece irrigation, intermittent bulb irrigation or no irrigation. A single clinician applied light forces, ultrasonic device was set to a fixed power setting and water flow was adjusted to 15 ml/min to reduce the number of study variables. Ultrasonic coolant temperature increases with duration of instrumentation and reaches a plateau, which is affected by power setting and irrigation volume. Bulb syringe irrigation and ultrasonic device water spray significantly reduced heat generation from ultrasonic scaling to physiologically tolerable levels. [15]

Thus, most studies conclude that powered scaling should not be considered without irrigation and the flow rate in the region of at least 20-30 ml/min. [9]

Thrombogenic Hazards

During dental treatment, the oscillating tip of ultrasonic scaler will be in contact with the tooth. It may be possible that the tooth acts as a waveguide conducting the vibrational energy from the scaler toward the apex of the root. If sufficient energy reaches the root, then it could pose a thrombogenic hazard to the blood vessels passing through the apical foramen into the pulp. This may lead to a potential loss of tooth vitality. [16]

A study conducted in vivo on mice to assess the effect of a wire vibrating at a frequency of 20 kHz placed against an intact blood vessel resulted in the production of platelet emboli and the formation of thrombi. [17]

This work was repeated with a commercially available ultrasonic scaler, which demonstrated similar findings. [9]

Thus, ultrasound transmissions into the tooth may result in potential damage to the structures such as blood vessels both within and around the teeth.

Alleviation of Thrombogenic Hazards

A probe tip operating at displacement amplitude of 44 μm directed perpendicular to the tooth surface under heavy contact pressure only resulted in displacement amplitude at the root tip of 1-2 μm. Thus, thrombogenic hazard may result when the longitudinal oscillations are directed perpendicular to the tooth surface. Thus, changing the direction of the oscillating tip so that it is parallel to the tooth reduces the vibration at the root apex to a barely detectable levels. [11]

Interruption of Electronic Devices

The electromagnetic device of vital importance is the cardiac pacemaker. The cardiac pacemaker is a tissue implanted electrical transmitter designed to regulate the rhythm of the heart. Two types are used, competitive (fixed rate type) and non-competitive (demand type), the former discharging at a fixed rate while the latter only discharges if the rate becomes irregular. [18]

The handpiece of the ultrasonic scaler produces an electromagnetic field and the severity of interference is dependent on the strength of this field. [9] The electromagnetic field produced by magnetostrictive ultrasonic scalers may interfere with the pacemaker discharge rate, resulting in a serious life-threatening hazard to the patient. [19] It has been suggested that any effects, which have been observed may be the result of a non-competitive type of pacemaker switching over to a fixed mode during the period of interference. [18] Work investigating the magnetostrictive scaler stated that interference can be caused if the pacemaker lead comes within 37.5 cm of the scaler. [20] No reports of interference caused by piezoelectric scaler have been reported.

[19]

Avoidance of Interference with Electromagnetic Devices

An elaborate medical history for every patient is prerequisite to rule out the presence of cardiac pacemakers. Consultation with the patient's physician and cardiologist is a must in patients with pacemakers. A safe distance of 50 cm or more is a must in these patients. [21] Magnetostrictive ultrasonic scalers should not be used on patients with a pacemaker. [22]

Auditory Hazards

Lesions of hearing apparatus can be chronic or acute. Acute acoustic trauma is caused by a high intensity noise stimulus such as an explosion or gunfire. The onset is painful and may be reversible or irreversible. Chronic acoustic trauma is caused by prolonged exposure to lower intensity sound irritant and is painless. The damage is irreversible because cochlear hair cells cannot regenerate. Although a certain amount of gradual hearing loss is considered normal as a part of ageing (presbycusis), prolonged exposure to excessive noise can greatly add to hearing loss.

The cognitive sound frequency for human ear is 20-20,000 Hz. Sounds below this range are infrasonic and those above are ultrasonic. The important speech frequency falls between the ranges of 250 Hz and 4000 Hz. A high-intensity, high-frequency noise can damage the high frequency receptors. [22]

Kilpatrick proposed a number of sounds in the dental office that may be hazardous to dentists hearing: High-speed turbineHigh-volume aspiratorUltrasonic scalerMixing devices for stone, amalgam, etc.Music playing loudly and continuously. [23]

Damage to operator hearing is possible through airborne sub-harmonics of the ultrasonic scaler. For the patient, damage can occur through the transmission of ultrasound through tooth contact to the inner ear through the bones of the skull. [9]

Degree of risk to the individual dentists depends on several factors.

Intensity of noiseFrequency spectrum of noiseDuration of exposure each dayDistance from the sourceIndividuals age, physical condition and susceptibilityType of procedureThe intensity of noise emitted from hand pieces differs from manufacturer to manufacturerPrevious exposure to damaging noise resulting in permanent injury to hearingWorking environment: Materials in the dental operatory, i.e., smooth cement walls and floors reflect noise almost completely, whereas draperies absorb noise considerably. [24] Hearing loss is expressed in terms of hearing threshold shifts in decibels (dB) as determined by audiometry. Permanent threshold shifts due to moderate noise levels, such as those encountered in dentistry would be detectable after years of exposure. [25]

In United Kingdom, the noise at work regulations state that a maximum exposure of 85 dB is permissible daily during an 8-h working period. This was ascertained using a formula given in the regulations. [26]

A study was undertaken to measure the noise levels made by different dental handpieces and equipment in dental practices and laboratories. Noise levels were measured in four dental practices and three dental laboratories. In the dental clinics, almost all noise produced by the dental instruments did not exceed the maximum permissible level of 85 dB. The only instrument that seemed to emit noise that was higher than 85 dB was the ultrasonic scaler in one of the dental clinics. [24]

Möller et al. reported temporary threshold shifts (TTS) in hearing in eight out of 20 subjects following a 5-min ultrasonic scaling procedure. [27] Unilateral changes of 10-20 dB in the frequency range of 3-10 kHz were demonstrated in these patients, three of whom had bilateral tinnitus. Both tinnitus and TTS are commonly accepted as early predictors of noise-induced hearing loss (NIHL). The liberal use of dental ultrasonic instruments may therefore pose a potential hazard to the hearing of the patient. [28]

A longitudinal study of 10 years duration on general practitioners and general dental practitioners concluded that dentists are at higher risk of hearing impairment although not generalized. [29]

Thus, ultrasonic scaler has been shown to cause no permanent harm to hearing through airborne noise.

Transmission of ultrasound through the bone may potentially damage the inner ear; although, this has not been demonstrated. Work is needed to identify if hearing loss is a problem for patients who receive regular ultrasonic scaling. [9]

Attenuation of auditory hazards

As NIHL is not a treatable condition it can only be partly relieved by rehabilitative means, prevention therefore assumes a great importance. [24]

Theoretically there are five methods of prevention of NIHL:

Exclusion from noise exposure of those who are most susceptible to NIHLTo reduce the exposure timePersonal evaluation: Technicians should have baseline otologic and audiometric examination to determine the current hearing status. Annual retests should be carried out to detect any degree of change taking placeReduction in noise level may be achieved by regular maintenance of equipment and early repair or replacement of defective items. The working room should be made more acoustically satisfactory by minimizing the hard surfacesPersonal protection with the use of ear muffs or plugs. Ear plugs are inserted into the ear canal, whereas ear muffs cover the entire external ear by means of a sealed cup. In general, plugs provide less noise attenuation than muffs and are useful in the noise levels from 100 dB to 105 dB. Muffs subdue noise levels from 110 dB to 115 dB. [30]Root Surface Removal by Ultrasonics

Evidence shows that ultrasonic and sonic scalers are effective in plaque and calculus removal, surface alterations including scratches, gouges and nicks increase exponentially as the ultrasonic power is increased from medium to high. Studies also reveal that as instrument contact time, tip to tooth angle and instrument pressure is increased, the likelihood of root surface damage is also increased. [31],[32] A growing body of evidence suggests that forceful instrumentation of the root surface to achieve cementum removal may be unnecessary and harmful. Cemental thickness can be assessed using fluorescence microscopy, contact microradiography and toluidine blue staining after the injection of labeling agents. [33] In fact, overzealous root planning removes important protein components such as bone morphogenetic proteins and slows down critical fibrous attachment from bone to root. [34]

Increasing the power setting from low to high may actually increase the loss of root substance from 11.37 +- 3.64 mm to 23.37 +- 15.76 mm. [35]

Diminution of Root Substance Removal

Defect volume and defect depth created by magnetostrictive and piezoelectric scalers are influenced by the combination of working parameters such as lateral force and tip angulations. Instrument power setting has to be low or medium to minimize tooth substance removal. 30B severe root damage at 40 s instrumentation occurred under most combination of lateral force tip angulation and power settings. Therefore, minimal forces, correct angulations and optimum power setting are mandatory to prevent the root surface damage. [2] Though, it is reported that thinner tips cause more recession the data are not conclusive to preclude the usage of these tips. [36] Rather than creating a glassy smooth root surface, Thompson believes that velvety smooth, clean surfaces with a resulting decrease in root sensitivity is most conducive to tissue healing. [34]

Dental Unit Waterline Contamination

Water recovered from dental units connected to municipal water supplies may contain millions of bacterial colony forming units per millimeter. Biofilms have been shown to be a primary source of contaminated water delivered by dental units. [37] The medical risk from the microbial contamination of water is the most significant to immunosuppressed individuals. Patients and clinicians temporarily compromised by infection and stress may also be at risk of infection. [2] This water can spread infection by the dispersed contaminated aerosols. [38]

A survey was undertaken by Williams et al. wherein DUWL samples were collected from 116 three-way syringe lines, 54 high-speed hand-pieces and 12 scaler lines from about 150 operatories at 54 sites in Washington, Oregon and California. Samples from 12 scalers showed a similar pattern of severe microbial contamination (mean 19,800 CFU/ml, SD = 37,300). Sections of functioning DUWL showed complete biofilm layers lining the

inner surface. [39]

Prevention of Duwl Contamination

The ADA has called for dental researchers and dental manufacturers to design equipment and measures to reduce waterline contamination. The announced goal was to match the standards for kidney dialysate, or 200 CFU/ml. [40]

The various approaches to risk reduction of DUWL contamination are: [41]

Anti-retraction valves and retrograde aspiration of oral fluids

Anti-retraction valves will limit re-aspiration and are most efficacious when fitted immediately distal to the handpiece. Autoclaving the hand-pieces after use and flushing of units for 30 s at the end of the day will augment the action of the anti-retraction valve and should help to eliminate any aspirated liquid. Back flow from dental units to the mains water supply may occur and it is necessary to install check valves to prevent this from occurring.

Filtration

Using filters on the dental waterline to eliminate bacteria from the water entering the handpiece, especially to reduce the planktonic bacteria. Therefore, disposable filters are recommended, which must be changed daily. Filters should be inserted just distal to the point of entry of water into the hand-piece for maximum efficiency. A pore size of 0.2 microns is recommended.

Flushing

ADA recommends that waterlines should be flushed through for several minutes at the start of each clinic day. Flushing for 20 min, which would be impractical in most dental surgeries, will reduce the bacterial count to zero. However, the persistent nature of contamination is demonstrated when 30 min later, shedding of bacteria from the biofilm returns the total colony counts to within pre-flush range.

Biocides and chemical disinfectants

Biocides have been used in an attempt to remove the biofilm and eliminate the planktonic bacterial count. These include chlorhexidine gluconate, povidone-iodine, ethanol, hypochlorite, peroxide and glutaraldehyde. The intrinsic resistance of the biofilm ecosystem has hampered their value.

Chlorination

Chlorine, as sodium hypochlorite, is the most commonly employed biocide in water treatment plants and has proven efficacy in cold water hospital systems. Independent reservoir clean water systems can be used to deliver chlorine flushes to the dental waterline. The system can be "shocked" or hyper-chlorinated intermittently with high doses of 50 ppm chlorine every 6 months.

Peroxide, ozone and ultraviolet light

Hydrogen peroxide and ozone are compounds that can be introduced continuously into waterlines. UV treatment of water has been used alone or in conjunction with ozone and other biocides for the control legionellae and reduction of endotoxins in water. A major advantage of these systems is that they avoid introducing chemical disinfectants into the effluent water system with the potential for pollution and destructive effects on wildlife.

Independent clean water systems

A separate pressurized clean water reservoir system filled with sterile water plumbed to the mains connections to the municipal water provides sterile water. The total volume of water consumed per day as an irrigant is in the range of 1-2 L/dental unit; thus, the use of small reservoir is sufficient. Reservoirs should be used preferably with sterile water or boiled water that is allowed to cool in a sterile sealable container. Letting the system to drain down to dry and purging with air or ethanol will help to prevent the biofilm proliferation due to desiccation.

Autoclavable systems

A fully autoclavable assembly of water reservoirs, silicon multi-lumen DUWL tubing and fittings to be sterilized between patients could be used for surgical procedures.

Conclusion

Considering the ethical issues of treating a patient under absolute safety it is the responsibility of every practitioner to pay heed to the above adverse effects and apply stringent measures to counteract the same.

Patents; Patent Application Titled "Method of Signal Processing in a Hearing Aid System and a Hearing Aid System" Published Online

Publication info: Computers, Networks & Communications (Jun 13, 2013): 2468.

Abstract: According to news reporting originating from Washington, D.C., by VerticalNews journalists, a patent application by the inventors WESTERMANN, Adam (Sydney, AU); BUCHHOLZ, Jorg Matthias (Sydney, AU); DAU, Torsten (Copenhagen, DK), filed on January 14, 2013, was made available online on May 30, 2013.

Full text: 2013 JUN 13 (VerticalNews) -- By a News Reporter-Staff News Editor at Computers, Networks &Communications -- According to news reporting originating from Washington, D.C., by VerticalNews journalists, a patent application by the inventors WESTERMANN, Adam (Sydney, AU); BUCHHOLZ, Jorg Matthias (Sydney, AU); DAU, Torsten (Copenhagen, DK), filed on January 14, 2013, was made available online on May 30, 2013.

No assignee for this patent application, patent application serial number 740417, has been made.

Reporters obtained the following quote from the background information supplied by the inventors: "The present invention relates to a method of signal processing in a hearing aid system. The invention, more specifically, relates to a method of noise suppression in a hearing aid system. The invention further relates to hearing aid systems having means for noise suppression.

"In the context of the present disclosure, a hearing aid should be understood as a small, microelectronic device designed to be worn behind or in a human ear of a hearing-impaired user. A hearing aid system may be monaural and comprise only one hearing aid or be binaural and comprise two hearing aids. Prior to use, the hearing aid is adjusted by a hearing aid fitter according to a prescription. The prescription is based on a hearing test, resulting in a so-called audiogram, of the performance of the hearing-impaired user's unaided hearing. The prescription is developed to reach a setting where the hearing aid will alleviate a hearing loss by amplifying sound at frequencies in those parts of the audible frequency range where the user suffers a hearing deficit. A hearing aid comprises one or more microphones, a microelectronic circuit comprising a signal processor, and an acoustic output transducer. The signal processor is preferably a digital signal processor. The hearing aid is enclosed in a casing suitable for fitting behind or in a human ear.

"It is well known that people with normal hearing can usually follow a conversation despite being in a situation with several interfering speakers and significant background noise. This situation is known as a cocktail party environment. As opposed hereto hearing impaired people will typically have difficulties following a conversation in such situations.

"In the article by Allen et al.: 'Multimicrophone signal-processing technique to remove room reverberation from speech signals', Journal Acoustical Society America, vol. 62, no. 4, pp. 912-915, October 1977, a method for suppression of room reverberation, from the signals recorded by two spatially separated microphones, is disclosed. To accomplish this the individual microphone signals are divided into frequency bands whose corresponding outputs are cophased (delay differences are compensated) and added. Then the gain of each resulting band is set based on the cross correlation between corresponding microphone signals in that band. The reconstructed broadband speech is perceived with considerably reduced reverberation.

"US-A1-20080212811 discloses a signal processing system with a first signal channel having a first filter and a second signal channel having a second filter for processing first and second channel inputs and producing first and second channel outputs, respectively. Filter coefficients of at least one of the first and second filters are adjusted to minimize the difference between the first channel input and the second channel input in producing the first and second channel outputs. The resultant signal match processing of the signal processing system gives broader regions of signal suppression than using Wiener filters alone for frequency regions where the interaural correlation is low, and may be more effective in reducing the effects of interference on the desired speech signal.

"One problem with the above mentioned systems is that noise from interfering speakers is not efficiently suppressed.

"It is therefore a feature of the present invention to overcome at least this drawback and provide a more efficient method for suppression of noise from interfering speakers.
"Hereby speech intelligibility for the hearing impaired can be improved in the otherwise very difficult situation of following a conversation despite several interfering speakers.
"It is another feature of the present invention to provide a hearing aid system incorporating means for suppression of noise from interfering speakers."
In addition to obtaining background information on this patent application, VerticalNews editors also obtained the inventors' summary information for this patent application: "The invention, in a first aspect, provides a method for processing signals in a hearing aid system comprising the steps of: providing a first signal representing the output from a first input transducer in a first hearing aid of the hearing aid system; providing a second signal representing the output from a second input transducer of the hearing aid system; transforming the first and second signal from the time domain and to the time-frequency domain hereby providing a third and fourth signal, respectively; calculating a value representing the interaural coherence between the third and fourth signal hereby providing a fifth signal; deriving a first gain value for the hearing aid system based on the fifth signal; applying the first gain value in the amplification of the third signal in the first hearing aid hereby providing a sixth signal; transforming the sixth signal from the time-frequency domain and to the time domain hereby providing a seventh signal for further processing in the hearing aid system; and wherein the relation determining the first gain value as a function of the value representing the interaural coherence comprises three contiguous ranges for the values representing the interaural coherence, where the maximum slope in the first and third range are smaller than the maximum slope in the second range and wherein the ranges are defined such that the first range comprises values representing low interaural coherence values, the third range comprises values representing high interaural coherence values, and the second range comprises values representing intermediate interaural coherence values.
"This provides an improved method for suppression of noise from interfering speakers in a hearing aid system.
"The invention, in a second aspect, provides a hearing aid system comprising at least one hearing aid, two microphones, analogue-to-digital converter means, time-frequency transforming means, interaural coherence calculation means, first gain calculation means adapted for suppressing interfering speakers, digital processing means adapted for alleviating a hearing deficit of the user wearing the hearing aid system, digital-to-analogue converter means, and output transducer means for providing an acoustical signal, wherein the first gain calculation means is adapted for using a relation determining a first gain value as a function of a value representing the interaural coherence comprising three contiguous ranges for the values representing the interaural coherence, where the maximum slope in the first and third range are smaller than the maximum slope in the second range, and wherein the ranges are defined such that the first range comprises values representing low interaural coherence values, the third range comprises values representing high interaural coherence values, and the second range comprises values representing intermediate interaural coherence values.
"The invention, in a third aspect, provides a hearing aid system comprising a hearing aid and an external device, said hearing aid having a microphone, analogue-to-digital converter means, time-frequency transforming means, interaural coherence calculation means, first gain calculation means adapted for suppressing interfering speakers, digital processing means adapted for alleviating a hearing deficit of the user wearing the hearing aid system, digital-to-analogue converter means, and output transducer means for providing an acoustical signal, and said external device having an acoustical-electrical input transducer means and link means for transmitting data derived from the input transducer to the hearing aid, wherein the first gain calculation means is adapted for using a relation determining a first gain value as a function of a value representing the interaural coherence comprising three contiguous ranges for the values representing the interaural coherence, where the maximum slope in the first and third range are smaller than the maximum slope

in the second range, and wherein the ranges are defined such that the first range comprises values representing low interaural coherence values, the third range comprises values representing high interaural coherence values, and the second range comprises values representing intermediate interaural coherence values.

"Further advantageous features appear from the dependent claims.

"Still other features of the present invention will become apparent to those skilled in the art from the following description wherein the invention will be explained in greater detail. BRIEF DESCRIPTION OF THE DRAWINGS

"By way of example, there is shown and described a preferred embodiment of this invention. As will be realized, the invention is capable of other different embodiments, and its several details are capable of modification in various, obvious aspects all without departing from the invention. Accordingly, the drawings and descriptions will be regarded as illustrative in nature and not as restrictive. In the drawings:

"FIG. 1 illustrates highly schematically selected parts of a hearing aid system according to an embodiment of the invention;

"FIG. 2 illustrates highly schematically a binaural hearing aid system according to an embodiment of the invention;

"FIG. 3 illustrates a computer simulation of the interaural coherence distribution and corresponding gain value, in a hearing aid system according to an embodiment of the invention, where the hearing aid system is worn by a user in a large room with a distant speaker;

"FIG. 4 illustrates a computer simulation of the interaural coherence distribution and corresponding gain value, in a hearing aid system according to an embodiment of the invention, where the hearing aid system is worn by a user in a large room with a nearby speaker;

"FIG. 5 illustrates a computer simulation of the interaural coherence distribution and corresponding gain value, in a hearing aid system according to an embodiment of the invention, where the hearing aid system is worn by a user in a large room with both the distant and the nearby speaker; and

"FIG. 6 illustrates highly schematically a binaural hearing aid system, including an external device, according to an embodiment of the invention."

Phonak Ag; "Hearing Assistance System and Method" in Patent Application Approval Process

Publication info: Telecommunications Weekly (Jun 12, 2013): 736.
ProQuest document link

Abstract: According to these systems, the wireless link not only serves to transmit audio signals captured by the wireless microphone, but in addition, also serves to transmit control data obtained from analyzing the audio signals in the transmission unit to the receiver unit(s), with such control data being used in the receiver unit to adjust, for example, the gain applied to the received audio signals according to the prevailing ambient noise and

the issue of whether the speaker is presently speaking or not.

Full text: 2013 JUN 12 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- A patent application by the inventors Callias, Francois (Fontaines, CH); El- Hoiydi, Amre (Neuchatel, CH); Richard, Claude (Fribourg, CH), filed on April 22, 2010, was made available online on May 30, 2013, according to news reporting originating from Washington, D.C., by VerticalNews correspondents.

Patent application serial number 642708 is assigned to Phonak Ag.

The following quote was obtained by the news editors from the background information supplied by the inventors: "The invention relates to a system and a method for providing hearing assistance to at least one user, wherein audio signals from an audio signal source, such as a microphone for capturing a speaker's voice, are transmitted via a wireless link to a receiver unit acting as an audio receiver for an ear-worn device, such as a hearing aid.

"Presently, in such systems, the wireless audio link usually is an FM (frequency modulation) radio link. According to a typical application of such wireless audio systems, the receiver unit is connected to or integrated into a hearing instrument, such as a hearing aid, with the transmitted audio signals being mixed with audio signals captured by the microphone of the hearing instrument prior to being reproduced by the output transducer of the hearing instrument. The benefit of such systems is that the microphone of the hearing instrument can be supplemented or replaced by a remote microphone which produces audio signals which are transmitted wirelessly to the FM receiver, and thus, to the hearing instrument. In particular, FM systems have been standard equipment for children with hearing loss in educational settings for many years. Their merit lies in the fact that a microphone placed a few centimeters from the mouth of a person speaking receives speech at a much higher level than one placed several feet away. This increase in speech level corresponds to an increase in signal-to-noise ratio (SNR) due to the direct wireless connection to the listener's amplification system. The resulting improvements of signal level and SNR in the listener's ear are recognized as the primary benefits of FM radio systems, as hearing-impaired individuals are at a significant disadvantage when processing signals with a poor acoustical SNR.

"A typical application of such wireless audio systems is at school, wherein the teacher uses a wireless microphone for transmitting the captured audio signals via the transmission unit to receiver units worn by the students. Since the receiver units and the respective hearing aids are usually owned by the students, the receiver units may be of different types within a class.

"Another typical application of wireless audio systems is the case in which the transmission unit is designed as an assistive listening device. In this case, the transmission unit may include a wireless microphone for capturing ambient sound, in particular from a speaker close to the user, and/or a gateway to an external audio device, such as a mobile phone; here the transmission unit usually only serves to supply wireless audio signals to the receiver unit(s) worn by the user.

"Examples of analog wireless FM systems particularly suited for school applications are described, for example, in European Patent Application EP 1 863 320 A1 and International Patent Application Publication WO 2008/138365 A1. According to these systems, the wireless link not only serves to transmit audio signals captured by the wireless microphone, but in addition, also serves to transmit control data obtained from analyzing the audio signals in the transmission unit to the receiver unit(s), with such control data being used in the receiver unit to adjust, for example, the gain applied to the received audio signals according to the prevailing ambient noise and the issue of whether the speaker is presently speaking or not.

"In applications where the receiver unit is part of or connected to a hearing aid, transmission is usually carried out by using analog FM technology in the 200 MHz frequency band. In recent systems the analog FM transmission technology is replaced by employing digital modulation techniques for audio signal transmission.

An example of such a digital system is available from the company Comfort Audio AB, 30105 Halmstad, Sweden under the trademark COMFORT DIGISYSTEM.RTM.

"A specific example of an analog wireless FM system particularly suited for school applications is described in International Patent Application Publication WO 2008/074350 A1, wherein the system consists of a plurality of transmission units comprising a microphone and a plurality of analog FM receiver units and wherein only one of the transmission units has an analog audio signal transmitter, while each of the transmission units is provided with a digital transceiver in order to realize an assistive digital link for enabling communication between the transmission units. The assistive digital link also serves to transmit audio signals captured by a transmission unit not having the analog transmitter to the transmission unit having the analog transmitter from where the audio signals are transmitted via the analog FM link to the receiver units.

"U.S. Pat. No. 7,778,432 B2 relates to a wireless network for communication of binaural hearing aids with other devices, such as a mobile phone, using slow frequency hopping, wherein each data packet is transmitted in a separate slot of a TDMA frame, with each slot being associated to a different transmission frequency, wherein the hopping sequence is calculated using the ID of the master device, the slot number and the frame number. A link management package (LMP) is sent from the master device to the slave devices in the first slot of each frame. The system may be operated in a broadcast mode. Each receiver is turned on only during the transmission during time slots associated to the respective receiver. The system has two acquisition modes for synchronization, with two different handshake protocols. Eight LMP messages are transmitted in every frame during initial acquisition, and one LMP message is transmitted in every frame once a network is established. Handshake, i.e., bi-directional message exchange, is needed both for initial acquisition and acquisition into the established network. During acquisition, only a reduced number of acquisition channels is used, with the frequency hopping scheme being applied to these acquisition channels. The system operates in the 2.4 GHz ISM band. A similar system is known from U.S. Pat. No. 8,229,146 B2.

"International Patent Application Publication WO 2008/135975 A2 relates to a communication network, wherein the receiver wakes up for listening to the preamble of a data packet and goes to sleep again, if no valid preamble is received.

"U.S. Patent Application Publication 2007/0086601 A1 relates to a system comprising a transmission unit with a microphone for transmitting a speaker's voice to a plurality of hearing aids via a wireless digital link, which may be unidirectional or bi-directional and which may be used for transmitting both audio data and control data to the hearing aids.

"U.S. Pat. No. 7,529,565 B2 relates to a hearing aid comprising a transceiver for communication with an external device, wherein a wireless communication protocol including a transmission protocol, link protocol, extended protocol, data protocol and audio protocol is used. The transmission protocol is adapted to control transceiver operations to provide half duplex communications over a single channel, and the link protocol is adapted to implement a packet transmission process to account for frame collisions on the channel.

"European Patent Application EP 1 560 383 A2 relates to a Bluetooth system, wherein the slave device, in a park mode or in a sniff mode, periodically wakes up to listen to transmission from the master and to re-synchronize its clock offset.

"U.S. Patent Application Publication 2007/0259629 A1 relates to the transmission of audio signals from a main device, such as a mobile phone, to a peripheral device, such as a headset, in order to establish a wireless personal area network by using an ultra-wide band link, wherein very short pulses of 1 ns or less duration, corresponding to transmission band width of about 500 MHz, are transmitted. In order to reduce power consumption, the transceivers are operated in an interpulse duty cycling mode. In order to better match the peak current consumption from the battery during powered-on times of the interpulse duty cycling to the average current drawn from the battery, a capacitive element is charged when pulses are not being transmitted or received and is then discharged to power the transceiver when pulses are being transmitted or received. It is

also mentioned that such system may be used with devices like a microphone and a hearing aid.
"In U.S. Pat. No. 5,083,095, which relates to a hearing aid having a microphone preamplifier using a junction field effect transistors (JFET), in order to enhance power supply rejection, it is mentioned that, due to the internal impedance of the power source, in connection with the relatively low power supply voltage, the power output stage may contribute a signal which, due to the high current drawn through the power supply impedance, is equal to or greater than the wanted signal. It is also mentioned that such ripple signals may be reduced by placing a capacitor across the power leads or by placing a large resistor between the power lead and the stage to be isolated, with a capacitor across the normal leads of that stage. It is also mentioned that the drawback of such solutions employing a RC-filter is the relatively large capacitor required therefore.
"U.S. Patent Application Publication 2008/0232623 A1 relates to a hearing aid which is recharged via the direct audio input by a battery included in a wireless communication device attached to the hearing aid via the direct audio input, with the transceiver of the communication device likewise being powered by that battery.
"U.S. Pat. No. 6,737,838 B2 relates to a DC/DC up/down converter, wherein first a supply voltage is converted to a lower voltage through a step-down DC/DC converter (buck converter) and then, during specific phases of work also the higher voltage is generated from the lower voltage using the same coil in a step-up converter (boost converter) architecture.
"Conventional radio receiver units ('boots') for hearing aids typically use FM-modulation in the VHF frequency band (169 to 220 MHz) and are connected to the hearing aid through a 3-pin plug-in interface having an audio signal pin, a power pin and a common ground pin, wherein the radio receiver boot is powered by the hearing aid battery. The hearing aid typically is provided with a so-called audio shoe, provided by the hearing aid manufacturer, for connection to the standard 3-pin interface. Typically, the batteries of the hearing aid provide for a supply voltage between 1 and 1.5 V, wherein a typical current consumption of, for example, a BTE hearing aid is between 1 and 2 mA. A digital transceiver operating in the 2.4 GHz band typically needs a supply voltage of 1.5 to 3 V and requires a typical current of 25 mA."
In addition to the background information obtained for this patent application, VerticalNews journalists also obtained the inventors' summary information for this patent application: "It is an object of the invention to provide for a hearing assistance system employing a digital audio link, wherein the receiver unit is powered by the battery of an ear-worn device comprising the stimulation means and wherein noise signals due to current ripples should be avoided. It is also an object of the invention to provide for a corresponding hearing assistance method.
"According to the invention, these objects are achieved by a hearing assistance system and a hearing assistance method as described herein.
"The invention is beneficial in that, by providing the receiver unit with a capacitor connected in parallel to the transceiver for supplying the transceiver during listening or transmission operation with current and for being recharged by the power supply of the ear-worn device, when the transceiver is sleeping and with a controlled current source for controlling the current flowing from the power source to the transceiver and the capacitor in a manner so as to prevent changes in that current which are expected to add an audible noise signal to the audio signals supplied to the stimulation means, the transceiver can be operated in a duty cycling mode for reducing power consumption, while nevertheless noise signals, which otherwise would be caused by the fast changes in the current consumed by the transceiver when switching between the sleeping state and the active listening/transmission state and vice-versa, can be prevented. By using a capacitor to provide for the necessary current peaks in the current consumed by the transceiver, the controlled current source is able to keep the current supplied by the power source close to the average current consumed by the transceiver.
"Preferably, the controlled current source is adapted to adjust the current flowing from the power source to the transceiver and the capacitor to a constant target current value selected according to the estimated quality of the audio link (or according to the estimated average current consumption of the transceiver). The current

flowing from the power source to the transceiver may be kept within -0% . . . +20% at the target value. In case of a change of the estimated quality of the audio link, the current may be adjusted to a new target current value corresponding to the changed quality of the audio link with a time constant of at least 0.05 sec. The target current value preferably is selected as the estimated average current to be consumed by the transceiver plus a safety overhead to account for transient changes in link quality. The link quality may be estimated from an output signal of the transceiver indicative of the packet level error rate and/or the bit level error rate of the received audio signals.

"Preferably, the controlled current source is adapted to monitor the voltage across the transceiver in a manner so as to keep it below a given threshold. To this end, dummy discharge of the capacitor may be caused. According to one example, the receiver unit may comprise a shunt circuit connected in parallel to the capacitor. The shunt circuit may comprise a load resistance, which is periodically switched on by the controlled current source. It can also be a circuit operating in an independent manner, as to prevent the voltage across the transceiver to go over a maximum value and/or to prevent the voltage across the current source to fall below a minimum value. Alternatively or addition, the transceiver may be forced to carry out dummy listening operation.

"These and further objects, features and advantages of the present invention will become apparent from the following description when taken in connection with the accompanying drawings which, for purposes of illustration only, show several embodiments in accordance with the present invention. BRIEF DESCRIPTION OF THE DRAWINGS

"FIG. 1 illustrates the variety of audio components which can be used with a system according to the invention;

"FIG. 2 is a schematic view of a use of a first example of a system according to the invention;

"FIG. 3 is a schematic view of a use of a second example of a system according to the invention;

"FIG. 4 is a schematic view of a use of a third example of a system according to the invention;

"FIG. 5 is a schematic block diagram of an example of a system according to the invention;

"FIG. 6 is a more detailed example of the audio signal path in the transmission unit of the system of FIG. 5;

"FIG. 7 is a more detailed block diagram of an example of the receiver unit of the system of FIG. 5;

"FIG. 8 is an example of the TDMA frame structure of the signals of the digital audio link used in a system according to the invention;

"FIG. 9 is an illustration of an example of the protocol of the digital audio link used in a system according to the invention in the connected state;

"FIG. 10 is an illustration of an example of how a receiver unit in a system according to the invention listens to the signals transmitted via the digital audio link;

"FIG. 11 is a schematic block diagram of an example of a receiver unit according to the invention including a controlled current source;

"FIG. 12 is a more detailed block diagram of an example of the receiver unit of FIG. 11;

"FIG. 13 are plots, from top to bottom, of the current consumed by a transceiver of the receiver unit of FIGS. 11 and 12, the transceiver supply voltage and the current consumed by the current controlled source, respectively, as a function of time;

"FIG. 14 is a block diagram of an alternative example of the receiver unit of FIG. 11;

"FIG. 15 shows a sequence of five phases of the current flow during operation of the receiver unit of FIG. 14;

"FIG. 16 is a block diagram of an another alternative example of the receiver unit of FIG. 11;

"FIG. 17 shows a sequence of five phases of the current flow during operation of the receiver unit of FIG. 16;

"FIG. 18 is a block diagram of a controller to be used in the receiver units of FIGS. 14 &16; and

"FIG. 19 are plots of examples of current profiles through the coil during a working period for various input and output voltages."

Evaluation of a Pinna Compensation Algorithm for Sound Localization and Speech Perception in Noise

Author: Kuk, Francis; Korhonen, Petri; Lau, Chi; Keenan, Denise; Norgaard, Magnus.

Publication info: American Journal of Audiology (Online) 22.1 (Jun 2013): 84-93.
ProQuest document link

Abstract: This study was designed to evaluate the effect of a pinna compensation (PC) algorithm on localization performance in the horizontal plane and speech intelligibility in noise. Nine and 18 experienced hearing aid users with bilaterally symmetrical sensorineural hearing loss participated in the localization study and the speech-in-noise study, respectively. Performance was evaluated unaided, aided with a behind-the-ear (BTE) hearing aid with an omnidirectional microphone (Omni), and aided with the same hearing aid with the PC algorithm (Omni+PC). Localization performance was measured using 12 loudspeakers spaced 30° apart on a horizontal plane. Speech-in-noise performance was measured with speech presented from 0°or 180°. A single-blinded, repeated measures design was used. Significant improvement in localization accuracy was found when comparing the Omni+PC condition to the Omni condition. Also, the Omni+PC condition improved the signal-to-noise ratio by 2.4 dB when compared to the Omni condition when speech was presented from the front in a diffuse noise background. Use of the PC algorithm improved localization on the horizontal plane and speech-in-noise performance. These results support use of the PC algorithm in BTE hearing aid fittings. [PUBLICATION ABSTRACT]

Purpose: This study was designed to evaluate the effect of a pinna compensation (PC) algorithm on localization performance in the horizontal plane and speech intelligibility in noise.
Method: Nine and 18 experienced hearing aid users with bilaterally symmetrical sensorineural hearing loss participated in the localization study and the speech-in-noise study, respectively. Performance was evaluated unaided, aided with a behind-the-ear (BTE) hearing aid with an omnidirectional microphone (Omni), and aided with the same hearing aid with the PC algorithm (Omni+PC). Localization performance was measured using 12 loudspeakers spaced 30° apart on a horizontal plane. Speech-in-noise performance was measured with speech presented from 0°or 180°. A single-blinded, repeated measures design was used.
Results: Significant improvement in localization accuracy was found when comparing the Omni+PC condition to the Omni condition. Also, the Omni+PC condition improved the signal-to-noise ratio by 2.4 dB when compared to the Omni condition when speech was presented from the front in a diffuse noise background.
Conclusion: Use of the PC algorithm improved localization on the horizontal plane and speech-in-noise performance. These results support use of the PC algorithm in BTE hearing aid fittings.
Key Words: pinna compensation, localization, hearing-in-noise, spectral cues
The latest hearing industry statistics reported the use of behind-the-ear (BTE) hearing aids (HAs) reaching

69.9% (Strom, 2012). This renewed popularity of BTEs is mostly fueled by the increased cosmetic acceptance of miniature thin-tube and thin-wire receiver-in-the-canal (RIC) and receiver-in-the-ear (RITE) devices. At the same time, algorithms to improve the precision of fitting have also resulted in a higher performance of BTE HAs. One such example is the use of pinna compensation (PC) algorithms that preserve or enhance some spectral characteristics of the pinna. This study examined the efficacy of one such algorithm.

One of the benefits of having binaural hearing (or HAs) is the ability to use the interaural level difference (ILD) and interaural time difference (ITD) of a sound perceived between the two ears as a means to localize its location (Kuhn, 1977; Wightman &Kistler, 1992). The spectral difference of the sound source when it is presented in front or from the back of a listener also provides a cue for localization. The ability to localize a sound source is important for safety (e.g., traffic) and functional reasons (e.g., turning to the direction of the speaker in a crowd). Localization gives listeners the ability to construct auditory scenes of their surroundings, which reinforces their sense of space and their relationship with the auditory objects in their surroundings (Stern, Brown, &Wang, 2006).

The spectral cue that is used for front-back localiza- tion is provided by the pinna. The pinna casts a shadow to sounds that originate from the back and has the effect of a linear filter with a frequency response determined by the direction of the sound source relative to the pinna. When sounds are presented directly from the back, the pinna reduces their intensity by ~ 5 dB between 2 kHz and 8 kHz at the ear canal opening. These spectral changes provide front-back localization cues (e.g., Blauert, 1997). The use of in-the-ear (e.g., ITE; ITC, or in the canal; and CIC, or completely in canal) style HAs preserves this pinna shadow (e.g., Best, Kalluri, McLachlan, Valentine, Edwards, &Carlie, 2010; D'Angelo, Bolia, Mishler, &Morris, 2001; Van den Bogaert, Carette, &Wouters, 2011; Westennann &Topholm, 1985) and has been demonstrated to partly preserve front-back localization. The use of BTE HAs with an omnidirectional microphone placed on top of the pinna reduces or modifies the pinna shadow. This is because an omnidirectional microphone is equally sensitive to sounds from all directions (measured in a free field). Although some directivity is achieved when the BTE is worn on the ear due to diffractions of the head, this directional sensitivity is typically less than what is achievable with a directional microphone (Dillon, 2001). This difference in front-to-back sensitivity could be sufficient to offset any cues that the pinna provides and could lead to increased front-back confusion.

Indeed, it has been shown in several studies that the use of BTE HAs increases the rate of front-back localization reversals when compared to ITE (Orton &Preves, 1979; Westermann &Topholm, 1985), CIC (Best et al, 2010), or more recently, in-the-pinna (ITP) (Van den Bogaert et al, 2011) HAs. If aided localization is an important issue to consider in an HA, it would be logical to correct for the absence of the pinna shadow so that, despite the use of a BTE HA, the wearer would still have the natural pinna localization cues for front-back differentiation. This is especially necessary given the recent interest in the use of RIC/RITE-style HAs.

It is possible to compensate for the difference in spectral cues that result from the difference in microphone location by electronically shaping the input that originates from the back. Such is the basis of PC algorithms. The natural attenuation of sounds coming from behind can be created by adjusting the polar pattern of the microphone system so it is in a directional mode >2000 Hz while leaving the lower frequency bands in an omnidirectional mode. This would simulate the pinna attenuation for the higher frequency sounds arriving from the back without affecting the lower frequency sounds. For sounds arriving from the front, the PC algorithm should yield an identical output as an omnidirectional microphone for all frequencies. Because a PC algorithm attenuates sounds from the back much like the action of a directional microphone, one would also infer that a directional BTE HA could provide enhancement in localization over its omnidirectional counterpart.

Keidser et al. (2006) examined the effect of compres- sion, noise reduction, and directional microphones on localization performance on a horizontal plane in 12 listeners with hearing impairment using a 360° loudspeaker array. Three directional microphone modes were examined: cardioid microphones in both ears, figure-8 microphone in one ear and cardioid in opposite ear, and omnidirectional in one ear and cardioid in opposite ear.

Although the effects of compression and noise reduction on localization were insignificant, the impact of a directional microphone was significant in all three modes. A reduction in front-back confusion was reported with use of the directional micro- phone over time. The same findings were also confirmed in a later study using a hypercardioid directional microphone in 21 listeners with hearing impairment (Keidser, Carter, Chalupper, &Dillon, 2007). Similarly, Mueller, Kegel, Schimmel, and Dillier (2012) created virtual environments to evaluate sound localization with BTE HAs and reported that a cardioid directional microphone reduced front-back confusion over that of an omnidirectional microphone or noise reduction algorithm.

Although a directional microphone (having directivity in all frequencies) could improve front-back localization, it may not be necessary to have directional attenuation across all frequencies in order to achieve PC. Partial directionality, especially that >2000 Hz, may be all that is needed. Keidser, O'Brien, Hain, McLelland, and Yeend (2009) compared the horizontal localization ability of 21 listeners with hearing impairment using a BTE HA programmed in four directional schemes: (a) omnidirectional across all frequencies, (b) omnidirectional <1000 Hz and hypercardioid >1000 Hz (partial-1, with a directivity index or DI of 0 dB at 1000 Hz rising to 4 dB >2000 Hz), (c) omnidirectional <2000 Hz and hypercardioid >2000 Hz (partial-2, with a DI of 0 dB at 2500 Hz rising to 2 dB at 4000 Hz), and (d) hypercardioid directionality in all frequencies (from 5 dB in the lows to 4 dB at -5000 Hz). Five different stimuli each covering a different range of frequencies were used to study the effects of directionality and stimulus characteristics on localization. Keidser et al.'s data showed that the partial-1 directionality condition improved front-back localization for mid- and high-frequency stimuli but not for low-frequency stimuli. No significant effect was observed on left/right localization. Unlike the partial directionality, the use of a full-band directional microphone had a small positive effect on front-back localization but a negative effect on left/right localization.

Other commercial PC algorithms have been marketed, although a detailed technical description often was not available. Phonak (2004) reported that its Real Ear Sound (RES) algorithm restored the pinna shadow by creating a polar pattern with a DI of 1 to 2 dB from 1500 Hz to 6000 Hz and 0 to -3 dB from 250 Hz to 1000 Hz. This is - 1 dB poorer than the unaided DI <1000 Hz and 1 dB better than the unaided DI >4000 Hz. A study reported by Phonak (2004) showed that the RES reduced the rate of front-back confusion by an average of 38%. In the study, 18 adults with hearing impairment were tested using a 12-loudspeaker array and a 500-ms speech-shaped noise as the stimulus.

However, the same observation was not replicated in an external study using 4- to 8-year-olds as the test participants. Marriage, Gardner, Stone, and Moore (2007) examined the impact of the RES feature on horizontal localization (front- back and left-right) in a group of 15 children with hearing impairment using only two loudspeakers (for either front- back or left-right evaluation). A 1-s duration pink noise was used as the stimulus to compare performance between the omnidirectional microphone and the RES conditions. No difference in front-back or left/right localization scores was noted between the conditions. A training session with feedback was also provided subsequently; nonetheless, no effect of training was noted.

Recently, Widex introduced its PC algorithm, called the Digital Pinna (DP). The DP is designed as a directional microphone with partial directionality >2000 Hz, resembling a hypercardioid polar pattern. The DP resembles the unaided in-situ directivity <1500 Hz and achieves a DI of 4 dB >2000 Hz. This DI is higher than the unaided in-situ DI (which is ~2 dB >2000 Hz) and could potentially facilitate front-back localization on the horizontal plane. Furthermore, because the PC algorithm attenuates sounds that originate from the back, much like a directional microphone, it is reasonable to expect that the DP would also improve the signal-to-noise ratio (SNR) of the listening environment over its omnidirectional microphone counterpart. It is also estimated that the magnitude of the SNR improvement should at least approximate the SNR improvement as one changes the microphone position from a BTE HA to an ITE/ITC HA. Pumford, Seewald, Scollie, and Jenstad (2000) showed that the SNR benefit offered by an ITE HA over a BTE HA was -2.4 dB in a diffuse noise condition.

Thus, we conducted the current study to validate the benefits of the DP. Specifically, we compared the potential

improvement in front-back localization and speech-in-noise performance between the DP (i.e., an omnidirectional microphone with a PC algorithm) and an omnidirectional microphone without such an algorithm.

Experiment #1: Localization in Horizontal Plane

Method

Participants

Based on data collected in a pilot study, we estimated that a sample size of eight participants was required to demonstrate that the PC algorithm can improve front-back localization with a power >0.8 (significance level a = 0.05). We recruited a total of nine adults (6 females and 3 males) from the Widex Office of Research in Clinical Amplification's research center. Their ages ranged from 65 to 81 years (x = 73 yrs, crs = 6). All participants were native English speakers, and all had mild-to-moderate sensorineural hearing losses. The averaged insert thresholds for the left and right ears are shown in Figure 1. The mean pure-tone averages (at 0.5 kHz, 1 kHz, and 2 kHz) were 39.8 dB HL for the left ear and 40.6 dB HL for the right ear. All participants had a <20-dB threshold difference between ears at any audiometric test frequency. Six of the nine participants were experienced HA wearers, with an average of 6.5 years HA use. Two participants wore BTE HAs and four wore custom HAs (ITE, CIC, ITC). Details of the participants, including the makes, models, and styles of their HAs, are provided in Table 1. Participants were explained the purpose of the research study, their tasks, and their benefits before signing an informed consent. They were financially compensated for their participation in the study.

HAs and Fitting

All participants were fitted bilaterally with Widex Clear440 Passion model HAs using Widex Compass (v. 5.1) fitting software. The Widex Clear440 Passion is an HA with wireless connectivity between the two HAs. However, all wireless functionality was disabled during this study. This RIC HA features 15-channel slow-acting amplitude com- pression and has a frequency response between 100 Hz and 7800 Hz (American National Standards Institute, 2003). The sampling frequency of the analog-to-digital converter stage is 32 kHz. Among the features of this device are noise reduction, adaptive feedback cancellation, and impulse noise management. The noise reduction algorithm was deactivated during the testing. The feedback cancellation algorithm remained in its default setting.

For Experiment 1, we compared two HA programs: omnidirectional microphone alone (Omni) and omnidirectional microphone with the PC algorithm (Omni+PC). The latter was commercially known as the DP feature. The PC algorithm was designed to achieve a hypercardioid polar pattern >2000 Hz without altering the in-situ directivity <2000 Hz. Figure 2 shows a comparison of the DI of the unaided, Omni, and Omni+PC conditions as measured on a KEMAR manikin in an anechoic chamber. Note that the DI of the DP feature exceeded that of the unaided condition by at least 2 dB across all frequencies >2000 Hz. The partici- pant's in-situ hearing thresholds were measured at 500 Hz, 1 kHz, 2 kHz, and 4 kHz, with the study HAs coupled to instant-fit eartips. Two participants (S4, S6) were provided with a closed vent, five participants (SI, S2, S3, S7, S9) were provided with a 1.7-mm vent, and two participants (S5, S8) were provided with open fit tips.

We conducted a feedback test to estimate the feedback path and to limit the maximum available gain before feedback. The appropriateness of the fitting was verified by examining the simulated real-ear output and predicted aided thresholds on the fitting software to ensure accuracy and efficiency. An acceptable fitting required that the predicted aided thresholds be <20 dB HL below 3 kHz and <30 dB HL at 4 kHz. Predicted aided thresholds were within 5 dB of the measured sound-field thresholds (Kuk, Ludvigsen, Sonne, &Voss, 2003). Simulated real-ear output and not actual real-ear output was measured because it was previously demonstrated that the sensation level (difference between threshold and output) shown on the fitting software was within + 2 dB of the measured real-ear output in >80% of cases (Kuk, 2012).

Test Setup

All testing was conducted in a double-walled sound- treated booth (Industrial Acoustics Company, Inc.) with

internal dimensions of 3 m x 3 m x 2 m (W x L x H). Localization performance was measured using a 12-loudspeaker array that was evenly distributed on a horizontal plane around the listener. The spacing between adjacent loudspeakers was 30°. The loudspeakers used were KRK-ST6 2-way passive studio monitors. The loudspeakers were individually calibrated using a sound level meter (Quest model 1800) placed 1 m in front of the loudspeaker within the booth. A speech-shaped noise was presented from each loudspeaker at an intended output level of 68 dB(C). Loudspeakers with an output deviation from this 68 dB(C) noise were electrically compensated to within +1 dB.

Afterward, the frequency response of each loudspeaker was measured at 1/3-octave intervals while using a white noise stimulus. Loudspeakers with substantial deviation from the other loudspeakers were not included for use. The 12 loudspeakers used had maximum deviations (among 12 loudspeakers) within +2.1 dB at 250 Hz, +1.6 dB at 500 Hz, +0.6 dB at 1000 Hz, + 1.1 dB at 2000 Hz, + 0.6 dB at 4000 Hz, and +1.1 dB at 8000 Hz. During testing, the listeners were seated 1 m from the loudspeakers in the center of the array facing the front loudspeaker. The listeners were instructed to keep their heads fixated toward the front loudspeaker. A foam headrest was placed behind the participants' head to help reduce head movement. In addition, the test administrator monitored the participants visually during the test to ensure that there was no head movement during stimulus presentations. A touch-screen computer display (17" Planar PT 1700 MU) was placed on a small computer table in front of the participants so that they could register their responses.

The target stimulus was presented from one of the 12 loudspeakers in a random order. The participant's task was to indicate the perceived location of the target sound by touching the position of a circle on the touch-screen monitor. The location of the participant's response on the circle was recorded by the computer. Thus, it was possible to register a perceived location between two loudspeakers. Stimuli were automatically presented at the participant's pace in a random order. The test software was implemented using Visual Basic programming language for the Windows XP operating system. During the course of the study, monthly calibration of all test equipment was conducted in addition to daily calibration checks.

Stimulus

The target stimulus was a steady-state 300-ms high- pass (2000 Hz) filtered noise burst that was generated by filtering a white-noise signal using an 18th-order Butterworth filter. Signal generation was carried out using Adobe Audition 1.0 audio editing software. The stimuli were presented using an Echo Audiofirel2 twelve-channel digital audio interface. Signals were amplified using a Niles SI-1230 power amplifier.

Pvoceduve

The participants' localization performance was evaluated under three test conditions: unaided, Omni, and Omni+PC. The test conditions were counterbalanced across participants. Stimuli were presented at a 30-dB sensation level (SL), or in cases where this was too loud, at the most comfortable listening (MCL) level. Each signal azimuth was presented a total of three times during each test trial.

Results

Performance Measures

The binaural localization cues (ILD, ITD) are virtually identical for sounds that originate from sources that are located at an equal distance from the listener's ear. This makes it impossible to judge the true location of a sound source as the signals originating from two different sources can create the identical auditory events. The typical errors in the horizontal plane that arise from this are front-back or back-front errors mirrored around the axis of the ears. Therefore, when assessing localization performance that extends across the whole horizontal plane (i.e., 360°), the root-mean-square (RMS) error frequently used for assessing localization may not be a consistent metric across all source angles. Thus, we reported individual localization perfor- mance as the percentage of correct responses within +15° from the source direction.

Figure 3 shows the averaged localization scores across all stimulus azimuths for all participants under the three test conditions. In the unaided condition, the participants responded correctly for 21.6% of the stimulus

presentations. In the aided conditions, the participants responded correctly for 17.9% of the stimulus presentations with Omni and for 26.9% with Omni+PC. A one-way repeated measures analysis of variance (ANOVA) was used to examine the effect of test condition. The results showed a significant effect of test condition, F(2, 16) = 3.62, p = 0.05, rf = 0.31, power = 0.6. Post hoc analysis with Bonferroni adjustment indicated that Omni+PC performed significantly better than Omni,/? = 0.01, effect size = 1.12, power = 0.8. Figure 4 shows a scatter plot comparing the individual localization scores between the unaided and Omni+PC conditions. In order to provide some insights on the potential influence of the participants' previous HA experience on localization, we used triangles to represent those participants who previously wore BTE HAs, circles for those who wore custom HAs (i.e., ITC, CIC), and squares for those who had never worn HAs. The localization scores ranged from 8.3% to 30.6% in the unaided condition and from 16.7% to 55.6% in the Omni+PC condition. Six of the nine participants had individual localization performance higher with the Omni+PC condition than with the unaided condition. No correlation was observed between the unaided localization performance and aided localization performance with Omni+PC (R2 = 0.09). Likewise, Figure 5 shows a compar- ison of the localization scores between the Omni and Omni+PC conditions. Omni+PC yielded higher localization performance than Omni for seven of the nine participants. The participants' previous HA styles did not suggest or provide any indication for aided localization performance with Omni+PC.

Front-Back Localization

We analyzed localization performance by focusing on the measured localization data for sounds originating from the three front (330°, 0°, 30°) and the three back (150°, 180°, 210°) loudspeakers. We analyzed the instances in which the participants identified these stimuli correctly as originating from the frontal hemisphere (270°... 90°) or the rear hemisphere (90°... 270°). Figure 6 shows the front- back localization scores averaged across all participants. Localization scores for sounds presented from the front were 59.3% with Omni and 70.4% with Omni+PC. Localization scores for sounds presented from the back were 30.4% with Omni and 60.0% with Omni+PC. The unaided localization scores were 71.1% for sounds presented from the front and 50.4% for sounds presented from the back.

A two-way repeated measures ANOVA was used to examine the effect of test condition (unaided, Omni, Omni+PC) and the effect of hemisphere (front, back). Results showed that the effect of test condition was significant, F(2, 16) = 7.02, p = 0.006, rf = 0.46, power = 0.9, whereas the effect of hemisphere was not significant, .Ffl, 8) = 3.19, p = 0.11, r\2 = 0.28, power = 0.4. The interaction effect between test condition and hemisphere also was not significant, F(2, 16) = 0.65, p = 0.53, rf = 0.07, power = 0.1. Post hoc analysis indicated that only Omni+PC performed significantly better than Omni for localization from the back, p = 0.02, effect size = 0.92, power = 0.7. No significant difference was observed between the unaided and the other two test conditions (p >0.05).

Experiment #2: Speech Understanding in Noise

Method

Participants

A total of 18 native English-speaking adults (11 females and 7 males) between 63 and 82 years (x=72, crs = 5.9) participated in this experiment. The nine participants who participated in Experiment 1 were among the 18 participants. A power analysis based on the first nine participants suggested that 23 participants were needed to demonstrate the SNR advantage of the PC algorithm with a power of 0.8 (significance level a = 0.05). The study was terminated after data collection was completed on the 18th participant when it was clear that the criterion for statistical significance was exceeded. All listeners had mild-to-moderate sensorineural hearing losses. The mean pure-tone average for left and right ears was 41.5 dB HL (crs = 4.8). Figure 7 shows the averaged insert earphone thresholds for the left and right ears.

Thirteen of the 18 participants were experienced HA wearers, with an average 7.8 years (crs = 4.5) of HA use. Three participants wore BTE HAs, 10 participants wore custom products (i.e., ITE, CIC, ITC), and five

participants did not wear any HAs. Details on the participants, including the makes, models, and styles of their HAs, are provided in Table 2.

HAs

The same HA that was used in Experiment 1 was also used in this experiment.

Test Setup

Participants' speech-in-noise performance was mea- sured with the Hearing In Noise Test (HINT; Nilsson, Soli, &Sullivan, 1994). All testing was conducted in the same double- walled sound-treated booth described previously. Test loudspeakers were positioned at 1 m from the participant at 0°, 90°, 180°, and 270°. Presentation of the HINT stimuli was controlled by a custom computer program implemented using Visual Basic for the Windows XP operating system.

Stimuli

A continuous speech-shaped noise that matched the spectrum of the male talker used in the HINT was presented at a fixed level of 68 dB SPL (C, slow). The level of the speech signal was adjusted in 4-dB steps for the first four sentences and 2-dB steps for the 5th to 20th sentences. The ratio of the average speech level (from the 5th to 20th sentence) and the noise level defined the reception threshold for speech (RTS).

Procedure

Speech-in-noise performance was measured under two stimulus conditions. In the first condition, the speech stimuli were presented from a loudspeaker at 0°, and the continuous speech-shaped noise was presented from the three loud- speakers at 90°, 180°, and 270°. This condition examined the potential SNR benefit provided by the PC algorithm as it attenuated sounds arriving from the back of the listener.

In the second condition, the speech stimuli were presented from the loudspeaker at 180°, and the continuous speech-shaped noise was presented from the three loud- speakers at 0°, 90°, and 270°. This condition examined the potential negative effect of the PC algorithm in reducing audibility for sounds >2 kHz when speech was presented from the back of the listener and noise was presented from the front and sides.

Results

The average RTS measured for stimuli presented from 0° or 180° are reported in Figure 8. Note that the concomitant speech-shaped noise was presented from the other three azimuths (90°, 270°, and 18070°). When speech was presented from the front and noise from the sides and back (speech 0°, noise 90°, 270°, and 180°), the RTS required for 50% performance was 4.5 dB in the unaided condition, 5.0 dB in the Omni condition, and 2.6 dB in the Omni+PC condition. A one-way repeated measures ANOVA compar- ing the absolute RTS of the three conditions was significant, $F(2, 34) = 6.65$, $p = 0.004$, $rf = 0.28$, power = 0.9. Post-hoc analysis with Bonferroni adjustment showed that Omni+PC was significantly better than the Omni and unaided conditions, $p < 0.005$, effect size >0.7, power >0.8.

Wien speech was presented from 180° and noise from the sides and front (speech 180°, noise 90°, 270°, and 0°), the RTS required for 50% performance was 6.8 dB in the unaided condition, 3.8 dB with Omni, and 4.6 dB with Omni+PC. A one-way repeated measures ANOVA compar- ing the absolute RTS of the three conditions was significant, $F(2, 34) = 16.86$, $p < 0.001$, $rf = 0.49$, power = 0.9. Post hoc analysis with Bonferroni adjustment showed that Omni and Omni+PC were significantly better than the unaided condition, $p < 0.005$, effect size >0.76, power >0.85. No significant difference was found between the Omni and the Omni+PC conditions ($p = 0.092$).

Discussion

The present study examined the effect of the PC algorithm on horizontal localization and speech-in-noise performance. First, laboratory data showed that the PC algorithm used in the HA study improved the overall localization accuracy in the horizontal plane from an omnidirectional microphone by 9.0% when collapsed across all azimuths and by 30.0% when comparing stimuli presented from the back. The PC algorithm also improved localization performance over the unaided condition by almost 10% for sounds presented from the

back. Second, the data showed that the PC algorithm reduced the RTS by 2.4 dB when compared to an omnidirectional microphone and by 2.0 dB when compared to the unaided condition when speech was presented in a diffuse noise background.

Front-Back Localization

The current study showed significant improvement in localization performance when comparing the omnidirectional microphone alone to the omnidirectional microphone with PC. The improvement did not seem to be affected by the style of HAs that the participants wore before the study (see Figures 4 and 5). The finding of a 30% reduction in front- back confusion compared favorably to the 27% improvement from the partial-1 directionality reported in the Keidser et al. (2009) study. The differences between this study and Keidser et al.'s study were differences noted in the DI between 1000 Hz and 2000 Hz, the loudspeaker set-up, the stimuli used, and the experience of the participants. Whereas Keidser et al.'s partial-1 condition had significant DI between 1000 Hz and 2000 Hz, the PC algorithm used here had close to 0 dB DI <2000 Hz. In addition, Keidser et al. used a 20-loudspeaker array with five stimuli each covering a different range of low, mid, and high frequencies. They were also significantly longer (750 ms to 2 s) than the stimulus used in this study. A 12-loudspeaker array system and only one 300-ms high-pass noise >2000 Hz were used in this study. Stimulus frequency and stimulus durations are known to affect the absolute localization performance (Irving &Moore, 2011).

A key difference in findings between the Keidser et al. study (2009) and this study was the time frame in which the effect of PC was realized. In the Keidser et al. study, no immediate benefit of the PC algorithm was seen at the initial visit: The benefit was reported only after 3 weeks of use of the algorithm. This suggests that an acclimatization period was needed to realize the benefit. On the other hand, the benefits seen with the DP feature in the current study were immediate. The participants demonstrated the improved front-back localization performance at the initial fitting of the study HA. It is unclear why the effect of the PC algorithm used in the current HA was more immediate: The slight difference in DI between the two HAs would not have led to such a difference. Perhaps the longer stimuli used in the Keidser et al. study made it easier for participants to localize, but they were less sensitive for the listeners to distinguish between HA conditions.

This study also confirmed that aided localization with an omnidirectional microphone was poorer than unaided localization for sounds presented from the rear, which was poor to begin with (-50%, Figure 6). Thus, it is gratifying to note that the aided performance with the Omni+PC condition was even slightly better than the unaided condi- tion. This may originate from a PC algorithm that has a higher DI (-3-4 dB) than the DI of the typical unaided ear (-2 dB). The higher DI provided a greater spectral contrast between signals presented to the front and to the back. Following this line of reasoning, one may expect a full-band hypercardioid directional microphone with a high-frequency DI of 6 dB to result in an even better front-back localization performance than the DP algorithm used in this study. Although Keidser et al. (2009) compared the localization performance between a full-band directional microphone, the partial-1 directional microphone, and the unaided condition, the high frequency DI for their full-band directional microphone condition was limited to the same 3^1 dB as the partial-1 directionality. Thus, their study was unable to answer if a higher high-frequency DI would lead to better front-back localization. Additional studies are necessary to examine the relationship between front-back localization and high-frequency DI.

Open-Ear Fitting

It is known that a directional microphone loses its directivity as the vent diameter of the HA/earmold increases. The loss is more noticeable in the low and mid frequencies than in the high frequencies. Indeed, in an open-ear fitting with a full-band directional HA, the DI <2000 Hz can be reduced to an unaided level (Dillon, 2001). This means that the effective DI of an open-fit full-band directional HA would primarily be concentrated at frequencies >2000 Hz, similar to that of the pinna shadow. The difference may be the magnitude of the DI in the high frequencies between the two. Although the DI in the high frequencies varies between 4 dB and 6 dB for a two-port, full-band directional microphone, the DI varies between 2 dB and 4 dB when it is implemented as a PC

algorithm. This has several implica- tions. First, it means that the SNR advantage of an open-fit directional HA could be similar to that of a BTE HA with a PC algorithm such as the Omni+PC microphone condition used in this study. For example, the 2.4-dB SNR benefit with the PC algorithm measured in the current study was similar in magnitude to Kuk, Keenan, Sonne, and Ludvigsen's study (2005a), which reported an average of 2-dB SNR improvement of an open-fit directional microphone over its omnidirectional counterpart. The DI of the full-band directional microphone used in the Kuk et al. study (2005a) was reportedly ~6 dB in the high frequencies. Second, if the effective DI of an open-ear directional microphone is similar to that of the PC algorithm, one may consider designing a dedicated directional microphone specifically for open-ear BTE fittings. In this case, the directional microphone may have an omnidirectional polar pattern <2000 Hz and a hypercardioid polar pattern >2000 Hz (similar to the PC used here). Because of the omnidirectional polar pattern in the lower frequency, no amplification is needed to offset the loss in the low-frequency output that is typically seen in a directional microphone (Ricketts, 2001). This will eliminate the extra circuit noise generated from amplifying the low frequencies. Thus, the results of this study, along with the reports that open-ear fitting improves vertical localization (Bryne &Noble, 1998), would support the use of partial directionality in an open-ear fitting HA for sound localization and speech-in-noise performance. This possibility needs to be validated.

Speech Intelligibility in Diffuse Noise

The PC algorithm improves speech intelligibility in a diffuse noise field by 2.4 dB, but it could also attenuate desirable sounds that originate from the back. The impact of the latter was not shown in the current study, where the difference in RTS between the Omni and Omni+PC condi- tions was 0.8 dB (and statistically nonsignificant). The nonsignificant effect could be due to use of the HINT and testing in a noise background. In a noise background, the impact of the noise on the elevation of SNR may be more dominant over the impact of the reduced sensitivity of the microphone to sounds originating from the back. This could mask the impact of a directional microphone for sounds that originate from the back. On the other hand, such "masking" effect would likely not be present in a quiet situation. Previously, Kuk, Keenan, Lau, and Ludvigsen (2005b) reported a 7.2% reduction of phoneme recognition scores with a fixed directional microphone when speech was presented from behind at 65 dB SPL in quiet. However, it needs to be pointed out that the directional microphone used in the Kuk et al. study had a DI of 6 dB across frequencies and would have produced greater attenuation of sounds originating from the back than the PC algorithm used in the current study. Additional studies with speech presented from the back in quiet are needed to fully assess the impact of the PC algorithm on speech intelligibility presented from the back.

Conclusion

The primary purpose of this study was to evaluate the use of an omnidirectional microphone with PC on front-back localization and speech-in-noise performance. The results demonstrated that the PC algorithm improved horizontal localization and speech-in-noise performance without significant loss in speech intelligibility for sounds arriving from the back.

Abstract: The aim of this study was to determine whether increasing the overall speech level or the individual spectral contrasts of vowel sounds can improve vowel formant discrimination for listeners both with and without normal hearing. Thresholds of vowel formant discrimination were examined for the F2 frequencies of 3 American English vowels for listeners with and without normal hearing. Spectral contrasts of the F2 were enhanced by 3, 6, and 9 dB. Vowel stimuli were presented at 70 and 90 dB SPL. The thresholds of listeners with hearing impairment were reduced significantly after spectral enhancement was implemented, especially at 90 dB SPL, whereas normal-hearing listeners did not benefit from spectral enhancement. These results indicate that a combination of spectral enhancement of F2 and high speech level is most beneficial to improve vowel formant discrimination for listeners with hearing impairment. Purpose: The aim of this study was to determine whether increasing the overall speech level or the individual spectral contrasts of vowel sounds can improve vowel formant discrimination for listeners both with and without normal hearing.
Method: Thresholds of vowel formant discrimination were examined for the F2 frequencies of 3 American English vowels for listeners with and without normal hearing. Spectral contrasts of the F2 were enhanced by 3, 6, and 9 dB. Vowel stimuli were presented at 70 and 90 dB SPL.
Results: The thresholds of listeners with hearing impairment were reduced significantly after spectral enhancement was implemented, especially at 90 dB SPL, whereas normal-hearing listeners did not benefit from spectral enhancement.
Conclusion: These results indicate that a combination of spectral enhancement of F2 and high speech level is most beneficial to improve vowel formant discrimination for listeners with hearing impairment.

Key Words: speech perception, hearing loss, speech enhancement

Listeners with hearing impairment (HI) have greater difficulty in speech perception than normal-hearing (NH) listeners (Henry, Turner, &Behrens, 2005; Leek, Dormán, &Summerñeld, 1987). Because poor communication performance for listeners with HI is often caused by reduced audibility of speech signals, a common method of compensating for hearing loss is to increase the intensity of speech sounds beyond audibility levels for listeners with HI (Humes, Dirks, Bell, &Kincaid, 1987). However, reduced frequency selectivity is often associated with sensorineural hearing loss and contributes to difficulty in speech perception for listeners with HI (Needleman &Crandell, 1997). Therefore, another compensatory method is to selectively enhance the spectral and temporal features that are important for speech perception (i.e., increase the spectral contrast of speech stimuli; Bunnell, 1990; Lyzenga, Festen, &Houtgast, 2002; Stone &Moore, 1992). The primary purpose of this study was to investigate whether increasing the speech level or enhancing the spectral contrasts of vowel sounds can improve vowel formant discrimination for listeners with HI.

A number of studies have suggested that vowel sounds are perceptually categorized by their characteristic spectral properties, such as the resonant peaks in the vowel spectrum (Hillenbrand, Getty, Clark, &Weeler, 1995). These peaks, called formants-especially the first two formants, FI and F2-are primary acoustic cues for vowel identification and categorization. Small changes to vowel formant frequency may result in a perceptual shift from one vowel category to another. Therefore, it is important to understand how sensitive the human auditory system is to differences in formant frequency. The threshold for vowel formant discrimination is defined as the smallest detectable difference of a single formant frequency. Many factors have been shown to significantly affect formant discrimination for NH listeners, including vowel category, level of linguistic context, and speech level (Liu, 2008; Liu &Kewley-Port, 2004).

To date, studies of vowel formant discrimination for listeners with HI are limited, providing equivocal results. Coughlin, Kewley-Port, and Humes (1998) and Richie, Kewley-Port, and Coughlin (2003) measured formant discrimination for four American English vowels presented at conversational levels (60-70 dB SPL) and relatively high sound levels (95 dB SPL) for NH and HI listeners. Results suggested that, for the listeners with HI, formant discrimi- nation improved significantly from low to high levels, especially for F2 frequency, in which the listeners with HI had hearing loss. These two studies argued that this improvement was due to the better audibility at high levels. However, the listeners with HI still had markedly higher thresholds than the NH listeners for F2 at 95 dB SPL, indicating that increased audibility alone was not sufficient for the listeners with HI to achieve NH performance.

Conversely, Liu and Kewley-Port (2007) reported that formant discrimination of F2 at a well-audible level (95 dB SPL) for listeners with HI was worse than at 70 dB SPL in three phonetic contexts: isolated vowel, syllable, and sentence. They argued that this reverse-level effect on formant discrimination was due to the reduced frequency selectivity and upward spread of masking on F2 produced by FI. Additionally, Liu and Kewley-Port concluded that in the earlier studies (Coughlin et al., 1998; Richie et al., 2003), F2 was not audible at low levels and became well audible at high levels, whereas in their study, F2 was audible at both the low and high levels. Together, these studies with listeners with HI suggest that formant discrimination was significantly affected not only by audibility, but also by other factors associated with hearing loss such as reduced frequency selectivity.

In addition to the studies that measured vowel formant discrimination of listeners with HI, other studies examined just-noticeable differences in F2 transition of listeners with HI, with a main focus on the effect of upward spread masking of FI on F2 discrimination (Danaher, Osberger, &Pickett, 1973; Danaher &Pickett, 1975; Van Tassell, 1980). Pickett and colleagues (Danaher et al, 1973; Danaher &Pickett, 1975) found that discrimination of F2 transitions in synthetic vowels was improved for listeners with moderate-to-severe flat or sloping hearing losses as FI was removed from the stimuli, indicating that the upward spread of masking from FI interfered with the F2 discrimination of the listeners with HI. In a later study, Van Tassell (1980) reported that as a group, listeners with HI performed similarly in F2 transition discrimination for stimuli with and without FI

presented, although the listeners with HI showed great individual variability. These studies indicate that the presence of low-frequency components (e.g., Fl) generates masking on F2 perception. Thus, spectral enhancement of F2 in the present study may increase the F2 representation to overcome the upward spread of masking by Fl.

Based on these findings of F2 discrimination (Coughlin et al, 1998; Danaher et al, 1973; Danaher &Pickett, 1975; Liu &Kewley-Port, 2007; Richie et al., 2003; Van Tassell, 1980), we proposed that the enhancement of specific acoustic features of vowels may improve discrimination for listeners with HI rather than only increasing overall vowel intensity. One such solution is to enhance spectral contrasts. Vowel formants are represented with much lower spectral contrast in the dysfunctional auditory system of humans (Liu &Kewley-Port, 2007) and animals (Miller, Calhoun, &Young, 1999b) as compared to the normal auditory system. Several studies have suggested that vowel identification improves as the spectral contrast of vowel formants are increased for both NH and listeners with HI, indicating the importance of spectral contrast for vowel perception (Leek et al, 1987; Liu &Eddins, 2008). Increasing the spectral contrasts of F2 and F3 improved the spectral representation of vowels and partially restored sensitivity to the F2 frequency in the responses of the HI auditory nerve (Miller, Calhoun, &Young, 1999a). Thus, spectral enhancement of vowel formants may be able to compensate for the spectral smearing that is caused by sensorineural hearing loss. Spectral enhancement may also improve vowel formant discrimination for listeners with HI.

In the present study, we increased the spectral contrasts of F2 for individual vowels. This is in contrast to the high- pass amplification of the F2 and F3 frequency ranges that are commonly used in hearing aid technology by both manufacturers and traditional prescriptive fitting methods (Mueller, 2005). When high-pass amplification is applied, the spectral valley between Fl and F2 could be increased, obscuring the spectral representation and worsening listener performance (Miller et al., 1999a). Thus, in this study, we enhanced the spectral contrasts of F2 by increasing the amplitude of F2 but not changing the spectral valleys near F2. If the spectral enhancement of selective formant peaks is found to improve speech perception for listeners with HI, this strategy may have potential implications in signal processing algorithms for amplification devices.

Altogether, the main purpose of this study was to investigate whether acoustic manipulation, via increase of the overall speech level or spectral contrast, is able to improve vowel formant discrimination for NH and HI listeners. We manipulated three factors: speech level (70 and 90 dB SPL), spectral enhancement of F2 (original and enhancement by 3, 6, and 9 dB), and F2 frequency of three English vowels (/a, x, i/).

Method

Stimuli

Three American English isolated vowels, /a, x, i/, were used as stimuli. The three original vowels were recorded in an /hVd/ context from a young American English female talker and served as the base stimuli for spectral enhancement. Isolated vowels were obtained by truncating the initial /hi and the final /d/, including the onset and offset formant transition, such that only the central vowel nucleus remained. The central 200-ms portions of the /hVd/ syllable that included only vowels in isolation were selected as the base stimuli for spectral enhancement and formant frequency shifts. Because previous studies (Coughlin et al., 2008; Liu &Kewley-Port, 2007; Richie et al., 2003) reported that listeners with HI primarily had difficulty discriminating differences of F2 frequency, the present study focused on formant discrimination of F2. The average F2 frequency of the three vowels over the entire vowel duration was 1442 Hz for /a/, 2078 Hz for /se/, and 2563 Hz for /i/.

There were four conditions of formant enhancement: unenhanced (original), and 3-, 6-, and 9-dB enhancement of F2. The left panel of Figure 1 illustrates the spectra of the original Ixl vowel (solid line) and the /ee/ vowel with 9-dB F2 enhancement (dashed line). The spectral enhancement of F2 was manipulated as follows: first, a three-dimensional (3-D) spectrogram (Amplitude x Time x Frequency) of the original vowel was obtained by analysis using STRAIGHT (Kawahara, Masuda-Kastuse, &Cheveigne,, 1999); second, at each time frame of the spectrogram, the valleys below Fl, between Fl and F2, and between F2 and F3 were defined as Vl, V2, and

V3, respectively. For the enhanced F2 conditions, only amplitudes at the frequencies between the valleys next to F2 (e.g., V2 and V3) were enhanced. The level of the F2 peak was amplified by 3, 6, and 9 dB, and the levels of the components between V2 and F2 and between F2 and V3 were linearly interpolated in a log scale. For example, the amplitude at the midpoint of V2 and F2 was amplified for 4.5 dB for the 9-dB enhancement conditions. Thus, there were four vowels with and without F2 enhancement serving as standard vowels for formant frequency shifts for each vowel category.

Stimuli were generated with different amounts of formant-frequency shift based on each standard vowel with the corresponding spectral enhancement. The procedure for shifting F2 frequency is briefly described below (for more details, see Liu &Kewley-Port, 2004). For each time frame of the 3-D spectrogram (Kawahara et al., 1999), as shown in the right panel of Figure 1, the F2 peak was shifted by flattening the frequency range corresponding to the formant shift at the spectral valley lower than the F2 frequency (V2) and replacing the original amplitude values with the shifted peak at the high-frequency valley (V3). In other words, the F2 shift was manipulated between the two spectral valleys, V2 and V3. This was also the same frequency range of the F2 enhancement. The F2-shifted vowels had the same amplitude of formant peaks (e.g., Fl, F2, and F3) as the standard vowel. The F2 values were shifted systematically from 0.5% to 20% of F2 frequency, with a step size of 0.5%, resulting in 40 formant-shifted vowels. This F2-shifted spectrogram was loaded into STRAIGHT and was used for vowel resynthesis. Thus, for each vowel, there were four sets of 40 F2-shifted vowel stimuli, with each set corresponding to one F2 enhancement condition. Additionally, a vowel /s/ was recorded from a middle-aged female speaker, different from the female speaker who recorded the three test vowels. The vowel /s/ served as the standard vowel for a 15-min training session before the test sessions. Like the test vowels, the F2 of the vowel /s/ was shifted from 0.5% to 20% of F2 frequency, with a 0.5% step size with the same formant shift method described above.

The stimuli with and without spectral enhancement were presented with 10-ms rise-fall ramps at two levels: 70 and 90 dB SPL. Sound pressure levels of vowel sounds were measured at the output of the ER-2 insert earphones via an NBS-9A 2-cc coupler that was connected to the microphone of a Larson-Davis (Model 2800) sound-level meter set to the linear weighting scale.

Study Participants

Six HI listeners with moderate sensorineural hearing loss at high frequencies and six NH listeners participated in this study. Participants were 18-55 years old; NH and HI listeners had mean ages of 23 and 37, respectively. All were native speakers of American English with normal middle-ear function. As shown in Figure 2, the audiometric thresholds of the listeners with HI were no more than 65 dB HL within the range of 250^000 Hz except participant SI at 4000 Hz. The NH listeners had pure-tone thresholds <15 dB HL at octave intervals between 250 and 8000 Hz (American National Standards Institute, 2010). All procedures were approved by the Institutional Review Board of the University of Texas at Austin. All listeners consented to participate in the study.

Procedure

Speech stimuli, sampled at 12207 Hz, were presented to the right ears of the listeners, who were seated in a sound- treated IAC (Industrial Acoustics Company) booth, via calibrated ER-2 insert earphones. Stimulus presentation was controlled by a series of TDT (Tucker-Davis Technologies) modules, including an enhanced real-time processor (RP2.1), a programmable attenuator (PA5), and a headphone buffer (HB7). Thresholds were measured using a three-interval, forced-choice procedure with a two-down, one-up tracking algorithm, estimating 71% correct responses (Levitt, 1971). There were 24 experimental conditions (3 formant frequencies x 4 spectral enhancements x 2 speech levels), the order of which was randomized.

For each trial, the standard vowel was presented in the first interval, followed by a standard vowel and a formant- shifted vowel randomly ordered in the second and third test intervals. The listener's task was to indicate which of the two test intervals contained the vowel that was different from the standard vowel via a

button press on an LCD monitor with an interface that simulated a handheld button box. The inter stimulus interval (ISI) was 400 ms. A light located above each interval button illuminated simultaneously with each presentation of the vowel stimulus. For each block, the F2 shift was started at 10% of the F2 frequency and was adjusted in a 1% step size for the first three reversals and then 0.5% thereafter. The threshold for each block of 60 trials was based on the average F2 shift at the last even number of reversals in the adaptive track, without counting the first three.

Across all conditions and listeners, a threshold of a given block was computed as a mean of 10 reversals. The threshold for each condition was taken as the average for two blocks. An additional block was conducted if thresholds for the two blocks differed by >1% of the F2 frequency (e.g., two steps of formant shifts). Across all of the listeners, this occurred an average of eight times out of a total of 24 experimental conditions. Listeners completed a 15-min training session using the vowel /s/ before the test session to gain familiarization with the procedure. The training and test sessions lasted ~5 hr, with each session lasting 90-120 min. The experimental design and process was manipulated using SykoFizX software application (TDT, Inc.).

Results

Overall Performance

Thresholds are expressed as Weber fractions (ÀF/F). Average thresholds across NH (left) and HI (right) listeners are plotted in Figure 3 as a function of F2 frequency for the four enhancement conditions and two speech levels. A four-factor (within-subjects factors: spectral enhancement, formant frequency, and speech level, and between-subjects factor: listener group) analysis of variance (ANOVA) of the thresholds was conducted. Thresholds were significantly affected by listener group, $F(1, 10) = 8.239$, $p <0.05$; formant frequency, $F(2, 20) = 7.722$, $p <0.05$; and spectral enhancement, $F(3, 30) = 20.299$, $p <0.05$, but not by speech level, $F{ 1, 10) = 0.158$, $p >0.05$. Of the six two-factor interactions, four were significant (Group x Formant Frequency, Group x Spectral Enhancement, Formant Frequency x Spectral Enhancement, and Speech Level x Spectral Enhancement; all $p <0.05$). Of the four three-factor interactions, only the Group x Speech Level x Spectral Enhancement interaction was significant ($p <0.05$).

Because the two listener groups differed significantly in overall performance (see Figure 3), and the interaction effect of group and spectral enhancement was significant, we conducted separate analyses for the NH and HI listeners. The effects of spectral enhancement and speech level are reported in the following two subsections for NH and HI listeners, respectively.

Effects of Spectral Enhancement and Speech Level for NH Listeners

Overall, as shown in Figure 3, neither spectral enhancement nor speech level produced an improvement for the NH listeners. A three-factor (spectral enhancement, formant frequency, speech level) repeated measures ANOVA with threshold (ÀF/F) as the dependent variable showed that NH listeners were not affected by speech level, $F(1, 5) = 0.098$, $p >0.05$; spectral enhancement, $F(3, 15) = 1.482$, $p >0.05$; or formant frequency, $F(2, 10) = 0.924$, $p >0.05$. None of the two-way interactions for NH listeners was significant (all $p >0.05$), but the three-way interaction of spectral enhancement, formant frequency, and speech level was significant, $F{6, 30) = 2.506$, $p <0.05$.

Effects of Spectral Enhancement and Speech Level for Listeners With HI

A similar ANOVA for the listeners with HI showed significant effects of spectral enhancement, $F(3, 15) = 20.206$, $p <0.05$, and formant frequency, $F(2, 10) = 6.370$, $p <0.05$, but no significant effect of speech level, $F(1, 5) = 0.116$, $p >0.05$. Of the two-factor and three-factor interactions, the interaction of speech level and spectral enhancement was significant, $F(3, 15) = 6.941$, $p <0.05$, as was the interaction of formant frequency and spectral enhancement, $F(6, 30) = 2.652$, $p <0.05$. Post hoc Tukey tests suggested that for the listeners with HI, thresholds were improved by spectral enhancement of 3, 6, and 9 dB (all $p <0.05$). Because the interaction effects of spectral enhancement and speech level or formant frequency were significant, we examined the simple main effect of spectral enhancement for each speech level and for each formant frequency, described in

the next two paragraphs.

In order to measure the simple main effect of spectral enhancement under each speech level for the listeners with HI, two-way (spectral enhancement and formant frequency) repeated measures ANOVAs were completed for 70 and 90 dB SPL, respectively. At 70 dB SPL, there was a significant effect of spectral enhancement, $F(3, 15) = 6.557$, $p < 0.05$, and formant frequency, $F(2, 10) = 5.565$, $p < 0.05$, on formant thresholds; there was no significant interaction effect of spectral enhancement and formant frequency, F{6, 30) = 1.397, $p > 0.05$. The average thresholds improved by 17% for 3-dB F2 enhancement, 24% for 6-dB F2 enhancement, and 34% for 9-dB F2 enhancement compared to the thresholds of original vowels. Post hoc Tukey tests indicated that thresholds for 6- and 9-dB enhancement were significantly better than thresholds of original vowels (both $p < 0.05$). For 90 dB SPL, spectral enhancement, $F(3, 15) = 17.015$,/? < 0.05, and formant frequency, $F(2, 10) = 4.421$, $p < 0.05$, showed a significant effect on formant discrimination; the interaction of spectral enhance- ment and formant frequency did not, $F(6, 30) = 1.544$, $p > 0.05$. Thresholds improved by 46% for 3-dB F2 enhancement, 60% for 6-dB F2 enhancement, and 71% for 9-dB F2 enhancement relative to the thresholds of original vowels. Post hoc Tukey tests reported that performance was significantly improved for all three spectral enhancement conditions compared to performance of the original condi- tion (all $p < 0.05$).

Similarly, in order to measure the main effect of spectral enhancement under each formant frequency, we conducted two-factor (spectral enhancement and speech level) repeated measures ANOVAs for the three formant frequencies. At all three formant frequencies, thresholds were significantly affected by spectral enhancement (all $p < 0.05$), but not by speech level (all $p > 0.05$). The interaction effect of speech level and spectral enhancement was significant for the F2 of /ae/ and /i/ (both $p < 0.05$), but not for the F2 of /a/. Post hoc Tukey tests suggested that thresholds of any of the three spectrally enhanced conditions were significantly lower than thresholds for the original conditions of the three formant frequencies (all $p < 0.05$). As shown in Table 1, individual variability of formant discrimination performance due to spectral enhancement was observed for the listeners with HI, possibly due to the different configurations and severities of hearing loss across them. It should also be noted that for the listeners with HI, an increase of speech level did not improve formant discrimination of original vowels with no F2 enhancement (see Figure 3). For instance, for original vowels with no spectral enhancement, thresholds degraded by 34% at 90 dB SPL compared to thresholds at 70 dB SPL, whereas for 3-dB, 6-dB, and 9-dB F2 enhancement, an increase of speech level from 70 to 90 dB SPL improved formant discrimination by 14%, 31%, and 42%, respectively. These results imply that benefits from 70 to 90 dB SPL, if any, were conditional upon F2 amplitude.

As described in the statistical results above, vowel formant discrimination was not affected by speech level but was significantly affected by the interaction of spectral enhancement and speech level. To reveal the simple main effect of speech level under each spectral enhancement condition, we completed two-factor (speech level and formant frequency) repeated measures ANOVAs for the vowels with original spectrum, and 3-dB, 6-dB, and 9-dB F2 enhancement, respectively. Results showed no significant effect of speech level at any of the F2 enhancement conditions: original, F(I, 5) = 2.005, $p > 0.05$; 3 dB, .Fifi, 5) = 0.321, $p > 0.05$; 6 dB, F(1, 5) = 0.648, $p > 0.05$; and 9 dB, .Ffl, 5) = 2.158, $p > 0.05$. In addition, no significant interaction effects of speech level and formant frequency were found for any of the F2 enhancement conditions: original, $F(2, 10) = 0.853$, $p > 0.05$; 3 dB, $F(2, 10) = 2.440$, $p > 0.05$; 6 dB, $F(2, 10) = 0.428$, $p > 0.05$, and 9 dB, $F(2, 10) = 0.575$, $p > 0.05$.

NH Listeners Versus Listeners With HI

As reported earlier, the HI listeners' overall perfor- mance was significantly worse than that of the NH listeners. In addition, we conducted three-factor (within-subjects factors: formant frequency and spectral enhancement; between-subject factors: listener group) ANOVAs at 70 and 90 dB SPL, respectively, indicating significantly worse performance for the listeners with HI than their NH peers (both $p < 0.05$). To determine if the increase of speech level and spectral enhancement of F2 could improve HI listeners' thresholds to NH listeners' level, we conducted a two-factor (formant frequency and listener group) ANOVA: the 9-dB F2 enhancement condition at

90 dB SPL that provided the greatest benefits for listeners with HI (e.g., the dashed line in the lower right panel of Figure 3) versus the original, unenhanced vowels at 70 dB SPL for NH listeners (e.g., the solid line in the upper left panel of Figure 3). The NH listeners showed significantly lower thresholds than the listeners with HI, Ffl, 10) = 5.054, p <0.05, suggesting that increasing speech level and spectral contrast were not able to help the listeners with HI reach the same level of performance as the NH listeners.

Discussion

The purpose of this study was to examine whether enhancing a crucial spectral prominence of vowel stimuli would improve NH and HI listeners' abilities to discriminate differences in F2 frequency. As shown in the left panels of Figure 3, the NH listeners did not show any significant improvement from increasing speech levels or spectral enhancements of F2. This is not surprising, because NH listeners do not have the reduced amplitude and secondary distortion associated with hearing loss. NH listeners only need 3- to 4-dB peak-to-valley contrasts for Fl and F2 to identify vowels with >80% accuracy (Leek et al., 1987). Given that peak-to-valley contrasts of F2 for the three original vowels in this study were >6 dB, spectral contrasts of F2 of the original vowels were well resolved for NH listeners such that F2 enhancement did not benefit NH listeners to discriminate formant frequency difference.

On the other hand, the listeners with HI did show marked benefits (see the right panels of Figure 3) when F2 amplitude was enhanced at both 70 and 90 dB SPL, indicating the importance of spectral contrasts of formant peaks on vowel perception (Leek et al, 1987; Liu &Eddins, 2008). In order to examine audibility and presentation of the vowel F2 peaks for the listeners with HI, excitation patterns of the vowels /se, i, a/ with the original spectra and F2 enhancements at 70 and 90 dB SPL were computed following Moore and Glasberg's (2004) excitation pattern model. Excitation patterns were also calculated for the NH listeners.

In general, as shown in Figures 4 and 5, spectral peaks at high frequencies (e.g., F2 and F3) were smeared in the excitation patterns for the listeners with HI, likely due to the loss of frequency selectivity, whereas spectral peaks of F2 and F3 were well represented in the excitation patterns for the NH listeners (see Figure 6). As shown in Figure 4, a 9-dB F2 enhancement resulted in an enhanced representation of F2 in the excitation pattern for listeners with a mild-to- moderate hearing loss (e.g., S6). On the other hand, for listeners with a moderate-to-severe hearing loss (e.g., SI), F2 may not be audible, and the spectral peaks were severely smeared for the original vowels /il and /se/ at 70 dB SPL, whereas F2 with the 9-dB enhancement may increase the F2 internal presentations and F2 audibility (see Figure 5). Thus, spectral enhancement of F2 peaks resulted in an enhanced internal representation and/or better audibility of F2 for the listeners with HI, especially those with severe hearing loss, thus improving their F2 discrimination.

However, vowel formant discrimination did not improve by simply increasing the overall speech level from 70 to 90 dB SPL with no F2 enhancement, suggesting that the difficulty of listeners with HI is accounted for not only by audibility, but also by reduced frequency selectivity (Needleman &Crandell, 1997). As indicated in Figures 4 and 5, the internal F2 presentations became more smeared by an increase in speech level from 70 to 90 dB SPL for the listeners with HI, whereas the upward spread of masking from Fl may increase as speech level increased, possibly accounting for the slightly worse vowel formant discrimination at 90 dB SPL. This is consistent with previous studies (i.e., only increasing speech level may not significantly compensate for spectral smearing of formant peaks for listeners with HI; Liu &Kewley-Port, 2007). However, it should be noted that Coughlin et al. (1998) and Richie et al. (2003) reported that formant discrimination was improved from low (e.g., 60/70 dB SPL) to high (e.g., 95 dB SPL) levels. The differential effects of speech level on vowel formant discrimination among these studies could be due to the audibility and internal representations of F2 peaks. That is, in the studies of Coughlin et al. and Richie et al., F2 was audible at high levels but not at low levels, and F2 was represented in the excitation patterns of their listeners with HI (for details, see Figure 6 of Liu &Kewley-Port, 2007).

In the present study, F2 audibility became better at the high speech level; however, F2 representation was

severely smeared (see Figures 4 and 5), suggesting that increased audibility of F2 may improve formant discrimination only when F2 was represented well internally for listeners with HI. Moreover, in this study, HI listeners' performance improved by 14%^42% from 70 to 90 dB SPL as spectral enhancement of F2 was implemented, possibly due to better audibility of F2 peaks. For example, the F2 peak with a 9-dB enhancement was audible for the listener with moderate-to-severe hearing loss (e.g., SI; see Figure 5) at 90 dB SPL, but not at 70 dB SPL for vowels Iii and /se/. Altogether, these results suggest that both audibility and representation of formant peaks were critical to vowel perception for listeners with HI.

In the present study, the vowel stimuli with F2 enhancement were presented at the same level with the original vowels, resulting in an increase of the F2 spectral contrasts and a slight attenuation of the Fl amplitude (see Figures 4-6). Such acoustic changes may reduce the upward spread masking of Fl on the F2 and enhance the F2 representation (e.g., higher spectral contrasts of F2, resulting in better sensitivity to F2 frequency discrimination). This is consistent with the behavioral and physiological findings in other studies (Danaher et al, 1973; Danaher &Pickett, 1975; Miller et al, 1999a).

In the studies of F2 transition discrimination, listeners with HI performed better for stimuli with Fl removed than for stimuli with Fl present (Danaher et al., 1973; Danaher &Pickett, 1975). When the F2 and F3 peaks were amplified with no change in the Fl area, termed contrast-enhanced frequency shaping, the neural representation of the F2 frequency for the auditory nerve with noise-induced hearing loss was also enhanced (Miller et al, 1999a). The reduction of the Fl masking effect may also interpret individual variability regarding improvement of formant discrimination spectral contrasts among the listeners with HI. That is, the masking effect of FI on F2 discrimination was greater for the listeners with a sloping high-frequency hearing loss compared to the listeners with a flat hearing loss such that the spectral enhancement of the F2 resulted in greater improvement in formant discrimination for the sloping high- frequency hearing loss (Danaher et al, 1973; Danaher &Pickett, 1975). For example, as shown in Table 1 and Figure 2, Listener S5 had a relatively flat hearing loss and showed less benefits than Listeners SI and S4, who had a sloping high-frequency hearing loss. However, individual variability of listeners with HI may also be related to their hearing loss severity. For instance, Listeners S4 and S6 had similar hearing loss configurations, yet Listener S4 had greater improvement of formant discrimination than Listener S6 with relatively more severe hearing loss. More research is needed to investigate the effect of hearing loss configuration and severity on the spectral enhancement benefits of vowel formant discrimination.

The findings of this study are also consistent with behavioral and physiological studies in speech processing regarding spectral enhancement for the dysfunctional auditory system (Bunnell, 1990; Lyzenga et al., 2002; Miller et al., 1999a; Stone &Moore, 1992). Bunnell (1990) manipulated spectral enhancement by applying filters in speech spectrum with different filter weights such that three sets of speech stimuli were produced in terms of spectral contrasts: normal, reduced, and enhanced. Results showed that stop consonant identification with spectral enhancement increased moderately (-5% in average) for listeners with HI compared to original speech sounds. Similarly, a 16-channel bandpass filter bank with each filter bandwidth close to the bandwidth of auditory filters of NH listeners was imple- mented by Stone and Moore (1992) to enhance spectral contrasts of speech sounds. Results of sentence recognition in noise indicated that there was no significant improvement in speech perception for the listeners with HI; however, listeners reported both higher quality and higher intelligibility of speech with spectral enhancement. Enhanced spectral contrasts of speech sounds combined with noise suppression also resulted in improvement of sentence recognition for listeners with simulated hearing loss (Lyzenga et al, 2002). Miller et al. (1999b) reported that the rate and temporal tonotopic representation of the F2 frequency in the abnormal auditory nerve was improved by amplifying the F2 spectral contrasts and F3 peaks.

Results of the present study indicate that spectral enhancement of vowel formant peaks may improve HI listeners' sensitivity to formant frequency changes. Given that thresholds of vowel formant discrimination were significantly related with vowel identification (e.g., lower thresholds of formant discrimination, better vowel identifi- cation; Kewley-Port, Bohn, &Nishi, 2005), improvement of vowel formant discrimination may help

listeners with HI achieve greater accuracy in vowel identification. In addition, researchers have recently reported that vowels play a critical role in sentence recognition for young and elderly listeners with normal and impaired hearing (Fogerty, Humes, &Kewley-Port, 2010, 2012; Fogerty &Kewley-Port, 2009), implying that enhanced acoustic features of vowel sounds (e.g., spectral contrasts) may improve listeners' sentence recognition. Overall, the present study and previous studies with spectral enhancement suggest that spectral enhancement of prominent peaks in speech spectrum may improve phonetic perception, speech recognition, or speech quality for listeners with HI. These findings could have implications for future hearing aid design as well as other assistive listening devices. On the other hand, the best performance of listeners with HI with a combined increase of speech level and spectral enhancement still could not reach the level of NH listeners, indicating that spectral enhancement may not be compen- sated solely by only an increase of the peak-to-valley contrasts, but perhaps also some other method, such as manipulation of formant bandwidth and/or spectral tilt. However, it should also be noted that spectral enhancement may result in changes of speech quality. More research is needed to study whether listeners with HI can benefit in vowel discrimination and identification from spectral enhancement.

Acknowledgments

A portion of the data was presented at the 158th Acoustic Society of America Meeting in San Antonio, TX. This study was funded by the University of Texas at Austin Undergraduate Research Fellowship to the first author. Special thanks are given to Craig Champlin for his comments on an earlier version of this manuscript.

Abstract: To examine the effects of temporal and spectral interference of masking noise on sentence recognition for listeners with cochlear implants (CI) and normal-hearing persons listening to vocoded signals that simulate signals processed through a CI (NH-Sim). NH-Sim and CI listeners participated in the experiments using speech and noise that were processed by bandpass filters. Depending on the experimental condition, the spectra of the maskers relative to that of speech were set to be completely embedded with, partially overlapping, or completely separate from, the speech. The maskers were either steady or amplitude modulated and were presented at +10 dB signal-to-noise ratio. NH-Sim listeners experienced progressively more masking as the masker became more spectrally overlapping with speech, whereas CI listeners experienced masking even when the masker was spectrally remote from the speech signal. Both the NH-Sim and CI listeners experienced significant modulation interference when noise was modulated at a syllabic rate (4 Hz), suggesting that listeners may experience both modulation interference and masking release. Thus, modulated noise has mixed and counteracting effects on speech perception. When the NH-Sim and CI listeners with poor spectral resolution were tested using syllabic-like rates of modulated noise, they tended to integrate or confuse the noise with the speech, causing an increase in speech errors. Optional training programs might be useful for CI listeners who show more difficulty understanding speech in noise. [PUBLICATION ABSTRACT]

Purpose: To examine the effects of temporal and spectral interference of masking noise on sentence recognition for listeners with cochlear implants (CI) and normal-hearing persons listening to vocoded signals that simulate signals processed through a CI (NH-Sim).
Method: NH-Sim and CI listeners participated in the experiments using speech and noise that were processed by bandpass filters. Depending on the experimental condition, the spectra of the maskers relative to that of speech were set to be completely embedded with, partially overlapping, or completely separate from, the speech. The maskers were either steady or amplitude modulated and were presented at +10 dB signal-to-noise ratio.
Results: NH-Sim listeners experienced progressively more masking as the masker became more spectrally overlapping with speech, whereas CI listeners experienced masking even when the masker was spectrally remote from the speech signal. Both the NH-Sim and CI listeners experienced significant modulation interference when noise was modulated at a syllabic rate (4 Hz), suggesting that listeners may experience both modulation interference and masking release. Thus, modulated noise has mixed and counteracting effects on speech perception.
Conclusion: When the NH-Sim and CI listeners with poor spectral resolution were tested using syllabic-like rates of modulated noise, they tended to integrate or confuse the noise with the speech, causing an increase in speech errors. Optional training programs might be useful for CI listeners who show more difficulty

understanding speech in noise.

Key Words: cochlear implants, hearing loss, speech perception

Typical environmental noises such as background conversations are temporally varying in frequency and amplitude. Listeners with normal hearing (NH) can take advantage of gaps in these fluctuating maskers. They are able to "listen in the dips" of temporally varying noise to extract information about the speech signal, thereby experiencing improvement in speech recognition (e.g., Bernstein &Grant, 2009; Festen &Plomp, 1990; Jin &Nelson, 2006). Such performance improvement in the presence of fluctuating compared to steady-state noise conditions is known as masking release. Previous studies have reported that NH listeners' speech recognition scores could improve by as much as 80 percentage points when noise was modulated versus steady (Jin &Nelson, 2006).

However, significant masking release reduction or no masking release has been found in cochlear implant (CI) users or in NH listeners identifying vocoded speech that simulates speech processed by a CI device (NH-Sim; Fu &Nogaki, 2004; Kwon, Perry, Wilhelm, &Healy 2012; Nelson &Jin, 2004; Nelson, Jin, Carney, &Nelson, 2003; Qin &Oxenham, 2003; Stickney, Zeng, Litovsky, &Assmann, 2004). For example, Nelson and colleagues (Nelson &Jin, 2004; Nelson et al, 2003) compared the performance of three listener groups (NH, CI, and NH-Sim) for sentence recognition in the presence of different masking noises, including steady-state noise and gated noise modulated at different frequencies. They found that the NH listeners showed significant masking release even at high levels of noise (-8 and -16 dB signal-to-noise ratios [SNRs]), whereas the NH-Sim and CI listeners showed limited or no masking release at more favorable SNRs (+8 and +16 dB SNRs).

Typically, robust and redundant speech cues (both spectral and temporal) help NH listeners to segregate relevant speech signals out of a noise mixture and to integrate the signals into a continuous perceptual stream. However, when spectral cues are reduced, via CI processor, for example, a broadband modulated noise might seem perceptually quite similar to the speech: Its frequency components are overlapped with those of speech, and the rate of fluctuation of noise and speech are similar. Without fine-grained spectral information in speech, listeners might rely more on temporal cues to process consonants and vowels. In the presence of modulated noise, such temporal information in speech is obscured by the noise modulations, and NH-Sim and CI listeners may experience modulation interference rather than (or in addition to) masking release (Kwon &Turner, 2001). As a result, little to no masking release has been observed from these groups of listeners.

One thing in common found from the previous studies of speech perception in noise was the positive SNRs used for CI or NH-Sim listeners (e.g., Fu &Nogaki, 2004; Kwon &Turner, 2001; Nelson et al, 2003; Qin &Oxenham, 2003; Stickney et al., 2004). Because these listeners were listening to impoverished spectral speech cues, they were tested at favorable (positive) SNRs in which the signal and noise are more similar in level in order to avoid a floor effect (Nelson et al., 2003). At those positive SNRs, CI or NH-Sim listeners may confuse the modulated noise with the speech and will not be able to take advantage of "dip listening" (Ihlefeld, Deeks, Axon, &Carlyon, 2010).

When the characteristics of a noise are quite different from those of speech, the negative effect of masking interference on CI or NH-Sim listeners might be negligible. In studies of spatial masking, when speech and noise were presented from different locations, NH listeners as well as CI and NH-Sim listeners showed spatial release from masking (Ihlefeld et al. 2010; Loizou et al., 2009). Furthermore, Kwon et al. (2012) showed that when the envelopes of modulated noise were less temporally overlapped with those of speech signals, ~50% of CI participants were able to benefit from the dips of modulated noise, resulting in significant masking release. These results suggest that if speech and noise are perceptually segregated, CI listeners would be able to experience masking release.

In the current study, we investigated differences in the masking of speech experienced by NH-Sim and CI listeners for maskers that overlap with speech in audio frequency and modulation rate. The purpose of the current study was to examine the conditions in which temporal and spectral interference affect sentence

recognition for NH-Sim and CI listeners, and to determine whether masking release might be seen in CI listeners when the spectrum of speech are distinct from that of noise.

We asked two research questions. First, do NH-Sim and CI listeners experience similar systematic increases in masking as the frequencies contained in a broadband masker overlap more closely with the speech signal? To answer this question, both speech and noise were processed by series of bandpass filters. Depending on the experimental condition, the spectra of the maskers relative to that of speech were set to be completely embedded, partially overlapping more (PO-more), partially overlapping less (PO-less), or completely separate from the speech (remote). We hypothesized that NH-Sim listeners would show a systematic reduction in masking of a speech signal as the masker overlapped less with the speech, but that CI listeners may not show such a clear relationship.

Second, under what conditions do NH-Sim and CI listeners experience masking release or modulation interference? Previous investigations indicated that the modula- tion index of speech is -3 Hz to 4 Hz, which corresponds to the syllable rate in speech (Drullman, Festen, &Plomp, 1994; Houtgast &Steenken, 1985). We hypothesized that, if NH- Sim and CI listeners rely more on the temporal envelope cues of speech, then masking interference may be strongest when the noise is amplitude modulated at these rates. Although studies on both NH-Sim and CI listeners (Ihlefeld et al., 2010; Kwon &Turner, 2001; Nelson et al., 2003; Qin &Oxenham, 2003) examined the effect of modulation rate on speech perception, no clear answers were reported. We hypothesized that NH-Sim and CI listeners would show no masking release but might show masking interference when the noise is amplitude modulated at a rate approaching the syllable rate. Furthermore, the masking interference associated with the rate effect may occur even when the speech is spectrally remote from the noise because CI listeners are not able to segregate speech from noise even when they are spectrally remote (Stickney et al, 2004).

Experiment 1: Sentence Recognition of NH-Sim Listeners

Method

Participants

Ten undergraduate or graduate students (5 male and 5 female) participated in the experiment. They were 19 to 32 years of age and were Native American English speakers. Their hearing was <20 dB HL at audiometric frequencies of 250, 500, 1000, 1500, 2000, 3000, 4000, 6000, and 8000 Hz (American National Standards Institute, 2010).

Stimuli

Both Institute of Electrical and Electronics Engineers sentences (IEEE, 1969) spoken by a female speaker and white noise were filtered through 16 filter bands whose cutoff frequencies were set based on the work of Fu and Nogaki (2004). Bandpass filters (4th-order Butterworth) were used. The output of each bandpass-filtered stimulus was numbered in order from 1 to 16: Band #1 contained the lowest frequency components, ranging from 200 Hz to 272 Hz, and Band #16 contained the highest frequency components, ranging from 5768 Hz to 7000 Hz. Table 1 shows the low and high cutoff frequencies of each of the 16 bandpass filters.

The speech temporal envelopes were extracted from the 10 lower individual speech bands, 1-10, by low-passing the bands of speech through a 4th-order Butterworth filter at a cutoff frequency of 160 Hz. Our previous study (Nie &Nelson, 2009) showed that low-pass filtered natural IEEE sentences at a cutoff frequency of 2000 Hz were equally intelligible as those sentences with a full spectrum to NH listeners and listeners with hearing impairment. In the pilot study (Nie &Nelson, 2009), the 10-band CI simulation satisfied our criterion of a >50% key word identification in NH listeners. The speech envelopes from the 10 bands were half-wave rectified and imposed on the white noise filtered through the same band. Each band carrying speech temporal envelopes was refiltered through the same bandpass filter to eliminate the spectral spread resulting from imposing envelopes on noise. The 10 bands of noise carrying a speech envelope were added to formulate the vocoded-speech stimuli.

White noise was bandpassed and then superimposed with sinusoidal amplitude modulation (SAM) to be presented as background noise. The spectra of the background noise were set to completely embedded, partially overlapping (PO), adjacent and not overlapping, or remote, with that of the speech. Table 2 shows spectral components of the noise bands for each noise condition. For the completely embedded condition, the individual noise bands 5 through 10 were combined into one noise band. There were two partially overlapping conditions: PO-more and PO-less, and their noise band components were 7-12 and 9-14, respectively. The noise band components of the adjacent condition included Bands 11-16. For the remote condition, the individual noise bands 13-16 were combined. Each SAM noise condition was modulated at five modulation rates: 0 Hz (unmodulated noise), 4 Hz, 16 Hz, 32 Hz, and 64 Hz. Total numbers of conditions per listener were 26: 5 noise-band conditions x 5 modulation rates plus 1 quiet condition.

Procedure

Both speech and noise stimuli were processed by a customized MATLAB code with a sampling rate of 22050 Hz and were presented via a SoundMAX card controlled by a Pentium 4 computer. The speech stimuli were presented at 70 dB A for the low-pass spectrum monaurally to the right ear when no background noise was present; when background noise was present, the speech stimuli were presented at 70 dB A and the noise was at an SNR of 10 dB. The SNR was determined by the difference between the level of the speech pass-band (i.e., 70 dB A) and the level of the pass-band of the background noise.

In each test condition (in quiet and in noise with different noise spectrum at different modulation rates), two randomly chosen lists of 10 sentences were presented to the participants. After each sentence was presented, participants wrote down on the response sheet what they heard and then pressed the "Enter" key on the computer keyboard to listen to the next sentence. Each participant's response was scored for the percentage of correct key words identified. The total number of key words from two IEEE lists was 100. If participants responded in homophones of key words, they were scored correct for these corresponding key words. No correct feedback was provided.

The order of experimental conditions was randomized across the 10 participants. In addition, the order of sentence presentation within each list was randomized. Participants took 4-6 hr in total to complete the speech experiment, which was broken into 1- to 2-hr listening sessions. Participants undertook the sessions on different days. Practice listening was given at the beginning of the first session of the speech experiment. For the practice session, two randomly chosen IEEE lists were presented to the participants. One of the two practice lists was presented without background noise (quiet condition); the other one was presented with background noise of Bands 13 through 16 (remote condition) modulated at 64 Hz.

Results

Figure 1 shows the percentage correct key word identification for the NH-Sim listeners. The scores varied greatly from one listener to another for the same conditions. For instance, the NH-Sim listeners correctly identified 53%-80% of the key words, with an average of 64.7%, in the quiet condition and 10%-54% of the key words, with an average of 20%, when the noise spectrum was completely embedded in the speech spectrum. Repeated measurement analysis of variance (ANOVA) on conditions with background noise revealed significant differences in the spectral (band) condition; that is, as the spectrum of the background noise approached or overlapped more with the spectrum of speech, listeners identified fewer key words, $F(A, 36) = 100.851$, $p < 0.001$. However, different amplitude modulated (AM) rates of the modulated bandpass noise did not result in significant improvement in speech understanding, $F(4, 36) = 1.707$, $p = 0.170$. Speech perception with modulated noise did not improve from that with steady-state noise, indicating no masking release. The interaction between the spectral separation (i.e., between speech and noise) and modulation rate was not significant, $F(16, 144) = 0.809$, $p = 0.673$.

Further pair-wise comparisons with Bonferroni adjust- ment were performed on the factor of spectral separation between noise and speech. The key word identification score of each noise-speech spectral separation was

significantly higher than those scores obtained in the smaller noise-speech spectral separations (allp <0.05). That is, with the five noise- speech spectral separations, from small to large-embedded, PO-more, PO-less, adjacent, and remote-the speech under- standing score significantly improved progressively.

As no difference in key word identification was found between AM-rate separations, the scores from different AM- rate separations in the same noise-speech spectral (band) separation were averaged to yield a single score for each noise-speech spectral separation. Pair-wise comparisons from the repeated measurement of ANOVAs conducted based on these averaged scores and the scores in the quiet condition showed that the performance in the quiet condition was significantly better than the performance in the conditions where the noise was present, except the remote condition.

Overall, the NH-Sim listeners showed two findings. First, they experienced a systematic increase in masking (decrease in speech recognition) as the masker was more spectrally overlapping with the speech signal. No masking was seen from the spectrally remote masker. Second, they showed neither masking release nor modulation interference from the modulated maskers in any noise-speech spectral separation condition at any modulation rate, suggesting that the large majority of the masking experienced was based on the spectral content of the speech and noise signals, with minimum effect of the envelopes of the maskers.

Experiment 2: Sentence Recognition of CI Listeners

We conducted a similar experiment with the CI listeners to confirm whether the findings of the NH-Sim listeners would cany over to actual users of CIs. We hypothesized that because CI listeners are more reliant on temporal envelopes, they may experience more modulation interference than the simulation listeners. Further, because of current spread from the CI devices, we hypothesized that CI listeners may experience masking from noises that were presumed to be spectrally remote from the speech signal.

Method

Participants

Seven postlingually deafened adult listeners with CI participated in this experiment. A detailed description of the CI listeners is shown in Table 3. Their mean age was 48 years, ranging from 21 to 73 years, and their average length of deafness before implantation was 26 years, ranging from 18 to 42 years. All listeners had worn their CIs for >2 years (M = 6 years, range = 13 years).

Stimuli

In order to create different degrees of spectral interference for the CI listeners, both speech and noise were spectrally filtered and were used to construct experimental conditions with various spectral distances between the speech signals and noise. In order to have the frequency components of the speech signals for CI listeners similar to those of the vocoded-speech for NH-Sim listeners (see Table 1), IEEE sentences were low-pass filtered at 2149 Hz, which is the high cutoff frequency of bandpass noise #10 used for the vocoded-speech. However, if the CI listeners did not achieve speech recognition scores of at least 50% in quiet, the low- pass cutoff frequency was changed to 3205 Hz, which is the high cutoff frequency of Band #11. This allowed those CI listeners to have more spectral information of the speech available. Two out of the seven CI listeners (CI 3 and 5) required the wider speech spectrum to achieve 50% correct in quiet. Because there was no significant modulation effect on speech recognition in the NH-Sim listeners, and previous studies by Nelson and colleagues (Nelson &Jin, 2004; Nelson et al., 2003) using speech materials with a full spectrum showed no significant performance difference between 16 Hz and higher modulation rates for CI listeners, three noise modulation rates-0, 4, and 16 Hz-were used to shorten the length of experiment time for the CI listeners. Similar to the noise conditions used for the NH-Sim listeners, a series of bandpass-filtered noises were created to design four noise conditions: embedded (noise completely embedded within the speech band), PO-more (partially overlapping more), PO-less (partially overlapping less), and remote (not overlapping) relative to the speech spectrum. The low and high cutoff frequencies for each noise condition are shown in Table 4.

Procedure

Six out of the seven CI listeners wore implants bilaterally. Throughout the experiment, they were asked to use only one device that works better and that he or she relies on more in everyday life. The other device was turned off. One CI listener, CI 6, used a single device without a hearing aid on the other side. Thresholds through each listener's CI device in the sound field were measured for filtered noises with identical spectra of speech and each masking noise (i.e., embedded, PO-more, PO-less, and remote) in order to confirm that speech and noise were fully audible to the CI listeners. Noises were presented monaurally via a loudspeaker located at 45° azimuth and 0° elevation, and in 1-meter distance to the ear with the CI device.

For the speech recognition test, the loudspeaker was set at the same azimuth and distance to the listeners' CI device as those set in the masking-noise threshold test. The level of speech was 70 dB A. When background noise was present, the noise was at a +10 dB SNR. In each condition, two randomly chosen lists of 10 sentences were presented to the participants. Participants were seated in a sound booth and were asked to repeat back what they heard after each sentence was presented. An examiner outside the booth was able to hear the verbal responses via a talk-back system and marked the key words that were repeated correctly on an answer sheet. After each response, the examiner pressed the "Enter" key on the computer keyboard to present the next sentence. Each participant was scored for the percentage of correct key words identified. The same scoring method used for the NH-Sim listeners was applied to calculate identification scores for each condition. No correct feedback was provided to the participants.

Conditions were randomized across the participants, as was the order of the 10 sentences within each list. Practice listening was given at the beginning of the first session of the speech experiment. First, CI listeners were presented with full-spectrum speech (unprocessed speech) in quiet to make sure their best speech recognition score was at least 70%. Second, they listened to low pass filtered speech at 2149 Hz in quiet. If the CI listeners were able to identify the key words at least 50%, this high cutoff frequency was employed to process speech stimuli. If CI listeners could not reach 50% key word identification, the cutoff frequency was increased to 3205 Hz, as described earlier. Once the appropriate cutoff frequency was set for each CI listener, another practice run was played in the remote noise condition with noise modulation of 16 Hz.

Results

Table 5 shows detection thresholds for individual CI listeners in each band of noise whose spectrum was similar to the speech or noise conditions. Detection thresholds for speech and each noise condition were measured in order to ensure that both speech and noise were audible to the CI listeners. Thresholds ranged from 19 dB SPL to 38 dB SPL, which were below the presentation levels for speech and noise.

Figure 2 shows the average scores of percentage correct key word identification for the CI listeners as a function of different listening conditions. In quiet, CI listeners understood 85% of full-spectrum speech on average, ranging from 72% to 100%. When the stimuli were low-pass filtered at 2149 Hz (for CI 1, 2, 4, and 7) or at 3205 Hz (for CI 3 and 5), the average performance in quiet was 68%, ranging from 54% to 86%. To compare speech recognition scores in quiet with those in noise, a one-way ANOVA was carried out with five levels of spectral listening conditions: embedded, PO-more, PO-less, remote, and quiet. Because there was no AM modulation applied to the quiet conditions, only speech recognition scores in steady-state noise (0 Hz modulation) at each spectral distance condition were analyzed. A significant overall spectral separation effect was revealed, $F(A, 30) = 19.017$, $p < 0.001$. Bonferroni post hoc tests showed that CI listeners' performance in the remote condition was significantly worse than in quiet ($p = 0.023$) and significantly better than in the rest of the noise conditions (all p values <0.026). The tests also indicated better performance in quiet than in all other spectral separation conditions (all p values <0.023). The results suggest that CI listeners' speech understanding is adversely affected by the presence of noise, even when the noise is spectrally remote from speech.

Two-way repeated-measures ANOVAs (Spectral Separation x AM Rate) with sentence recognition scores as the dependent variables showed significant effects of both spectral, $F(3,18) = 22.48$, $p < 0.001$, and AM-rate differences, $F(2, 12) = 19.86$, $p < 0.001$. However, there was no significant interaction between the two factors,

F(6, 36) = 1.39, p >0.05. Bonferroni post hoc tests for the effect of spectral separation between speech and noise revealed that the performance of the CI listeners in the remote noise condition was significantly better than those in three other noise conditions, embedded, PO-more, and PO-less (p <001). Interestingly, speech understanding scores were not significantly different (p >0.05) when the spectrum of noise was either completely embedded with or partially overlapping (PO-more and PO-less) the speech bandwidth. This suggests that the internal spectral masking was greater than what would be expected by the physical spectral characteristics of the noise (the distance from the speech signals), which might be due to the fact that CI listeners experienced significant spectral interaction between the masker and speech.

Examining the effect of AM rate, Bonferroni post hoc tests showed that the CI listeners' sentence recognition was significantly poorer in noise modulated at 4 Hz than in steady noise (0 Hz) or in noise modulated at 16 Hz regardless of spectral separation. This is illustrated in Figure 2, showing the lower performance across noise spectra at 4 Hz compared to the performance at 0 Hz and 16 Hz.

In general, the CI listeners showed evidence of modulation interference when the masker was modulated at 4 Hz, which is a rate similar to the syllabic rate of the speech stimuli. Further, the CI listeners showed significant masking even in the presence of spectrally remote or slightly over- lapping noises, indicating significant internal current spread of speech and noise spectra.

Comparison Between NH-Sim and CI Listeners

To examine performance differences between the two listener groups, we compared the results of Experiments 1 and 2. First, a one-way (listener group) ANOVA with speech recognition scores in quiet as the dependent variable showed that there was no significant listener group difference in quiet, i*U,15) = 0.565, p >0.05, which indicates that the NH-Sim and CI listeners were able to understand the low- pass filtered speech equally well in quiet.

To examine performance differences between the NH- Sim and CI listeners in noise, a three-way repeated-measures ANOVA was carried out with two within-subject factors (Spectral Separation x AM Rate) and one between-subject factor (listener group). Only the noise conditions used for both listener groups were included in the analysis (four spectral separations: embedded, PO-more, PO-less, and remote, and three AM rates: 4 Hz, 16 Hz, and steady state). Figure 3 shows the performance of both the NH-Sim and CI listeners as a function of noise conditions at each AM rate (the top panel for 0 Hz, the middle for 4 Hz, and the bottom for 16 Hz). Overall, the CI listeners performed significantly worse than the NH-Sim listeners in the presence of noise (between-subject factor) regardless of the modulation rate, *F('l,15) = 8.312, p <0.05. In addition, significant effects of spectral separation, F(3, 45) = 86.079, p <0.001, and AM rate, F(2, 30) = 17.723, p <0.001, were found. A Bonferroni post hoc test showed that when noise was modulated at 4 Hz, listeners performed worse compared to their performance in steady and 16-Hz modulated noise (all p values <0.001). Listeners' performance in steady noise was not significantly different from that in the modulated noise at 16 Hz (p >0.813). There were no significant two- or three-way interactions among the three factors (p >0.05). This result suggests that noise modulated at a syllabic rate (4 Hz) caused both the NH-Sim and CI listeners greater difficulty under-standing speech than a steady noise or a noise with faster modulations.

The nonsignificant interaction between the AM rate and listener group was somewhat unexpected. Based on the previous separate analysis for the NH-Sim group and for the CI group, the CI listeners were significantly affected by the AM rate difference (with 4-Hz modulated noise showing a negative effect on performance), whereas the NH-Sim listeners were not. This ambiguous finding might be due to the fact that the NH-Sim listeners were originally tested with more AM-rate conditions. To test this assumption, we conducted a two-way repeated-measures ANOVA on the performance of the NH-Sim group, including only the conditions that were the same as those for the CI group. The results showed that there was a significant effect of modulation rate, F(2, 18) = 5.23, p = 0.016, and spectral separation, ^(3, 27) = 80.07, p <0.01. A Bonferroni post hoc test revealed a significant difference in the NH-Sim listeners' performance between 4 Hz and 16 Hz (p = 0.025), but

not between steady and 4 Hz or 16 Hz (allp values >0.05). Thus, we conclude that both the CI and the NH-Sim listeners were somewhat negatively affected by the 4-Hz AM rate, resulting in modulation interference, although the interference was stronger for the CI group than for the NH-Sim group. On the other hand, there was no performance difference between the 16-Hz modulated noise and the steady noise conditions for both listener groups, which suggests neither masking release nor modulation interference for the faster AM rate.

Modulation of the noise seemed to affect CI users in a manner somewhat different from the simulation listeners. Figure 4 shows the average performance difference between modulated noise (either 4 Hz or 16 Hz) and steady-state noise (0 Hz) for the NH-Sim (upper panel) and the CI listeners (lower panel) as a function of the noise conditions. The difference >0 indicates masking release (i.e., the score in modulated noise exceeds the score in steady noise), whereas the difference <0 suggests modulation interference, with the performance in modulated noise poorer than that in steady noise. For NH-Sim listeners, the performance differences in most noise conditions except remote at 4 Hz were <0, showing masking interference. At 16 Hz, the difference for NH-Sim listeners was >0, indicating some masking release. For CI users, the performance differences in 4-Hz modulated noise were mostly <0 and were always poorer than those in 16-Hz modulated noise. This suggests that at the 4-Hz modulation rate, CI listeners seem to be experiencing modulation interference, especially when compared to their performance at 16 Hz.

Discussion

Effect of Noise on NH-Sim and CI Listeners

The purpose of the current study was to investigate the possible contribution of temporal and spectral interference to sentence recognition in modulated noise for NH-Sim and CI listeners. Both speech and noise were processed via various sets of bandpass or low-pass filters (Fu &Nogaki, 2004) to create different spectral distances between the target speech and noise. The amplitudes of noise masker were also modulated at different rates to examine whether a certain modulating rate might cause more interference than others. Overall, the results suggest that even when the NH-Sim and CI listeners are equated for their speech understanding in quiet, there are important differences between the two groups in noise conditions. For example, sentence recogni- tion of the CI listeners was significantly poorer than that of the NH-Sim listeners in all types of noise, even though their performances were equivalent in quiet, suggesting that there is considerable spectral spread for "real" CI listeners that is not captured in NH-Sim listeners. Syllabic rates of modulation had negative modulation interference effects on both listener groups, with more noticeable interference for the CI listeners. When speech and masker noise were spectrally separated, the NH-Sim listeners were not adversely affected by the noise, which resulted in similar performance in quiet and in spectrally remote noise. When the noise and target speech were spectrally overlapped, greater spectral over- lapping of vocoded speech and masker resulted in a larger and systematic decrease in speech understanding. The NH- Sim listeners did not show significant masking release when the noise masker was amplitude modulated (seen in Figure 3). Furthermore, the various AM rates on masker did not result in much increased difficulty in understanding vocoded speech, suggesting that the amplitude modulation itself might not substantially interfere with the temporal envelope cue for vocoded speech. However, it should be noted that there was large intersubject variability for listeners' understanding vocoded speech in noise, similar to that seen by others (Fu &Nogaki, 2004; Nelson et al., 2003). The CI listeners were significantly affected by noise even when the spectrum of noise was remote from that of speech, which was different from the NH-Sim listeners, whose performance did not drop in the remote condition. The sentence recognition scores of the CI listeners dropped even further when the noise spectrum was overlapped with the speech spectrum. For the three overlapping noise conditions-embedded, PO-more, and PO-less-the CI listeners' performance remained poor and approximately the same. It should be noted, however, that a potential limitation of the current study might have affected generalization of the findings to the CI population.

In order to examine the effect of spectral interference of noise on speech perception when spectral distances

between noise and speech signal were varied, we decided to use speech stimuli that were low-pass filtered at 2149 Hz or 3205 Hz instead of full-spectrum speech, which is a more natural and realistic listening condition. Overall for CI users, the AM rate of the modulated noise had an effect, stronger than their NH-Sim counterparts. Their 4-Hz modulated noise performance was significantly lower than both steady ($p < .001$) and 16 Hz ($p = .005$) noise, with no difference between steady and 16-Hz modulated noise. Overall, no masking release was observed. In fact, within a given spectral condition (remote, overlapping), performance in steady noise was often better than that in modulated noise, indicating some modulation interference. In particular, performance in 4-Hz AM noise (shown in filled bars with zero or negative masking release) was the poorest.

Clinical Implications for CI Listeners

One of the common findings from the studies of CI users is individual variability in their speech recognition scores regardless of speech materials or noise conditions (e.g., Fu &Galvin, 2008; Gifford, Shallop, &Peterson, 2008; Kwon et al., 2012), which was also found in the current study. Table 6 shows the performance of individual CI listeners in several conditions: quiet with full-spectrum speech and low-pass filtered speech, remote noise for the three AM conditions, and embedded noise for the same AM conditions. Note that CI 2 and CI 6, who performed best in quiet conditions (both full-spectrum and low-pass filtered speech), understood sentences better in most of the noise conditions than the rest of the CI listeners. CI 7 performed almost as well in quiet but scored poorer in noise. Among the remaining CI listeners, CI 3 and 4 had the worst scores in quiet; however, their recognition scores in the noise conditions were not consistently lower than the others. Overall, the current findings of individual variability suggest that a CI listener's performance in quiet does not always predict how much he or she is affected by noise in real life (as suggested by Smoorenberg, 1992).

Unlike the NH-Sim listeners, the CI users were significantly affected by the noise even when its spectrum was distant from the speech spectrum, as in the remote condition (see Figure 2). As suggested before, this might be due to channel interactions between speech and noise, which is a peripheral effect of the remote masker. It could also be possible that such a spectrally distinct noise masker may interfere with the central processing of a speech signal. This central masking could result from the listener's reduced ability to separate the target and masker due to the high degree of target-masker similarity, sometimes also referred to as informational masking (Arbogast, Mason, &Kidd, 2002; Brungart, 2001).

It has been reported that CI users may have an effective number of four to eight channels, even though more channels are built in the speech processor (Fishman, Shannon, &Slattery, 1997; Friesen, Shannon, Baskent, &Wang, 2001; Gamham, O'Driscoll, Ramsden, &Saeed, 2002). Thus, the temporal envelopes of the speech represented at the central auditory system may be perceived as more similar to those of the masker for CI users than for the simulation listeners. The central/informational masking was demonstrated in the Stickney et al. (2004) study, where CI listeners did not show better speech recognition when the talker of single-talker maskers was different from the signal talker. If this is true, then peripheral manipulations on the current commercial CI devices such as developments in signal processing algorithms or mapping strategies might not be enough to reduce the negative effect of background noise on speech perception of CI listeners. Perhaps, specific auditory training such as speech-in-noise training or targeted speech training in modulated maskers could be recommended based on listeners' individual needs (Fu &Galvin, 2008).

Previous studies reported that auditory training was helpful for listeners with hearing impairment to detect/ recognize simple stimuli such as musical tones (Galvin et al, 2007; Gfeller et al, 2002) and to understand speech recog- nition in difficult listening conditions (Fu &Galvin, 2008). Furthermore, behavioral changes due to auditory training seem to be correlated with training-related neurophysiologi- cal changes (Tremblay et al, 1998). Further studies need to be conducted to develop and verify an effective training method for CI users listening in modulated noise, in order to improve their segregation of speech from modulated back- ground noise. In the meanwhile, clinicians may recommend commercially available computer-based training such as Computer Assisted Speech Training (Fu, Galvin, Wang, &Nogaki, 2005), Listening and Auditory Communication

Enhancement (Sweetow &Henderson-Sabes, 2004), or a word-based auditory training program (Humes, Burk, Strauser, &Kinney, 2009), to CI users who have more difficulty understanding speech in noise. These programs have been shown to alleviate their stress levels in unfavorable listening conditions and to improve their understanding of speech in general.

Conclusion

CI users show more spectrally based masking than do their NH-Sim counterparts. Noise that was thought to be spectrally remote from the speech signal nevertheless interfered with CI listeners' perception of bandpass speech signals. Even when noise was designed to be spectrally remote from the speech signal, the presence of the noise (modulated or unmodulated) produced masking in CI listeners but not in simulation listeners. This can be presumed to result from the current spread of the speech and noise signals, and could be one reason why even the presumably remote masker showed some modulation interference for the CI users. In the simulation listeners, performance in the remote masker was equivalent to that in the quiet low-pass speech, and no modulation interference is seen. Presumably, then, the simulation listeners could still segregate the speech from the remote noise, and the envelope of the modulated remote noise did not cause interference or confusion with the use of the speech envelope.

Both NH-Sim and CI listeners show some evidence of modulation interference when listening to speech in modu- lated noise, with modulation interference showing up more strongly in CI users than in their NH-Sim counterparts. This interference happened whether the noise was spectrally embedded, overlapping, or remote from the speech signal. This could be an important factor in understanding the lack of masking release in these listeners, and could add to our understanding of their poor performance in background noise. When listeners have poor spectral resolution and they are tested using syllabic-like rates of modulated noise even at favorable SNRs, they apparently tend to be disrupted by the modulated noise, resulting in increased speech processing errors.

Sertoma club tackles hearing health

Author: Gitt, Tammie.

Publication info: McClatchy - Tribune Business News [Washington] 01 June 2013.
ProQuest document link

Abstract: People with properly equipped hearing aids can flip a switch on the hearing aid and the hearing aid effectively becomes a loudspeaker in the ear and filters out the background noise.

Full text: June 01--ENOLA -- Maureen Royer of the Carlisle Area Sertoma Club saw a recent Harrisburg Senators game as an opportunity to advance the club's mission of raising awareness of hearing issues.
It was, however, fireworks night. Fireworks can top 130 decibels, according to the American Speech-Language-Hearing Association. Hearing loss starts with anything over 85 decibels.
Royer saw irony as opportunity, handing out earplugs at the club's information table.
Nearly everyone knows someone affected by hearing loss, Royer said. One in five Americans experience some form of hearing loss.
"The hearing we have today won't get better," Royer said. "It will only get worse."
The next opportunity for the clubs to proclaim their message comes at the Celebrate Sound: Don't Walk in Silence fun walk on June 29.
Celebrate Sound is a national fundraiser co-sponsored by Sertoma and its sister nonprofit, Hearing Charities of America. The walk raises awareness about communication disorders, educates people about hearing health and promotes activities that can improve the quality of life for those with hearing issues.
Royer said the 18 clubs in the East and West Central Penn districts will hold walks on the same day in Harrisburg, York and Lancaster.
Capitol Area Sertoma, Carlisle Area Sertoma, Hearts-N-Hands Sertoma-Mechanicsburg, Middletown Hearts-N-Hands and West Shore Sertoma clubs are working together on the Harrisburg walk. Royer said this is the first time the clubs have held a joint event with a singular focus.
The walk will start at 9 a.m. June 29, at Adams-Ricci Community Park in Enola. Sertoma member RJ Harris, the morning show host at WHP 580, will be the emcee for the event.
Registration for the walk is $20. People can visit the website, mycelebratesound.com/Carlisle to register or make a donation. Royer said people can also participate as "virtual walkers" by donating $20, who would still

receive the free T-shirt.
Royer said the goal of the Harrisburg area teams is to raise $12,000.
Half of the proceeds from the walk will go back to the club to use in the community and the other half will go to the national Sertoma headquarters to fund national projects.
Local projects may include looping public meeting rooms. A looped room has an inductive coil installed and connected to the public address system. People with properly equipped hearing aids can flip a switch on the hearing aid and the hearing aid effectively becomes a loudspeaker in the ear and filters out the background noise.
The club also gives scholarships to students from local high schools who intend to pursue careers in hearing-related fields such as audiology and special needs education. Royer said they have given away about $40,000 since 1998.

Abstract: For those of us old enough to have experienced the British Invasion (The Beatles, The Rolling Stones, The Kinks and, of course, The Who), hearing troubles are likely a combination of age and the ear-damaging decibels that came through Marshall amplifiers, those early Walkmen or cranking the volume past 60 percent! If your problem is inner-ear damage, you'll go through a series of hearing tests and evaluations to find which type of aid will work best and which you can most easily adjust to.

Full text: Dear Amy: Ever since we broke off our serious relationship, I've realized how much I compromised to please this woman and how I practically changed myself during the course of our relationship. She has moved away, we're on good terms now, and she's seeing someone new. I think she learned her lesson from our relationship and changed. I still have strong feelings for her. In all honesty, I really want her back. -- Regrets
Dear Regrets: Your former girlfriend seems to have changed because she has changed -- she has changed her love object and her address, for instance. She is no longer controlling you because she is no longer with you. This could be why she seems so patient and reasonable to you -- she has a new person to bend to her will and whim. Chasing an ex who is with someone else is considered to be in poor taste. Consider objectively the possibility she hasn't changed at all but that you miss her anyway.
Realize that's OK, and normal, and then put yourself in healthy situations to meet new people.
Dear Amy: My boyfriend of several years claimed he wanted to get married and then said he wanted to live together first, even though I object to doing so.
He then said, after a breakup, that he was ready to get married and was prepared to propose. A proposalfree year and a half passed, and I asked him directly why he had done that. He held steadfast to needing to live together, and I finally agreed to it a month ago, gave my landlord notice and told my kids.
Today he texted that he no longer thinks that we should live together. He refuses to talk face to face and will not return my calls. What is the best thing to say to him at this point? -- Confused
Dear Confused: This guy will not take your calls -- but he's really doing you a favor, because you should not be talking to him. Do not communicate with him again. Talk to your landlord, apologize to your kids and restart your life.

Q u e s t o n :

I'm turning 60, and maybe all those rock 'n' roll concerts I went to are finally taking their toll on my hearing. I think I need a hearing aid, but I don't want to look like my grandmother. Any advice? -- Adele, C., Boulder

Answer: Oh, yes. For you -- and all the rock 'n' rollers in their 60s and 70s -- the answer to "Tommy, can you hear me?" finally might be YES, because of the amazing breakthroughs audiologists are making these days.

For those of us old enough to have experienced the British Invasion (The Beatles, The Rolling Stones, The Kinks and, of course, The Who), hearing troubles are likely a combination of age and the ear-damaging decibels that came through Marshall amplifiers, those early Walkmen or cranking the volume past 60 percent! Almost 10 million folks ages 45 to 65 report problems with their hearing, but we believe there's a lot more.

Fortunately, hearing aids are now coming in loud and clear, with five digital types: behind the ear; on the ear (s m a l l e r than behind the ear); in the ear; in the ear canal (barely visible); and comple tely in the ear canal (invisible). They work off p r o g r a m - mable computer chips that can differentiate between speech and background noise and can filter out the background. Amazing! And they don't look anything like your grandma's earpiece.

So, get thee to a specialist. If your problem is inner-ear damage, you'll go through a series of hearing tests and evaluations to find which type of aid will work best and which you can most easily adjust to. Be patient and persistent. Take various models for a test drive. The process of choosing the right hearing aid may take some time. But the rewards of being able to comfortably participate in the noisy world around you more than make up for the hassles you may have.

Petrosquamosal sinus in the temporal bone as a cause of pulsatile tinnitus: a radiological detection

Author: Liu, Zhaohui;Chen, Chengfang;Wang, Zhenchang;Gong, Shusheng;Xian, Junfang;Liang, Xihong

Publication info: Clinical Imaging 37.3 (2013): 561-3.
ProQuest document link

Abstract: We report a newly evidenced cause of venous pulsatile tinnitus--the petrosquamosal sinus in the temporal bone. We also present the case of a 45-year-old woman who presented with an incapacitating objective pulsatile tinnitus in the left ear for 10 years. The radiology evidenced a petrosquamosal sinus in the air cells of the left temporal bone. The symptoms of pulsatile tinnitus disappeared completely after surgical treatment.

Full text: 1 Introduction

Pulsatile tinnitus is the perception of a rhythmical noise that is synchronous with the heartbeat. It frequently induces anxiety and depression in patients. Sometimes, it becomes an unbearable sound that even drives patients to commit suicide [1] . Because the treatment is based on the cause of pulsatile tinnitus, accurate diagnosis is imperative.

Pulsatile tinnitus is a multifactorial disease and can be categorized into vascular and nonvascular. In the present study, we reported the first case of pulsatile tinnitus as a result of petrosquamosal sinus. The petrosquamosal sinus was surgically treated, and the pulsatile tinnitus disappeared.

2 Case report

A 45-year-old woman complained of objective pulsatile tinnitus in the left ear, which started 10 years ago. The tinnitus was enhanced in physical activity or in a stooping position of the body and decreased in rotation of the head to the left or by external compression of the ipsilateral vascular structures. Otoscopic examination revealed no abnormal findings.

Dual-phase contrast-enhanced CT was performed from the vertex to approximately the sixth cervical level. The venous phase CT showed a petrosquamosal sinus that originated at the junction of the transverse and sigmoid sinuses and traveled in the left temporal bone. The form of bifurcation was demonstrated at the anterior end of the petrosquamosal sinus, without anterior communications. A dehiscent cortical plate around the petrosquamosal sinus and an extensive pneumatized temporal bone filled with air were also found (Fig. 1). Digital subtraction angiography (DSA) confirmed the presence of the petrosquamosal sinus. The manifestation of the petrosquamosal sinus on DSA resembled that on computed tomography (CT) (Fig. 2), but the petrosquamosal sinus was not demonstrated on magnetic resonance imaging (MRI). Dual-phase contrast-enhanced CT, MRI, and DSA did not evidence any known cause of pulsatile tinnitus.

The petrosquamosal sinus was treated by surgery. Briefly, a postauricular incision was made and an anterior skin flap was raised over the mastoid. A superiorly based mastoid periosteal flap was created and pedicled on the temporal muscle to expose the mastoid cortex. The petrosquamosal sinus in temporal bone was skeletonized. Temporal muscle and fascia were placed on the surface of the petrosquamosal sinus. The repair was then covered with the superiorly based periosteal flap. The skin was closed, and a compressive mastoid dressing was placed. The pulsatile tinnitus disappeared completely after surgery and did not reappear during 33 months of follow-up.

3 Discussion

Although the petrosquamosal sinus usually declines in size in fetuses of 60 mm in length and disappears by the time of birth [2] , it sometimes may persist after birth. Previous anatomical and radiological studies have described this venous channel in occasionally healthy people [3-5] . However, petrosquamosal sinus has not been reported as a cause of pulsatile tinnitus in previous studies. Because the petrosquamosal sinus was located close to the inner ear and coexisted with a dehiscent cortical plate and an extensive pneumatized temporal bone in the patient of the present study, we hypothesized it might be the cause of the tinnitus. This hypothesis was also supported by the clinical examination and surgical treatment.

Although the petrosquamosal sinus presented in the embryonic period, the tinnitus occurred in the patient at 35 years old. We suspect that the cortical plate between the petrosquamosal sinus and the air cells of the temporal bone may be complete before the presence of pulsatile tinnitus. The complete cortical plate is considered as an insulation characteristic and may impede the noise from flowing in the petrosquamosal sinus to transmit to the air cells [6,7] . A dehiscent cortical plate caused by long-term impacting effect of blood flow on the cortical plate may destroy this insulation characteristic. The noise from blood flow can be easily transmitted to the air cells through the dehiscent cortical plate. Large air cells filled with air can increase the resonance of noise by prolonging, amplifying, and filtering the sound being transmitted to the cochlea [6,7] .

Pulsatile tinnitus has numerous causes and can be divided into vascular and nonvascular. To date, about 20 causes of vascular pulsatile tinnitus have been reported [6-17] . The majority of patients have a treatable underlying cause which can be detected in about 70% of them radiologically [8] . Therefore, detailed imaging studies are recommended. Radiological investigations of pulsatile tinnitus include dual-phase contrast-enhanced CT, inner ear MRI, and DSA at our institution. Dual-phase contrast-enhanced CT serves as an initial survey for pulsatile tinnitus because it can provide highly detailed images of the temporal bone and the vascular anatomy. MRI should then be performed for detection of possible neoplasm or vascular malformation. Although arterial phase CT and MRI can screen dural arteriovenous fistulas in patients with pulsatile tinnitus [9,10] , DSA remains the gold standard for this disease [18] . In our case, although the petrosquamosal sinus can also be confirmed on DSA, the relationship between the petrosquamosal sinus and the temporal bone can only be evaluated on contrast-enhanced CT.

In conclusion, this newly described treatable cause of pulsatile tinnitus, namely, the petrosquamosal sinus in the temporal bone, is a rare venous variation. It should be included in the differential diagnosis of pulsatile tinnitus in clinical practice. Contrast-enhanced CT is recommended as the primary diagnostic tool with the suspicion of the disease. The surgical treatment of such a lesion is an effective and safe method.

What's New and Notable in Hearing Aids: A Friendly Guide for Parents and Hearing Aid Wearers

Author: Neumann, Sara, AuD, CCC-A, FAAA; Wolfe, Jace, PhD, CCC-A.

Publication info: Volta Voices 20.3 (May/Jun 2013): 24-29,6.
ProQuest document link

Abstract: Audiologists should properly select good candidates for frequency-lowering technologies, program this technology appropriately for the individual's needs, and verify the benefit the wearer receives through the use of probe microphone measures (ask your audiologist about probe microphone measures if you are unaware of this important hearing aid assessment tool).\n Because the microphone is positioned closely to the mouth of a parent or teacher, the speech signal captured by the system's microphone is typically much higher in volume level than the surrounding background noise. Studies have shown that hearing aid and cochlear implant users receive great benefit from dynamic digital RF systems when compared to traditional/classic and dynamic FM systems (Thibodeau, 2013; Wolfe et al., in press).

Full text: Sometimes, it seems that hearing aid technology changes as quickly as computer technology. By the time you get a new one, there's something else on the horizon that will make your "new" hearing aids seem outdated. However, there are some great things happening that will likely stick around for quite a while. Investing in new hearing aids or maybe even your first pair can be overwhelming. Today, some advanced technology features, which were formerly only available in expensive, high-end hearing aids, are now available in economy-level hearing aids. This article discusses several new hearing aid technologies and suggests

questions that you may want to ask your hearing health providers when you select your next set of hearing aids.

Access to HighFrequency Information

Audibility of high-frequency sounds is essential for developing speech and language. The ability to hear high-frequency speech sounds is crucial for understanding speech as well as the rules underlying language and grammar, such as plurality, possessives and subject-verb agreement. Furthermore, research has shown that when children with hearing loss cannot adequately hear sounds above 4,000 Hz, they will have to be exposed to three times as many words as children with typical hearing to learn new vocabulary and concepts due to the reduced acoustic bandwidth caused by the hearing loss (Pittman, 2008). The "Familiar Sounds Audiogram" shown in Figure 1 illustrates the large number of consonants that reside in the high frequencies. Unfortunately, hearing aids have typically been limited in their ability to provide sufficient audibility for high-frequency sounds. The speech sounds on the audiogram are placed in the pitch and intensity range at which the sounds are typically heard. You can see that high-frequency sounds like Ik/, If/, Is/, and /th/ occur in the highfrequency range (3,000-8,000 Hz) and at very soft levels. These sounds are important to understand plurality, possessives, and for overall clarity of speech.

Hearing loss is frequently poorer in the high frequencies relative to the low frequencies. In response to the aforementioned difficulties, hearing aid manufacturers have developed several approaches to improve audibility and understanding of high-frequency speech and environmental sounds.

Traditionally, hearing aids have been unable to provide sufficient amplification for sounds beyond 4,000 to 6,000 Hz. This constraint was primarily attributed to a limitation of the hearing aid receiver (the term used to refer to the miniature speaker of the hearing aid), which simply could not provide adequate amplification of high-frequency sounds. Additionally, the hearing aid would often produce acoustic feedback (i.e., whistling, squealing) with attempts to amplify high-frequency sounds.

Recently, several manufacturers have introduced "extended bandwidth" hearing aids, which promote improved receivers that sufficiently amplify sounds to 8,000 Hz and beyond. Although this technology is promising, there is a paucity of studies showing significant improvements in speech recognition with the use of extended bandwidth amplification. Research studies addressing technologies designed to enhance access to high-frequencies will be discussed following the proceeding discussion on frequencylowering technology.

Rather than attempting to extend the limits of the hearing aids frequency response, some manufacturers have developed hearing aids with frequency-lowering technology. Frequency lowering can be achieved by linear frequency transposition (LFT), non-linear frequency compression (NLFC), or spectral envelope warping (SEW). A brief explanation of each follows.

Linear frequency transposition (LFT) (Figure 2B) takes high-frequency sounds, transfers them down into a lower frequency range, filters the transposed sound and then mixes it in with the amplified lowfrequency sounds, where the patient has better hearing, so that the high-frequency and low-frequency sounds are overlaid on one another.

Non-linear frequency compression (NLFC) (Figure 2C) takes high-frequency information above a designated frequency range, referred to as the crossover frequency, and compresses it into a lower range as determined by a pre-set frequency compression ratio. Sounds below the crossover frequency are not compressed, and low-frequency and high-frequency sounds are not mixed with one another.

Spectral envelope warping (SEW) (Figure 2D) is designed to capture a high-frequency sound information and replicate it at a lower frequency. Similar to LFT, the bandwidth of the high-frequency sound information is not altered, SEW moves the high-frequency of sound to a lower frequency range, where the low-frequency and high-frequency sounds are overlaid on one another. However, in contrast to LFT, SEW also amplifies the high-frequency sound and presents it at its original frequencies as well (Rodemerk et al., n.d.; Simpson, 2009).

All of the aforementioned frequency-lowering strategies possess potential advantages and limitations, and there

are no published research studies showing one approach to be superior to another. However, published studies have shown that each of these different frequency-lowering technologies can improve audibility and speech understanding of high-frequency speech sounds for children and adults with severe to profound hearing loss (Auriemmo et al., 2008; Glista et al., 2009; Kuk et al., 2010; Simpson et al., 2005; Galster et al. 2011). Additionally, Wolfe and colleagues (2010; 2011) determined that NLFC improves audibility for and recognition of high-frequency speech sounds for children with moderate highfrequency hearing loss, and they showed that performance with NLFC improved with experience (i.e., acclimatization) with the frequency-lowering technology. As such, several weeks of NLFC use may be necessary before benefit is fully realized. More recendy, Wolfe and colleagues (submitted, 2013) compared aided thresholds and speech recognition for a group of children who had mild hearing loss and used hearing aids with NLFC and extended bandwidth. NLFC provided better access to low-level high-frequency sounds as well as better recognition of high-frequency speech sounds when compared to hearing aids with extended bandwidth.

As previously mentioned, there can be disadvantages associated with frequencylowering technology. In particular, if the frequency-lowering is too aggressive, then speech and environmental sounds may become distorted resulting in poor sound quality and a reduction in speech understanding. Audiologists should properly select good candidates for frequency-lowering technologies, program this technology appropriately for the individual's needs, and verify the benefit the wearer receives through the use of probe microphone measures (ask your audiologist about probe microphone measures if you are unaware of this important hearing aid assessment tool). Further, the benefits of frequency-lowering technology should be validated with behavioral testing and feedback from parents, speech therapists, and teachers. Researchers have suggested several different practices to effectively fit and verify frequencylowering technology as well as to determine candidacy for these technologies (Glista &Scollie, 2009; Kuk, 2013; Simpson, 2009; Wolfe et al., 2010, 2011).

Hearing Aid Noise Reduction Technologies

One of the most pressing difficulties of persons with hearing loss is an inability to effectively understand speech in the presence of noise. Studies have shown that around 40% of adult wearers continue to be unsatisfied with their ability to hear in noise after being fitted with hearing aids (Kochkin, 2010). Numerous research studies have shown that children with hearing loss experience even more difficulty understanding speech in noise when compared to their peers with typical hearing or adults with hearing loss (McCreery et al., 2010; Stelmachowicz et al., 2001). Hearing aid manufacturers have developed numerous technologies to improve performance in noise, including directional microphones, digital noise reduction (DNR), wind noise reduction, and dereverberation algorithms.

Directional microphone technology typically employs two or more microphones to amplify sounds coming in from the front as prescribed, while limiting or reducing amplification for sounds coming from the sides and back. This approach assumes that the wearer will face the signal of interest in a noisy environment, and consequently, the speech will be enhanced and the surrounding noise will be reduced. Numerous research studies have shown that directional microphones improve speech understanding in noise more than any other technology currently built into hearing aids (although directional microphones do not provide as much improvement in speech understanding in noise as remote microphone radio frequency systems - also commonly known as FM systems - which are an assistive technology that may be used with hearing aids to provide the most improvement in speech recognition in noise (Schäfer &Thibodeau, 2004)). As a result, directional technology is routinely recommended for adult hearing aid wearers.

In contrast, there are conflicting recommendations regarding the use of directional microphones in children (Bagatto et al., 2010; King, 2010; McCreery et al., 2012; Ricketts et al., 2010). For instance, the Ontario guideline for fitting hearing aids for children discourages the use of directional microphones for children, while the Australian guideline recommends the use of directional hearing aids for children (Bagatto et al., 2010; King, 2010). The hesitation associated with directional microphone use in infants centers around the concern that

directional amplification may limit a child's access to important sounds that arrive from behind him/her. We know that incidental listening, the term used to describe a child's tendency to listen to speech that, is not directed specifically to him or lier, is responsible for a great deal of a child's vocabulary and social development. In fact, Dr. Carol Flexer has estimated that as much as 90% of what a child learns during the first few years of life comes from incidental listening (Cole &Flexer, 2010). Could directional microphones, which inherently limit access to sounds arriving from behind a child, interfere with incidental listening? There has not been enough research examining directional hearing aid use in young children to fully answer that question yet.

It should be noted that many contemporary hearing aids feature what is often referred to as adaptive directionality, in which the hearing aid amplifies sound from all directions equally (e.g., omni-directional) in quiet environments and automatically switches to directional mode in noisy environments. In fact, some hearing aids even go a step further and remain in omni-directional mode if the primary signal arriving from behind the user is speech. With this approach, the risk of missing out on important speech signals arriving from behind or from the side of a hearing aid wearer is limited. It is likely that there are differences in adaptive directional algorithms from one manufacturer to another, and consequently, there is not enough evidence to determine whether they are suitable for children.

Although directional microphones may improve speech recognition in noise, it is probably prudent to refrain from their use until a child is old enough to consistently orient toward the signal of interest and provide verbal feedback about the potential perceived advantages and limitations of directional amplification. Hopefully, ongoing research and development will clarify the question of whether young children should use adaptive directional amplification and possibly even result in a hearing aid that limits the potential disadvantages of directional amplification for children.

Digital noise reduction (DNR) is another hearing aid noise technology designed to improve performance in noisy environments. DNR analyzes the sound arriving to the hearing aid, determines whether it is speech or noise, and reduces the aided gain when background noise is the dominant input. Research conducted with adult hearing aid users has shown that DNR significantly improves listening comfort in noise, and wearers consider DNR to be one of the most important features in their hearing aids (Powers et al., 2006; Kochkin, 2010). Other studies have indicated that DNR provides at most a modest improvement, and in many cases, no change in speech understanding in noise (Bentler, 2005; Peeters 2009). Most studies have shown no degradation in speech recognition in noise for adults using DNR. Like directional technology, DNR is routinely recommended for adult hearing aid wearers.

As with directional hearing aids, we are still examining the appropriateness of DNR for young children. Research with pediatric hearing aid users has essentially shown that DNR does not degrade or improve speech recognition in noise (Bentler et al., 2010; McCreery et al., 2010). Bender and colleagues (2010) did show that DNR may improve listening comfort for children in noisy situations. They also showed that children's novel word learning abilities were improved with the use of DNR, a fact they attributed to a decrease in the cognitive processing load afforded by improved listening comfort associated with DNR. Taken collectively, these findings suggest that DNR may be quite beneficial for children and should be considered for use with pediatric hearing aid wearers (McCreery et al., 2010; Stelmachowicz et al., 2010).

However, it is important to remember that not all hearing aids work alike, and it is possible that some DNR algorithms may reduce gain for speech. It is imperative that the audiologist verify that gain is not reduced when speech is present. Contemporary hearing aid testing equipment typically allows for this type of verification. The interested audiologist is referred to an excellent review by McCreery and colleagues on electroacoustic assessment of hearing aids with DNR (McCreery, Gustafson, &C Stelmachowicz, 2010). Once the audiologist does determine that DNR does not reduce gain when speech is present, DNR should be considered for pediatric hearing aid wearers.

Binaural Processing

There is a reason we have two ears. In people with typical hearing, the ears work together to better understand speech in noisy environments as well as to determine the direction from which a sound originates. For instance, we can tell that a sound originates from our right side, because it is a little louder and arrives a little earlier at the right ear than the left. Hearing aids are now capable of sharing information with one another in an attempt to preserve the natural differences that exist between sounds arriving at the two ears and mimic the way the natural auditory system works.

Furthermore, some hearing aids work together so that a wearer may adjust the volume or a program on one hearing aid and the change automatically happens at the other hearing aid. Some hearing aids also have the capability of allowing the user to hear the sound from a telephone in both ears simultaneously when the phone is placed next to one of the hearing aids. Finally, some advanced hearing aids share information between their microphones in order to allow for "super directionality." As shown in Figures 3B and 3C, beamforming achieved by two hearing aids working together can be much more precise than either hearing aid working alone.

Streaming Accessories

Almost every major hearing aid manufacturer now has a way to wirelessly link your hearing aids with your personal technology (from phones to computers to TVs). Some companies use "streamers" (a device you wear around your neck to allow you to interface between the hearing aids and the accessory) to wirelessly connect to your personal products, while other manufacturers have developed hearing aids that allow you to wirelessly connect without an interface device. Some manufacturers also offer a wireless microphone accessory, which can pick up an important voice and wirelessly send it to the hearing aids directly or via the streamer. This type of technology is great for noisy environments such as a restaurant, because the voice of a parent (or spouse) can be captured by the microphone and sent directly to the hearing aids of the child (or significant other). Smartphone technology is also paving the way to allow you to use an app to control your hearing aids. This is an everevolving technology, so ask your hearing professional about the best option for your lifestyle.

Digital Modulation (DM) Radio Frequency (RF) Systems

Personal remote microphone radio frequency (RF) systems have been around for a long time, and have long been recognized as the most effective means to improve speech recognition in noisy places. In short, these systems possess a microphone/transmitting unit that captures the signal of interest and sends it by way of a radio signal to small receivers that are coupled to the user's hearing aids or cochlear implant sound processors. Because the microphone is positioned closely to the mouth of a parent or teacher, the speech signal captured by the system's microphone is typically much higher in volume level than the surrounding background noise. The transmitting device may also be plugged into a computer, MP3 player, classroom smart board, etc., to directly capture and send that audio signal of interest to the receivers.

Historically, these types of systems have used an analog frequency modulated (FM) RF signal to transmit the signal of interest. Recently, manufacturers have started introducing digitally-modulated RF systems, which are similar to Bluetooth* technology used in several recreational and business applications. Digital RF systems are able to provide a higher level of analysis and control over the signal that is captured by the microphone and eventually delivered to the receiver. Furthermore, these systems typically use a carrier frequency that "hops" from frequency to frequency many hundred times per second, a characteristic that makes digital RF systems less susceptible to interference from nearby RF devices (Wolfe et al., in press). Studies have shown that hearing aid and cochlear implant users receive great benefit from dynamic digital RF systems when compared to traditional/classic and dynamic FM systems (Thibodeau, 2013; Wolfe et al., in press).

Waterproof /Water Resistant

Perhaps it's just icing on the cake, but besides all of the great technology that allows individuals to hear better in a variety of settings, several hearing aid companies have now made some of their products water-resistant. Some even claim you can swim with them. It is important to consider how the warranty works if you do choose to participate in water activities with the hearing aids on. Some are not "waterresistant" per se, but have a

special coating inside the electronics that helps repel moisture - especially good if you (or your child) are susceptible to excessive sweating or have wax problems. If you know that you have this specific concern, let your provider know so they can request that special coating is applied to your hearing aid as it may not be standard in all cases.

In summary, hearing aid technology has improved significantly over the past few years. Although it is not perfect, contemporary technology can improve the communication abilities of most everyone with hearing difficulties. If you are struggling with your hearing, you should consult your audiologist to determine whether new technology may alleviate your communication difficulties. Your hearing is too important to struggle through life with inferior technology. Additionally, make certain you see a licensed audiologist who is experienced with providing new technology for patients in your age range (or the range of your child). The best technology in the world can be worthless if it is not selected and fitted appropriately to meet the wearer's needs. Remember, we should work together to use new technology so that each person with hearing loss reaches his/her full potential. Your hearing is worth it!

AuthorAffiliation

Sara Neumann, Au.D., CCC-A, FAAA, co-author of "What's New and Notable in Hearing Aids: A Friendly Guide for Parents and Hearing Aid Wearers," is a clinical audiologist at Hearts for Hearing in Oklahoma City, Okla., where she works primarily with the pediatric population, but also works with adults who have cochlear implants. In addition, Neumann works as a deaf education consultant and educational audiologist for a local school district through Hearts for Hearing. She received her B.S. in deaf education from Northern Illinois University in 2003 and her Doctorate of Audiology from Illinois State University in December 2012. Neumann's special interests include cochlear implants, personal FM systems, transition from Part C to Part ? programs, and hearing conservation for young musicians, especially those in drum corps and marching band programs.
Jace Wolfe, Ph.D., CCC-A, co-author of "What's New and Notable in Hearing Aids: A Friendly Guide for Parents and Hearing Aid Wearers," is the director of audiology at the Hearts for Hearing Foundation in Oklahoma City, Okla. He also is an adjunct assistant professor in the Audiology Department at the University of Oklahoma Health Sciences Center and Salus University. Wolfe is a member of the Better Hearing Institute's Pediatric Advisory Board as well as the Audiology Advisory Boards for Cochlear Americas, Advanced Bionics, and Phonak. He also serves on the editorial board of The Hearing journal, and is a reviewer for several peer-reviewed journals. His areas of interests are pediatric amplification and cochlear implantation, personal FM systems, and signal processing for children.

Digital hearing aids

Author: Roizen, Michael; MD; and Mehmet Oz.

Publication info: Telegraph - Herald [Dubuque, Iowa] 14 Apr 2013: E.3.
ProQuest document link

Abstract: Fortunately, hearing aids are now coming in loud and clear, with five digital types: behind the ear; on the ear (smaller than behind the ear); in the ear; in the ear canal (barely visible); and completely in the ear canal (invisible).

Full text: Question: I'm turning 60 next week, and maybe all those rock'n'roll concerts I went to are finally taking their toll on my hearing.
I think I need a hearing aid, but I don't want to look like my grandmother. Any advice? - Adele, C., Boulder, Colo.
Answer: Oh, yes. For you - and all the rock'n'rollers in their'60s and'70s - the answer to "Tommy, can you hear me?" finally might be yes, because of the amazing breakthroughs audiologists are making these days.
Fortunately, hearing aids are now coming in loud and clear, with five digital types: behind the ear; on the ear (smaller than behind the ear); in the ear; in the ear canal (barely visible); and completely in the ear canal (invisible).
They work off programmable computer chips that can differentiate between speech and background noise, and

can filter out the background.
Be patient and persistent. Take various models for a test drive. The process of choosing the right hearing aid could take some time.

STOP THAT NOISE!

Author: Nickens, T Edward.

Publication info: Field & Stream 117.11 (Apr 2013): 68-69.

Abstract: Wearing some type of hearing protection now-whether you go with plugs or muffs-is an investment in your future sanity. 1 / Mack's Ultra SoftFoam Earplugs $4 FOR 10 * MACKSEARPLUGS.COM THE LOWDOWN With a noise reduction rating (NRR) of up to 32 decibels, these ubiquitous plugs make highrepetition shooting safe and comfortable. WHO SHOULD BUY Any shooter who is looking for a big step up from drugstore foam plugs but doesn't want the bulk of a full muff. 3 / Caldwell Platinum Series G3 Earmuffs $80 * BATTENFELD TECHNOLOGIES.COM THE LOWDOWN Many midpriced earmuffs use cut-offtechnology that cycles on and offwhen presented with a loud noise, resulting in gaps in hearing.

Full text: Headnote

We test and rate four types of hearing protection, so you can find one that matches your shooting style and your wallet

After a youth misspent by scoffing at hearing protection, I have learned my lesson: For what my digital hearing aids cost, I could cram an iPad and an English double gun into my ears. So be smart and wear one of the four types of hearing protection featured here, which run the gamut from dirt-cheap to hmm-that's-a-bit-of-cash (in that order). Any will preserve your hearing, and the more expensive devices can vastly improve your enjoyment in the field and on the shooting range. Take it from me: Wearing some type of hearing protection now-whether you go with plugs or muffs-is an investment in your future sanity.

1 / Mack's Ultra SoftFoam Earplugs

$4 FOR 10 * MACKSEARPLUGS.COM

THE LOWDOWN With a noise reduction rating (NRR) of up to 32 decibels, these ubiquitous plugs make highrepetition shooting safe and comfortable. The low-pressure polyurethane memory foam compresses easily and re-forms in the ear canal for a tight fit that blunts sounds. Covered with a skin of slick material, they are easier to insert and more comfortable to wear than bargain-basement PVC stopples.

HITS They are easy to use and inexpensive, and they work.

MISSES Proper insertion takes two hands and more time than you have when ducks are coming in. Once inserted, they render you practically deaf.

WHO SHOULD BUY The hunter who needs the least costly solution-but everyone should carry them as backups. I keep foam earplugs stashed in jacket pockets, blind bags, and gun cases.

2 / E.A.R. Inc. Insta-Mold Earplugs

$65 * EARINC.COM

THE LOWDOWN E.A.R. Inc. providers make these custom earplugs on the spot at outdoor expos and can be scheduled for fittings at your local gun range. Here's how it's done: Hypoallergenic silicone is injected into the ear canal, which hardens into a pliable mold in less than 10 minutes. The mold is removed, trimmed, allowed to

cure for an hour, and coated with a lubricant. Done. Insta-Molds are super comfortable and provide an aesthetically subtle and very effective sound barrier (about 30dB NRR).
HITS Excellent wind protection and no clanking against the gunstock, as full muffs can do. They are available with acoustic filters that allow normal conversation.
MISSES It takes some practice to get the knack of inserting the somewhat corkscrew-shaped plugs.
WHO SHOULD BUY Any shooter who is looking for a big step up from drugstore foam plugs but doesn't want the bulk of a full muff.
3 / Caldwell Platinum Series G3 Earmuffs
$80 * BATTENFELD TECHNOLOGIES.COM
THE LOWDOWN Many midpriced earmuffs use cut-offtechnology that cycles on and offwhen presented with a loud noise, resulting in gaps in hearing. Not these. Like many higher-end muffs, the G3s use compression technology to dampen muzzle blasts (21dB NRR), whereas low-level sounds are clearly amplified. I found these muffs very comfortable to wear. On the shooting range and in the duck blind, normal conversation and other ambient sounds came through loud and clear.
HITS They use AAA batteries, which can be found just about anywhere.
MISSES The ear cups occasionally banged on the gunstock. They picked up a little wind noise in a stiffbreeze.
WHO SHOULD BUY Anyone who wants good electronic muffs but not the typical price tag. These are a steal for the money.
4 / ProEars Stalker Gold Electronic Earmuffs
$330 * PROEARS.COM
THE LOWDOWN These muffs are packed with features-compression technology, circuit boards in each ear cup, twin 360-degree microphones, and hybrid analog-digital technology-that combine to produce ample hearing protection (25dB NRR), high-fidelity sound reproduction, and a significant boost in amplification. There's also a 3.5mm jack that allows users to plug in two-way radios for field communication-or an iPhone, if you must.

HITS The slim-profile design stays clear of gunstocks. Leather ear cups reduce sweat, which is common when wearing vinyl cups.
MISSES Uses harder-to-find N-style medical batteries. An external batteryon lamp would be nice.
WHO SHOULD BUY Shooters who need top-end quality for frequent high-volume situations, such as at the range or dove field-and anyone already experiencing some degree of hearing loss.
THE TEST
First, I wore each device and mounted shotguns and rifles with varying stock designs to test for ease of use and any issues with stock clearance and cheek weld. Then I set a window box fan on its medium setting and moved around in the artificial breeze to gauge how wind might affect each device. And of course, there was the shooting: I used each device in dove fields, in duck blinds, in a treestand, and at the shooting range. -T.E.N.

Effects of Noise Suppression on Intelligibility: Experts' Opinions and Naïve Normal-Hearing Listeners' Performance

Author: Hilkhuysen, Gaston L M; Gaubitch, Nikolay; Huckvale, Mark.

Publication info: Journal of Speech, Language and Hearing Research (Online) 56.2 (Apr 2013): 404-415.
ProQuest document link

Abstract: In this study, the authors investigated how well experts can adjust the settings of a commercial noise-reduction system to optimize the intelligibility for naive normal-hearing listeners. In Experiment 1, 5 experts

adjusted parameters for a noise-reduction system while aiming to optimize intelligibility. The stimuli consisted of speech presented in car- cabin noise or babble at 5 different signal-to-noise ratios (SNRs). In Experiment 2, the effects of processing with these settings were measured with 10 listeners undertaking an intelligibility test. In Experiment 3, the intelligibility of a broad range of settings was investigated with another 10 listeners to determine whether the experts' chosen settings could have been improved. Low Cronbach's alphas indicated that parameter settings varied considerably within and across experts. For very low SNRs, mean proposed settings differed from those for higher SNRs. The different settings had no significant effects on intelligibility for naive normal- hearing listeners. At high SNRs, the settings proposed by experts were found to deteriorate intelligibility. Superior intelligibility for naive normal-hearing listeners was achievable from settings other than the ones proposed by the experts. While attempting to enhance noisy speech, experts may propose settings that deteriorate intelligibility for naive normal-hearing listeners. [PUBLICATION ABSTRACT]

Purpose: In this study, the authors investigated how well experts can adjust the settings of a commercial noise-reduction system to optimize the intelligibility for naive normal-hearing listeners.
Method: In Experiment 1, 5 experts adjusted parameters for a noise-reduction system while aiming to optimize intelligibility. The stimuli consisted of speech presented in car- cabin noise or babble at 5 different signal-to-noise ratios (SNRs). In Experiment 2, the effects of processing with these settings were measured with 10 listeners undertaking an intelligibility test. In Experiment 3, the intelligibility of a broad range of settings was investigated with another 10 listeners to determine whether the experts' chosen settings could have been improved.
Results: Low Cronbach's alphas indicated that parameter settings varied considerably within and across experts. For very low SNRs, mean proposed settings differed from those for higher SNRs. The different settings had no significant effects on intelligibility for naive normal- hearing listeners. At high SNRs, the settings proposed by experts were found to deteriorate intelligibility. Superior intelligibility for naive normal-hearing listeners was achievable from settings other than the ones proposed by the experts.
Conclusion: While attempting to enhance noisy speech, experts may propose settings that deteriorate intelligibility for naive normal-hearing listeners.
Key Words: noise suppression, opinion-based intelligibility, performance-based intelligibility

Signal processing methods for the enhancement of poor-quality speech audio are currently found in a range of commercial applications, such as hearing aids, mobile phones, and digital audio workstations (DAWs). Many of these relate to the reduction or suppression of unwanted noise (see Loizou, 2007, for review). It has been found that these methods typically reduce or at best make little difference to intelligibility (Hu &Loizou, 2007a; Ludvigsen, Elberling, &Keidser, 1993), although occasional improvements in intelligibility are reported (Arehart, Hansen, Gallant, &Kalstein, 2003; Tsoukalas, Mourjopoulos, &Kokkinakis, 1997).

Most noise reduction systems come with large parameters sets. From studies that consider the effects of parameter changes (Boll, 1979; Lim, 1978; Ludvigsen et al, 1993; Tsoukalas et al, 1997), it emerges that the choice of settings may influence intelligibility. Little information is available on how one might determine settings that optimize intelligibility. Adjusting the parameters is left to experts: the dispenser of the hearing aid, the forensic audio specialist, or the engineer developing the algorithm. Typical intelligibility studies measure a listener's ability to reproduce the speech correctly, but such measurements are time-consuming. This makes them infeasible for evaluating parameter setting in practical settings. Various authors (Goldsworthy &Greenberg, 2004; Ludvigsen et al, 1993; Ma, Hu, &Loizou, 2009) have tried to predict the intelligibility of noise-reduced noisy speech with existing physical intelligibility metrics but found that these metrics gave poor predictions. Others (Loizou &Ma, 2011; Taal, Hendriks, Heusdens, &Jensen, 2011) have developed metrics

especially designed for predicting the intelligibility of noise-reduced speech. But it is not yet clear whether these new metrics can be used to find parameter settings that optimize intelligibility; so currently the task of finding the best settings for a noise-reduction algorithm is left to experts.

Little is known about experts' abilities to estimate the intelligibility of noisy speech after noise reduction. Studies that have investigated whether opinions can be relied on have focused on speech in noise without noise reduction (Beck &Speaks, 1993; Cienkowski &Speaks, 2000; Cox &McDaniel, 1989; Fabry &Van Tasell, 1990; Magnusson, Karlsson, Ringdahl, &Israelsson, 2001; McDaniel &Cox, 1992; Rankovic &Levy 1997; Studebaker, Bisset, Van Ort, &Hoffnung, 1982) or on filtered speech (Fabry &Van Tasell, 1990; Purdy &Pavlovic, 1992; Rankovic &Levy, 1997). The outcomes of these studies suggest that these opinions can be measured reliably (Beck &Speaks, 1993; Cox &McDaniel, 1989). High correlations with intelligibility measures (Cienkowski &Speaks, 2000; Magnusson et al., 2001; Purdy &Pavlovic, 1992; Rankovic &Levy, 1997; Studebaker et al, 1982) or with physical metrics (Fabry &Van Tasell, 1990; Magnusson et al, 2001) have been observed. Purdy &Pavlovic (1992) have shown that opinions have validity. In some studies (McDaniel &Cox, 1992; Studebaker et al, 1982), it has been reported that opinions are sensitive to differences in intelligibility caused by different hearing aids. However, all of these studies considered situations where the same listeners provided both the opinions and the intelligibility measures. With noise reduction, experts tend to decide on the settings that are subsequently used by naive listeners. For example, in forensic applications, an audio specialist can decide to apply noise reduction, while the processed audio may later be heard by transcribers or jury members. With mobile phones, it is the engineer designing the device that usually decides on the settings that are experienced by users. To our knowledge, no studies have investigated whether these experts' opinions can be relied on.

Despite the numerous studies showing congruence between opinions and intelligibility measures, there are reasons to question the experts' abilities to find settings optimal for intelligibility. It has been reported that noise reduction can improve the perceived quality of speech but deteriorate intelligibility at the same time (Arehart et al, 2003; Hu &Loizou, 2007a, 2007b). Consequently, speech quality cannot be used as a cue to find settings optimal for intelligibility. Additionally, noise reduction can reduce listening effort in conditions where intelligibility is invariant (Sarampalis, Kalluri, Edwards, &Hafter, 2009). Hence, listening effort may also be a fallible cue for experts trying to optimize intelligibility.

It could be argued that the failure of noise reduction to improve intelligibility could be caused by the fact that experts are unable to provide optimal parameter settings for a given audio environment. To investigate this argument, we report the results of three experiments that contrast expert opinions on the intelligibility of noise-reduced noisy speech with corresponding intelligibility scores obtained with naive normal-hearing listeners. For the current work, such listeners were preferred over listeners with hearing impairment. The application of noise reduction appears to be widespread, and the work of our experts focused on speech processing in general. In Experiment 1, experts were asked to set the parameters of a commercial noise-reduction system to values that, according to their opinion, optimized intelligibility. In Experiment 2, speech recordings processed with these settings were evaluated with intelligibility measurements obtained from naive normal-hearing listeners. In Experiment 3, intelligibility was measured with a broad range of parameter settings, verifying whether the settings chosen by the experts optimized intelligibility.

Experiment 1: Opinions on Optimal Parameter Settings

Method

Participants. Five experts provided parameters settings. Four had a background in electrical engineering; one was an experimental psychologist involved in speech enhancement research. The mean and standard deviation of their ages was 30 and 7 years, respectively. All were male and experienced listeners. They were selected on the basis of their experience in speech processing and familiarity with different speech enhancement algorithms. None reported hearing difficulties. For three of them, the normal status of their hearing was later confirmed by measurement of their pure-tone hearing thresholds (International Organization for Standardization,

2004). These were below 20 dB at octave frequencies ranging from 0.125 to 8 kHz.

Materials, stimuli, and procedure. The noise-reduction system was a commercial program adding functionality to a DAW, also known as a plug-in. The system operated on the basis of multiband compression and had eight parameters. The first parameter controlled the frequency resolution, reflecting the frame size of the fast Fourier transform. The second and third parameters controlled the user's estimates of the noise threshold and signal level, respectively. These parameters were combined with an automated noise estimation procedure that measured changes in magnitudes and phases over time in order to find a time-varying noise threshold for each frequency band. The time constant for the noise estimate was approximately 2 s. A fourth parameter allowed fine-tuning of the estimated noise floor by a common over- or underestimation factor.

Once a decision had been made as to which components in a frame and subband were noise, a fifth parameter specified the maximum attenuation applied to these components. The smoothness of the noise reduction was controlled by the sixth and seventh parameters, specifying the rate at which noise was reduced over time and across frequencies, respectively. The final, eighth, parameter activated additional smoothing of the noise estimation over time.

We judged that the parameters controlling the maximum noise attenuation and the one controlling the noise threshold (excluding the fine-tuning) gave the most audible differences. In addition, their adjustments were particularly recommended in the system's user manual. Consequently, the fifth and second parameters were chosen as targets in our experiments, and are here labeled X and Y, respectively. X could be changed between 0 and 40 dB; possible values of Y ranged from 0% to 100%. All other parameters were fixed to their default values. This reduced the complexity of the experts' task and of the problem space encountered in the subsequent experiments. The fast Fourier transform frame size was set to 512 points. The fine-tuning of the noise threshold and signal level were fixed at 2 and 2.5 dB, respectively. Spectral and temporal smoothing were set at 100 Hz and 140 ms per 60 dB, respectively. Additional smoothing of the noise estimation was always switched on.

Stimuli were generated using MATLAB release 2008a with a 16-kHz sampling rate and 16-bit depth. During the experiment, stimuli were presented diotically over Sennheiser HDA200 headphones connected to an RME Fireface 800 D/A converter.

Each stimulus consisted of three concatenated Institute of Electrical and Electronics Engineers (IEEE) sentences (Rothauser et al., 1969; Smith &Faulkner, 2006), randomly selected and mixed to random fragments of car-cabin noise (Hilkhuysen, Gaubitch, Brookes, &Huckvale, 2012) or babble (Varga &Steeneken, 1993). The latter noise is a recording of 100 people speaking in a canteen, in which individual voices are slightly audible. For each noise type, five signal-to-noise ratios (SNRs) were used. For car-cabin noise, the SNRs were -21 to -9 dB in 3 dB steps; with babble noise, the SNRs were -12 to 0 dB in 3 dB steps. According to the Speech Intelligibility Index (American National Standards Institute, 1997), the SNRs used for the two noises should give rise to comparable intelligibilities. The five SNRs will be addressed as "very low," "low," "medium," "high," and "very high," independent from the noise type.

After loading a particular stimulus in the DAW, the experts activated the plug-in. Using looped playback, they were asked to set the sliders of X and Y to values that according to their opinions gave optimal intelligibility. Both sliders could be adjusted in real time, that is, experts heard the effect of a change in a parameter as its value was modified. Besides adjusting the two parameters, they were allowed to bypass the noise suppressor and to adjust the presentation level to their liking. Given their expertise, it was assumed that they were able to adjust the stimulus level to optimal intelligibility; these levels were not monitored. Experts could listen to each stimulus as often as they wanted or needed to find proper settings.

Throughout this article, a set of experimental conditions excluding replications will be addressed as the experimental kernel. The five noise levels for each of the two noise types gave rise to an experimental kernel with 10 different experimental conditions. Stimuli within this kernel were presented in random order.

Presentation of the kernel was repeated five times using different sets of sentences. Consequently, each expert provided settings for a total of 50 different stimuli, which took about 3 hr excluding regular breaks.

Results

Figure 1 shows the relation between the settings proposed by all experts for the parameters X and Y in all experimental conditions. Circles and squares denote settings proposed for speech in car-cabin noise and babble, respectively. The size of the markers represents the SNR of the stimulus, with a larger size denoting a higher SNR. Markers are spread along both axes: A wide range on each parameter was used. There appears to be some trade-off between settings: High values for X are never combined with high values for Y. However, at times, experts recommended low values for both. Consequently, the correlation between the settings of X and Y is low ($r = -0.14$, $\rho < .05$). Although significantly different from zero, the correlation was judged to be low enough to inspect each parameter with a separate 5x5x2x5 analysis of variance (ANOVA) for repeated measurements, including the factors Expert χ Repetition χ Noise Type χ SNR.

Among all main effects used to predict X only, the Expert effect attained significance, $F(4, 10.3) = 5.34$, $\rho < .05$. Besides this significant main effect, the following interactions reached statistical significance: Expert χ SNR, ^(16, 8.4) = 3.83, ρ <.05; Repeat χ Noise Type, F{4, 16) = 3.14,77 <.05; and Noise Type χ SNR, F(4, 16) = 3.82,/? <.05. The Expert χ SNR interaction was significant as a result of Expert 4. He proposed settings around 9 dB at very low SNR and substantial higher settings close to 19 dB at all other SNRs. A lower setting at very low SNR was less pronounced for the other experts. The Repeat χ Noise Type interaction was also the result of settings made at very low SNR. At subsequent repetitions of the experimental kernel, X was set to lower values in very low SNR conditions. At the other SNRs, settings varied less across repetitions.

The Noise Type χ SNR interaction is specified in Table 1, showing the mean settings of X for each combination of noise type and SNR, averaged across experts and repetitions. Except for the car-cabin noise at very low SNR, settings of X are close to 13 dB. In an a posteriori Duncan test, we found that only the average setting of 9 dB proposed for the car-cabin noise at very low SNR differed significantly from any other condition except from babble noise at very low SNR. All other paired comparisons were nonsignificant.

The ANOVA predicting Y showed significant main effects only for Expert, $F(4, 4.7) = 6.33$, $\rho < .05$; and SNR, $F(A, 16) = 3.09$, $\rho < .05$. All interactions and other main effects did not attain significance. Table 1 also shows the mean settings of Y for the different levels of SNR averaged across all other factors. The results of an a posteriori Duncan test indicated that only the average setting of 40% at very low SNR differed significantly from other SNRs, except from medium SNR. None of the other paired comparisons attained significance. The average setting for the low to very high SNR equaled 48%.

In the current study, the experimental kernel was repeated five times. Given the significant effects of the Expert and Repeat factors, intra- and interexpert reliabilities were calculated. To address intra expert reliability, a matrix for each expert and parameter was constructed in which the rows and columns indicated the 10 experimental conditions and five sessions, respectively. Matrix entries represented the settings that a particular expert proposed for the corre- sponding experimental condition and repetition. The corre- lation matrices of the repetitions formed the basis of the calculation of standardized Cronbach's alphas. These are displayed in Table 2. Intraexpert reliability was highest for Expert 4, with values of 0.8 and 0.7 on Parameters X and Y, respectively. Experts 1 and 5 showed negative reliabilities on Parameter X. Expert 1 additionally showed a negative reliability with Parameter Y. Such negative reliabilities indicate that the mean correlation between repetitions is negative, for example, for the settings of X supplied by Expert 5, the average correlation equaled -0.13. The 95% confidence intervals, obtained by bootstrapping, include values above 0.7 for Expert 4 on both X and Y and for Expert 5 on Y only. For all other combinations of experts with parameters, these confidence intervals cover values at or below 0.7.

The last row in Table 2 displays the interexpert reliabilities. Calculations were based on matrices with rows and columns representing the 10 experimental conditions and five experts, respectively. Cells contained the mean

setting for each condition and expert averaged across repetitions. The resulting standardized Cronbach's alphas were 0.2 and 0.6 for the settings of X and Y, respectively. The 95% confidence interval of X includes values above 0.7.

Discussion

Settings showed a partial perceptual trade-off between the two parameters. Experts avoided simultaneous high settings on X and Y. All other combinations were proposed. Consequently, the correlation of two parameters remains low, justifying their presence in the plug-in. The low correlation also warrants an independent analysis of the settings.

In general intraexpert reliabilities were poor. Only Experts 4 and 5 reached Cronbach's alphas of 0.7 and above. Lower values are usually interpreted as unacceptable (Nunnally, 1978). The other three experts showed poor intraexpert reliabilities, indicating that their settings for equivalent experimental conditions differed across repetitions. Experts 1, 2, and 5 even showed negative reliabilities, implying that the same experimental condition gave rise to both higher-than-average settings and lower-than-average settings in different repetitions.

One explanation for the low reliabilities could be that optimal settings were independent from the noise types and SNRs used here. The calculation of Cronbach's alpha is based on the assumption that different experimental conditions require different settings to optimize intelligibility. Only then will it be possible to obtain the substantial correlations between repetitions essential for acceptable reliabilities. A possible cause for the poor reliabilities is that changes in settings have little consequence for intelligibility. This will be investigated in Experiments 2 and 3.

Both ANOVAs showed significant effects of expert, indicating that participants held diverse opinions on the best settings. Given the reliability scores, one could question participants' expertise and wonder whether a group of forensic audio engineers or audiologists may have been more consistent. However, the experts included in this study are representative of the group of researchers typically involved in the development of speech enhancement algorithms. Their poor interexpert reliability could indicate that they were uncertain about which settings to propose.

Following classical test theory that forms the basis of the Cronbach's alpha statistic, each setting proposed is the result of a true intended setting plus some random error. Assuming that the random errors are independent and defining "best" in terms of least squared error, the best estimate of the intended setting will be the mean across repetitions and experts. On average, experts opted for different values in some experimental conditions. For both noise types, the mean setting for Y was significantly lower at the very low SNRs (40%) compared with most other SNRs (48%). X was set to a lower value for speech in car-cabin noise at the very low SNR (9 dB) compared with the other SNRs (13 dB). This suggests a preference to apply less noise reduction when intelligibility was very poor, perhaps because experts were trying to preserve the available information in the signal. In Experiment 2, the effects of the mean expert settings on intelligibility were evaluated by observing the performance of naive normal-hearing listeners.

Experiment 2: Performance-Based Intelligibility With Mean Opinion-Based Settings

Method

Participants. Experiment 2 involved 10 listeners. The mean and standard deviation of their ages were 25 and 7 years, respectively. They were recruited from the Psychology Subject Pool of University College London. All had pure- tone hearing thresholds of 20 dB HL or less at octave frequencies ranging from 0.125 to 8 kHz as measured with circumaural headphones (International Organization for Standardization, 2004). All listeners were native speakers of British English, had never participated in intelligibility experiments or been exposed to the speech materials before, and were paid for their efforts.

Materials. In Experiment 2, the DAW and the plug-in were used to generate noise-reduced stimuli. Stimulus presentation and response collection were accomplished with an application written in MATLAB. Stimuli were played back on an RME Fireface 400 D/A converter connected to Sennheiser HDA-200 headphones. The

presentation levels of the stimuli were calibrated using a 0.5-in. microphone (Brüel &Kjier 4192) placed in a 2-cc coupler (Brüel &Kjíer 4153), polarized with a microphone power supply (Brüel &Kjíer 2804) and connected to a spectrum analyzer (Onno Soki cf-350z). Speech and noise materials were equivalent to the ones used in Experiment 1.

Stimuli and design. Looking at signals processed by the plug-in, we found that the noise estimator stabilized after about 2 s. Therefore, while generating a stimulus, we embedded a target sentence into two sentences that were different from the target sentence. This triplet was mixed with a random fragment of noise with duration equal to the duration of the sentence triplet. To create a noise-reduced stimulus, the noise-perturbed triplet was subsequently processed by the commercial noise-reduction plug-in installed on the DAW. This step was omitted for the unprocessed speech condition. In a next step, the first and third sentences in the triplet were deleted. Because the shortest sentence used in this study had a duration of 2.55 s, initial embedding followed by extraction of the target sentence allowed the noise estimator to stabilize before processing of the target sentence.

The noise types and SNRs were equivalent to the ones previously used in Experiment 1. Noise-reduced stimuli were generated with the mean settings determined in Experiment 1. X and Y settings of 13 dB and 48%, respectively, were applied to speech at all SNRs and both noise types. The X value of 13 dB corresponds to the mean proposed setting across all conditions excluding the settings for car-cabin noise at very low SNR. Similarly, the value of 48% for Y corresponds to the mean setting across all conditions excluding the settings proposed for the lowest SNRs. This combination of parameter settings will be referred to as seti3,4S. In Figure 1, these settings are represented by a cross of dashed lines. Many markers are located near the center of this cross, indicating that the experts had proposed similar parameter combinations several times. Because the experts proposed different settings at very low SNRs, two additional experimental conditions were included. For speech in car- cabin noise at a very low SNR, an additional condition with X and Y set at 9 dB and 40%, respectively, was added (seteno). These settings correspond to the mean settings proposed for speech in car-cabin noise at a very low SNR. A cross of dotted lines in Figure 1 marks this parameter combination. For speech in babble at a very low SNR, Y was additionally set at 40%, while the setting for X was kept at 13 dB (seti3,4o). which are the mean settings proposed by the experts for this condition. In Figure 1, this setting is marked by the crossing of the dotted horizontal line with the dashed vertical line. The smallest markers representing lowest SNRs are at times distant from the mean settings. But assuming that the proposed settings contain random errors, these mean settings are the best estimates of the intended settings.

Consequently, the kernel experimental design excluding repetitions had the following 22 conditions: Noise (car, babble) χ SNR (very low, low, medium, high, very high) χ Suppressor (off, seti3,4S) + Noise (car) χ SNR (very low) χ Suppressor (set9,4o) + Noise (babble) χ SNR (very low) χ Suppressor (seti3,4o)· This kernel was repeated 10 times using different sets of sentences from the first 220 IEEE sentences divided into 10 groups of 22 target sentences each. For each listener, target sentences within a group were randomly combined with the experimental conditions. Across listeners, sentence groups were presented according to a Latin square design.

Procedure. Data collection took place in a sound-attenuated booth. Listeners performed two tasks: an intelligibility test and a scoring task. In the intelligibility test, a stimulus was presented diotically over headphones. To ensure that the speech was presented above hearing thresh- olds, we made certain that the naive listeners had no control over the presentation levels. Speech Intelligibility Index calculations predicted that in the absence of noise, the speech presented within the range of 42-78 dB SPL would be fully intelligible to a listener with a flat hearing loss of 20 dB HL. Following these calculations, speech was presented at a constant level of 51 dB SPL, while noise levels varied according to the required SNR. The low level of the speech ensured that even at the lowest SNRs with the highest noise levels, the stimulus was still presented at a comfortable level. After listening to a sentence, participants were asked to repeat it verbatim. Each stimulus was presented only once, and participants were encouraged to guess in the situations where the sentence was not

fully intelligible. Their verbal responses were audio-recorded.

During the scoring task, participants listened to the recorded responses given by previous participants. The first participant listened to recordings obtained in a pilot experiment, and the responses of the last participant were scored by an additional, eleventh, listener who did not perform the intelligibility task. During scoring, the five key words available in each sentence making up the stimuli were displayed on a computer screen, and the response was played back to the participant. Each participant could listen to each response as many times as needed to determine whether it contained the key words. They ticked the correct key words on the computer screen by using a mouse. While scoring, participants could adjust the presentation level to their liking. A particular set of sentences was scored only once it had been presented to the participant as an intelligibility test. Hilkhuysen et al. (2012) found that scoring by normal- hearing participants is as reliable as scoring by experimenters. Full data collection consisting of providing information about the study, taking informed consent, measuring the audiogram, responding to the stimuli, and scoring of the responses usually took about 75 min per participant.

Statistical analysis. To obtain intelligibility measures for various listening conditions, we calculated the base-two logarithm of the ratio of the number of correct and number of incorrect key words. Hilkhuysen et al. (2012) labeled the resulting quantity performance level with units in Berksons (Bk). A one-unit decrease in performance level signifies that for a fixed number of correct key words, the number of incorrect key words has doubled. Using Berksons instead of percentage correct scores gives a more linear relation between intelligibility and SNR. On a percentage scale, psychometric functions are usually S-shaped and exhibit floor and ceiling effects for intelligibilities near 0% and 100%. At these ends, it becomes difficult to detect differences between functions. The linearization allows a better inspection of subtle differences even at the extremes of the percentage scale. Classic linear statistical models, such as ANOVA, are less appropriate for percentage scores because they can predict values outside the 0%-100% word correct range and falsely assume that sample variance is independent from the absolute percentage (Hilkhuysen et al., 2012). Additionally, ANOVAs are inappropriate for unbalanced designs (Max &Onghena, 1999; Quené &Van Den Bergh, 2004), created here by including set9 4o and set 13,40 only at very low SNRs. Multilevel logistic regression as proposed by Goldstein (1995) and Hox (2010) overcomes these limitations. This technique, also known as mixed-effects logistic regression (Agresti, 2007), is a generalization of traditional linear regression. It takes into account the binary character of the data as well as the fact that the same listener provided observations under all experimental conditions.

Results

Figure 2 displays the psychometric functions. To facilitate comparison of performance levels with the more commonly used percentage scale, we display the correspond- ing percentage values on the right axis. The marker for the single condition with seteno coincides with the marker for unprocessed car-cabin noise at -21 dB SNR. The marker representing the measurement with set 13,40 is covered by the marker for intelligibility of speech in babble at -12 dB SNR processed with set 13,4g. Most filled markers are located below the corresponding open markers, suggesting a trend toward deleterious effects of noise reduction with set 13,4s on speech intelligibility.

A plot of performance level versus the repetition number of the kernel experimental design (not shown here) showed an improvement of about 0.5 Bk in performance over the first six repetitions and a decrease of less than 0.1 Bk during the remaining repetitions. To address and compensate for these effects-likely caused by learning-we included in the logistic regression the factor Repeat, representing the repetition number of the kernel experimental design. For this factor, a linear and a quadratic component centered on the sixth repetition were included.

The results of the mixed-effects logistic regressions, one for each noise type, are displayed in Table 3. Row 1 indicates the estimated performance level for unprocessed speech at medium SNR during the sixth repetition of the kernel experiment, with car-cabin noise and babble performance estimated at -0.2 and -0.4 Bk, respectively.

These values do not differ significantly from zero, meaning that the SNRs in the reference condition resulted in performance levels that do not differ significantly from 0 Bk (50%). Rows 2 to 5 indicate the effects of changing the SNR from medium to very low, low, high, and very high levels, respectively, while the other factors remain at their reference levels. Changing the SNR evidently influences intelligibility for both noises: All coefficients differ significantly from zero. Row 6 specifies the effect of applying noise reduction with seti3,4S parameters while all other factors are at reference levels. Although the corresponding coefficients for car-cabin noise and babble are negative, values do not differ significantly from zero. In other words, for speech in noise at medium SNR during the sixth repetition of the kernel, no significant effects of noise reduction on intelligibility were found. Rows 7 to 10 specify the additional effects of noise reduction with seti3,4S at other SNRs. At high SNR, the coefficients of -0.8 and -0.9 Bk for car-cabin noise and babble, respectively, differ significantly from zero. Added to the -0.2 Bk effects of noise reduction observed in the reference condition, the total effect of noise reduction in the high SNR condition is -1.0 Bk for both noise types. At very high SNR in babble, noise reduction also significantly reduced intelligibility by -0.9 Bk. The total effect of noise reduction added to its effect in the reference condition again results in a total performance shift of-1.0 Bk. At very high SNR in car-cabin noise, no significant effect of noise reduction was observed. For both noise types, regression coefficients at the very low and low SNRs do not differ significantly from zero. In summary, noise reduction with seti3, 4S caused significant reductions in intelligibility of 1 Bk at high SNR for both noises and at the very high SNR of babble noise. At all other SNRs, noise reduction had no significant effect on intelligibility.

The experimental design included two additional parameter settings that were applied only at very low SNR. Their effects relative to the effects previously discussed for seti3,4s are specified in Row 11. For speech in car-cabin noise at the very low SNR, changing the settings from seti3,4S to set9,4o gave rise to a nonsignificant increase in performance of 1.2 Bk. For noise-reduced speech in babble at very low SNR, changing seti3,4S to seti3,40 had no effect on intelligibility. Rows 12 and 13 specify the effects of learning. In both noise types, the linear component reached significance, but only with car-cabin noise did the quadratic component attain significance.

Discussion

Noise reduction with the settings proposed by the experts had little effect on intelligibility. For nine out of the 12 conditions, the experts' attempts to enhance the noisy speech had no significant effect. At very low SNRs, their mean settings differed from their settings at other SNRs. However, these different settings had no significant effect on the intelligibility for the naive normal-hearing listeners. From the performances observed with set9,40 and seti3,40, we deduce that the application of noise reduction to speech in car-cabin noise and babble with these settings has no impact on intelligibility.

For three out of 12 conditions, the mean settings proposed by experts deteriorated the intelligibility for our naive normal-hearing listeners. In these cases, noise reduc- tion doubled the number of incorrect words for a fixed number of correct words.

The outcomes of Experiments 1 and 2 are remarkable. At very low SNRs, experts suggested different settings to other SNRs, although there were no significant consequences for intelligibility. At high SNRs in both noise types and at a very high SNR in babble, mean proposed settings that were also proposed by individual experts deteriorated intellig- ibility. One interpretation of this result would be that experts cannot be relied on to choose optimal settings for noise reduction. At least in the conditions where intelligibility deteriorated, experts should have opted for no enhancement. However, one could argue that the experts were instructed to apply noise reduction and that refraining from its application was not a valid response in this task. It could be that they opted for optimal settings in the sense of those that were the least detrimental. This possibility was considered in Experiment 3, where intelligibilities for naive normal-hearing listeners were measured over a broad range of parameter settings. Because the deteriorating effect of noise reduction on intelligibility was observed for both noise types at high SNRs, these levels were specifically tested.

Experiment 3: Performance-Based Intelligibility Across a Broad Range of Settings

Method

Participants. Ten listeners different from those who participated in Experiment 2 were included in Experiment 3. The criteria for inclusion were equivalent to Experiment 2. In Experiment 3, the mean and standard deviation of the listeners' ages was 25 and 5 years, respectively.

Materials, stimuli, design, and procedure. Materials and generation of the stimuli were similar to Experiment 2. Compared with the previous experiment, the number of parameter sets tested was extended. For both parameters of interest, four equally spaced settings were used. X was set to 0, 13, 26, or 39 dB. Values of Y were at 0%, 33%, 66%, or 99%. Each of the four values of X was combined with the four levels of Y, leading to 16 combinations. These will be addressed as setij, with i and j indicating levels of X and Y, respectively. Additionally, the intelligibility of unprocessed speech was measured, giving rise to a total of 17 different types of processing applied, represented by the factor Process. Intelligibility was measured for two noise types: car-cabin noise and babble. To obtain a feasible experimental design, we took measurements only at the high SNR, corresponding to -12 dB SNR for car-cabin noise and -3 dB SNR for babble. The kernel experimental design contained Process (17) χ Noise Type (2), for a total of 34 conditions. As done previously, these conditions were randomized within a listening task using a set of 34 different IEEE sentences. The kernel was presented 10 times using different sets of IEEE sentences.

When the X and Y parameters were both set at high values, the signal level dropped considerably. To prevent masking of the speech by the listeners' hearing thresholds, we raised the presentation level of the stimuli 9 dB compared with Experiment 2, resulting in a level of 60 dB SPL for unprocessed speech. Because all stimuli with a fixed speech level had a high SNR, none of the stimuli were uncomfor- tably loud.

Intelligibility tests were interleaved with scoring tasks. Acquiring informed consent, measuring the participant's audiogram and collecting the data took between 2 and 2.5 hr per participant, including a break halfway through the data collection.

Results

Figure 3 shows the measured intelligibilities expressed in Berksons as functions of Parameter X. Each curve represents measurements at a fixed level of Parameter Y, as labeled on the right of each curve. Figure 3 suggests that when one of the parameters is set at zero, changing the other has little consequence for intelligibility, which is close to that of unprocessed speech. However, when both parameters are set at nonzero values, intelligibility deteriorates when the setting of any one parameter is increased. The significance of these visual impressions was tested in two mixed-effects logistic regressions that included the observations either in car-cabin noise or in babble. Lowest and highest perfor- mance was observed for the first and seventh repetition of the kernel experimental design, respectively, over which range performance increased by 0.5 Bk. To account for eventual learning, we included linear and quadratic components centered on the seventh repetition in the regression equations. Consequently, the models included the following factors: a random Subject factor; Noise Type and Processing as fixed categorical factors; and Repetition as a covariate. The intelligibility of unprocessed speech during the seventh repetition of the kernel experimental design was taken as reference. The main outcomes of the mixed-effects logistic regression are represented in Table 4. The left side describes the results for speech in car-cabin noise at high SNR. Unprocessed noisy speech forms the reference condition. In general, settings with either X or Y set at zero, such as setoo,oo, setoo,33, set00,99, set26,oo, and set395oo, did not result in significant shifts in intelligibility relative to the reference condition. Exceptions are set00,66 and set13 0o· Similar to settings where both parameters had nonzero values, noise reduction with set00,66 and set 13,00 deteriorated intelligibility relative to unprocessed speech. The linear and quadratic components of the Repeat factor did not reach significance; hence, no significant learning occurred.

On the right side of Table 4, effects of different parameter settings for the intelligibility of speech in babble are shown. Again, performance in unprocessed babble at the high SNR forms the reference condition. When both

parameters were set at nonzero values, intelligibility dete- riorated significantly, as previously found with car-cabin noise. But in contrast to the previous findings, set00,66 and set 13,00 had no effects on the intelligibility of speech in babble. No significant learning could be shown, that is, the linear and quadratic components of the Repeat factor did not attain statistical significance.

Discussion

To inspect whether the mean parameter settings proposed by the experts were the least detrimental, we evaluated intelligibility for naive normal-hearing listeners across a broad range of settings and with various parameter combinations. We found that in general, only settings of either X or Y close to zero resulted in intelligibility similar to that of unprocessed speech. When both parameters had values differing much from zero, intelligibility deteriorated. From these results, we conclude that in Experiment 1, our experts did not provide settings that optimized intelligibility. It could be argued that this conclusion is the result of an artifact introduced by averaging individual settings. For example, suppose that some experts always proposed settings of X close to zero, combined with high values for Y, whereas other experts suggested high values of X combined with low values of Y. Then averaging across experts would result in mean settings for X and Y that both have middling values. The outcome of Experiment 3 would then suggest that although individual settings would have little effect on intelligibility, the average settings would be deleterious. This line of thought is further explored in Figure 4.

The contour plots in Figure 4 visualize the shifts in intelligibility for various combinations of settings relative to unprocessed speech. Each contour plot was generated by interpolating the intelligibility for the different settings evaluated in Experiment 3. Two constellations of bold lines indicate the settings for speech in car-cabin noise and babble at high SNR as provided by Experts 2 and 5 in Experiment 1. These experts showed poor intraexpert reliabilities in Table 2. The lines connect the five repetitions to their average setting on X and Y. Each constellation shows that the proposed settings spanned a broad range of values for X as well as for Y. Such unstable behavior contributed to their poor intraexpert reliabilities. However, the deteriorations in intelligibility for the settings proposed during the repetitions are stable within a range of 0.6 Berkson per expert and similar to the effects observed with the settings averaged across experts and repetitions. These findings suggest that poor intraexpert and interexpert reliabilities could be the result of the fact that different combinations of settings have similar intelligibility. Although the two experts caused similar amounts of degradation in intelligibility, they did so with different combinations of settings. Although less pronounced, comparable findings hold for the other three experts. Of the 30 sets of parameters for speech at high SNR as proposed by these three experts in Experiment 1, only five sets resulted in intelligibility shifts of less than -0.5 Bk. Hence, we see little evidence to believe that averaging across repetitions and experts increased the detrimental effects of noise reduction on intelligibility.

General Discussion

The current results suggest that experts are unable to set the parameters of a commercial noise reduction system to values that optimize intelligibility. None of the settings considered in listening tests improved intelligibility, but some settings different from the ones proposed by the experts were less detrimental. Processing with the experts' settings resulted at times in lower intelligibilities for naive normal- hearing listeners than the unprocessed noisy speech. At times, experts proposed settings that reduced intelligibility by more than 1 Bk. From these findings, we conclude that when attempting to improve the intelligibility of noisy speech with noise reduction, experts may actually deteriorate its intelligibility.

This study was designed to investigate whether experts are able to propose settings leading to optimal intelligibility. Explaining why experts sometimes suggest settings that deteriorate intelligibility could be a research goal for a follow-up study. At this point, we can only speculate about the possible causes.

One explanation is that listeners are poor in estimating intelligibility in general. Such an explanation goes against findings by many authors (Beck &Speaks, 1993; Cienkowski &Speaks 2000; Fabry &Van Tasell, 1990;

Magnusson et al., 2001; McDaniel &Cox, 1992; Rankovic &Levy, 1997; Studebaker et al., 1982) that report good abilities, in particular at high SNRs (Cox &McDaniel, 1989; Gray &Speaks, 1978). In the current study, opinions on intelligibility failed specifically at high SNRs. But there are other differences between the current study and previous studies that may account for the difference in outcomes. Whereas in the current study, intelligibility was estimated by experts and measured with naive listeners, in the previously mentioned studies, intelligibility was estimated and measured with the same listeners. Maybe the intelligibilities estimated in those studies were valid only for each individual listener. Different listeners were used in this study because we expect that in most applications of noise reduction, experts are providing settings for others. If it is the case that experts provide nonoptimal settings for naive listeners, we would expect an even stronger effect for noise reduction applied in audiology. Audiologists need to provide hearing aid settings for listeners with diverse hearing impairments and can rely even less on their own hearing. Follow-up studies could focus on parameter settings for noise reduction as available in hearing aids.

Other differences between the current study and previous research concern the method used to obtain the opinions. In most previous studies, listeners had to rate the intelligibility of various stimuli (Beck &Speaks, 1993; Cienkowski &Speaks, 2000; Fabry &Van Tasell, 1990; McDaniel &Cox, 1992; Rankovic &Levy, 1997), reporting good abilities in particular at high SNRs (Cox &McDaniel, 1989; Gray &Speaks, 1978). In other studies (Magnusson et al, 2001; Studebaker et al., 1982), listeners had to select the most intelligible in a paired comparison task. Here the experts had to adjust two sliders to settings that, according to their opinion, led to optimal intelligibility. Possibly they considered only a subset of all possible combinations of X and Y. Although adjusting sliders may be common in most applications of noise reduction, experts may be able to generate more valuable opinions with more formal tasks, such as intelligibility ratings or paired comparisons, as used in previous studies involving opinions.

Given the deleterious effects found, experts appear to use the wrong cues while attempting to optimize intelligibility with noise reduction. We consider speech quality and listening effort as potential fallible cues. At higher SNRs, intelligibility and speech quality improve (Arehart, Kates, Anderson, &Harvey, 2007). Hence, across SNRs, speech quality provides an informative cue to estimate intelligibility. But this cue may fail when used to estimate intelligibility after noise reduction. Outcomes from Hu and Loizou (2007a, 2007b) imply that noise reduction can improve speech quality and deteriorate intelligibility at the same time. Hence, if our experts optimized speech quality in an attempt to improve intelligibility, this could have led to the results found.

Listening effort could make another fallible cue for estimating intelligibility after noise reduction. Effort typically is inversely related with intelligibility. Increasing the SNR of noisy speech diminishes listening effort and augments intelligibility (e.g., Houben, van Doorn-Bierman, &Dreschler, 2013; Howard, Munro, &Plack, 2010). Noise reduction can alter this relation. Sarampalis et al. (2009) found that at a fixed level of intelligibility, noise reduction diminished listening effort. Our experts may have minimized listening effort while attempting to increase intelligibility. Such a strategy may appear legitimate if intelligibility is preserved at least, but such was not the case in the current study. At high SNRs, experts tolerated reductions in performance from 1.7 Bk (76%) down to 0.7 Bk (62%).

Low intra- and interexpert reliabilities revealed that the settings proposed by the experts were unstable. We previously mentioned that if the experimental conditions required similar settings, such poor reliabilities should be expected. From Figure 4, an additional explanation emerges. Curves denoting equal intelligibility suggest that there is not one optimal pair of settings giving the highest intelligibility but that different settings can lead to equivalent intelligibilities. The fact that numerous settings instead of one were optimal may have contributed to the low intra- and interexpert reliabilities.

Lack of expertise may also have contributed to the poor reliabilities. We hold that our experts were representative of those involved in the development of noise-reduction algorithms. They had ample experience in speech audio processing, and all knew that noise reduction tends to decrease intelligibility. Yet our experts suggested

settings that incidentally reduced intelligibility. Outcomes could be different if forensic audio specialists or audiologists had supplied the settings.

The fact that none of the settings seemed to improve intelligibility could be seen as a weakness of this study. Urged to improve intelligibility, our experts may have opted for settings that had at least some perceptual effect. The findings may have been different if the noise-reduction algorithm had settings that improved intelligibility. But in our opinion, the approach taken here fits well to typical applications of noise reduction. We are not aware of guidance that experts can call on to make best use of noise reduction. We think that the findings reported here underline the need for physical intelligibility metrics that predict intelligibility after noise reduction. Various authors (Loizou &Ma, 2011; Taal et al, 2011) have proposed such metrics, but at this moment, it is not clear whether these metrics can be used to optimize the settings of noise-reduction algorithms. A valid metric should be able to reveal the consequences for intelligibility of a noise-reduction system designed to improve speech quality or minimize listening effort. Additionally, such a metric would allow the inspection of a much broader range of listening conditions and parameter settings than feasible in listening experiments. Given the abundance of parameter combina- tions, it may well be possible that contemporary single- microphone noise-reduction algorithms are able to improve intelligibility once provided with settings that are appropriate for a particular listening condition.

Amplitude Rise Time Does Not Cue the /ba/-/wa/ Contrast for Adults or Children

Author: Nittrouer, Susan; Lowenstein, Joanna H; Tarr, Eric.

Abstract: Previous research has demonstrated that children weight the acoustic cues to many phonemic decisions differently than do adults and gradually shift those strategies as they gain language experience. However, that research has focused on spectral and duration cues rather than on amplitude cues. In the current study, the authors examined amplitude rise time (ART; an amplitude cue) and formant rise time (FRT; a spectral cue) in the /ba/-/wa/ manner contrast for adults and children, and related those speech decisions to outcomes of nonspeech discrimination tasks. Twenty adults and 30 children (ages 4-5 years) labeled natural and synthetic speech stimuli manipulated to vary ARTs and FRTs, and discriminated nonspeech analogs that varied only by ART in an AX paradigm. Three primary results were obtained. First, listeners in both age groups based speech labeling judgments on FRT, not on ART. Second, the fundamental frequency of the natural speech samples did not influence labeling judgments. Third, discrimination performance for the nonspeech stimuli did not predict how listeners would perform with the speech stimuli. Even though both adults and children are sensitive to ART, it was not weighted in phonemic judgments by these typical listeners. [PUBLICATION ABSTRACT]

Purpose: Previous research has demonstrated that children weight the acoustic cues to many phonemic decisions differently than do adults and gradually shift those strategies as they gain language experience. However, that research has focused on spectral and duration cues rather than on amplitude cues. In the current study, the authors examined amplitude rise time (ART; an amplitude cue) and formant rise time (FRT; a spectral cue) in the /ba/-/wa/ manner contrast for adults and children, and related those speech decisions to outcomes of

nonspeech discrimination tasks.
Method: Twenty adults and 30 children (ages 4-5 years) labeled natural and synthetic speech stimuli manipulated to vary ARTs and FRTs, and discriminated nonspeech analogs that varied only by ART in an AX paradigm.
Results: Three primary results were obtained. First, listeners in both age groups based speech labeling judgments on FRT, not on ART. Second, the fundamental frequency of the natural speech samples did not influence labeling judgments. Third, discrimination performance for the nonspeech stimuli did not predict how listeners would perform with the speech stimuli.
Conclusion: Even though both adults and children are sensitive to ART, it was not weighted in phonemic judgments by these typical listeners.
Key Words: speech perception, children, adults, amplitude rise time
When a person speaks, the actions of the larynx and vocal tract shape all forms of structure in the resulting speech signal: spectral, temporal, and amplitude. It would seem that all those forms of structure would contribute equally to phonemic decisions, but decades of speech perception research have shown otherwise. Listeners attend to, or weight, the various kinds of structure in the signal differently depending on many factors, including what their first language experience was; what the decision is that needs to be made; and what the other phonetic, syntactic, and lexical properties of the signal are.

Children's Weighting Strategies

Another factor that affects how acoustic structure in the speech signal gets weighted is the age of the listener. For example, it has been found that young children (ages 3-7 years) weight formant transitions more than adults when making judgments about the sibilants /s/ and /J*/ in the syllable-initial position but weight static fricative noises less than adults in these same decisions (Mayo, Scobbie, Hewlett, &Waters, 2003; Nittrouer, 1992; Nittrouer &Miller, 1997; Nittrouer &Studdert-Kennedy, 1987; Siren &Wilcox, 1995). Complementary to those results, research also has found that children weight formant transitions more in decisions concerning the voicing of syllable-final stops, but they weight the duration of the vocalic syllable portion less than adults (Greenlee, 1980; Krause, 1982; Nittrouer, 2004; Wardrip-Fruin &Peach, 1984). Finally, children rely on formant transitions to the same extent as adults in decisions regarding place of articulation for syllable-initial, voiceless stops but are poorer at using the burst or aspiration noise in those decisions (Parnell &Amerman, 1978). In this case, formant transitions are weighted strongly by adults in place decisions regarding stop consonants; thus, there likely is no way for that weighting to be any stronger. In a similar manner, adults weight formant transitions strongly in decisions regarding place for weak fricatives (Harris, 1958), and it has been found that children weight formant transitions in those decisions to a similar extent as adults (Nittrouer, 2002). Taken together, the evidence across these studies reveals that children generally pay more attention to the time-varying spectral structure of formant transitions than do adults and pay less attention to durational cues and static spectral structure. In other words, children's weighting strategies differ from those of adults. These strategies change for children-at least, for those children who are learning language typically-as they gain experience with language, a trend that has been termed the developmental weighting shift (Nittrouer, Manning, &Meyer, 1993).

Researchers have collected evidence supporting the developmental weighting shift largely employing the methods used in studies of categorical perception, but with two acoustic cues varying across stimuli instead of just one. In this type of study, one cue is set to vary in equal-sized acoustic steps along a continuum. In sibilant labeling experiments, for example, researchers have used single-pole noises to model the sibilants, and the center frequencies of those noises have spanned a range from one appropriate for an /J/ noise to one appropriate for an /s/ noise. Each of those noises was then combined with each of two vocalic segments: one with formant transitions appropriate for a syllable-initial /J/ and one with transitions appropriate for a syllable-initial /s/. All stimuli resulting from those combinations were presented to listeners multiple times for labeling, and the proportion of one labeling category was plotted as a function of noise frequency, separately for each

vocalic segment. Outcomes for one such experiment (Nittrouer, 1992) are shown in Figure 1, for adults (top panel) and 3-year-olds (bottom panel). Estimates of the perceptual weighting of the sibilant noises and formant transitions can be gathered from the shapes of the functions and the separation between them: The steeper the functions, the more weight that was assigned to the sibilant noises. The greater the separation between functions, the more weight that was assigned to the formant transitions. One can infer from Figure 1 that children paid less attention to the fricative noises than did adults (the labeling functions are shallower) and paid more attention to formant transitions than did adults (the functions are more separated). This method of collecting data was used in the present study.

Weighting Strategies or Auditory Sensitivity

In spite of the robust evidence supporting the suggestion that children weight acoustic cues to phonemic contrasts differently than do adults, the following question can be asked: Are children simply less sensitive to some acoustic properties in the speech signal than are adults? Perhaps children's weighting strategies actually reflect their underlying auditory capacities; perhaps children make linguistic decisions on the basis of what acoustic structure is most salient to them. That specific question has already been addressed in two studies that tried to relate children's labeling of speech stimuli to their discrimination thresholds for nonspeech analogs of those speech stimuli. One experi- ment compared outcomes for adults and for 3-year-olds (Nittrouer, 1996), and the other compared outcomes for adults and for 5- and 7-year-olds (Nittrouer &Crowther, 1998). Similar results were reported in both cases: Slightly greater acoustic differences were needed between two stimuli in order for children to report that those stimuli were different, but those outcomes could not explain labeling results. One reason was that children's difference limens were greater than those of adults for all acoustic properties examined, even the spectral glides used to model the formant transitions that children so strongly weight in speech perception. In addition, children's difference limens were sufficiently small for each property that it seemed unlikely that sensitivity could be a factor in children's weighting strategies. For example, 5- and 7-year-olds in Nittrouer and Crowther's (1998) experiment had a mean difference limen of 83 Hz, which was larger than the 39 Hz found for adults. However, in the sibilant labeling experiments, step size for the sibilant noises was 200 Hz, so children's sensitivity to the frequency of those noises was considered adequate to dismiss a lack of sensitivity as a possible explanation for their weaker weighting of the noises. Overall, no correspondence was found between the specific properties for which children had diminished sensitivity (compared to adults) and their weighting strategies.

A similar lack of correspondence between auditory sensitivity to acoustic properties and processing of speech signals has been observed for populations other than typically developing children. For example, in several studies, researchers have investigated potential relationships between sensitivity to acoustic properties and recognition of phone- mic segments related to those properties for children with dyslexia (e.g., Bishop, Carlyon, Deeks, &Bishop, 1999; Mody, Studdert-Kennedy, &Brady, 1997; Nittrouer, 1999). None of these studies found a clear connection. A particularly elegant demonstration of this kind of finding was provided by Rosen and Manganari (2001). Those investiga- tors expanded on a report by Wright and colleagues (1997), which showed that children with dyslexia demonstrated enhanced backward masking compared with typically read- ing peers. Using that report as a starting point, Rosen and Manganari were able to replicate the finding of greater backward masking for nonspeech stimuli in teenagers with dyslexia, compared with typically reading peers. However, no evidence was found that the enhanced backward masking deleteriously affected recognition of syllable-initial pho- nemes, as would have been expected if that auditory deficit accounted for the phonological problems of children with dyslexia. Thus, evidence of poor performance on a psy- choacoustic task using nonspeech stimuli could not predict recognition of a phonemic contrast related to that task.

Another line of investigation has consistently failed to find evidence of a link between auditory sensitivity to acoustic properties in the speech signal and the processing of the speech signal itself. Empirical evidence from second- language learners shows that listeners may be sensitive to change in an acoustic property but

nonetheless fail to base phonemic decisions on that property if linguistic experience has not promoted the use of that particular property. For example, Miyawaki et al. (1975) examined sensitivity to third formant glides, which on their own are not heard as speechlike, and labeling of stimuli along a /ja/-to-/la/ continuum, which is based on those third formant glides. Three groups of listeners participated: (a) native English speakers, (b) native Japanese speakers who were experienced second-language users of English, and (c) native Japanese speakers who were inexperienced second-language users of English. Japanese does not have a /ja/ /la/ distinction. The results showed that the Japanese listeners were just as sensitive to the third formant glides as the English speakers, but they did not pay attention to that property when it was integrated into speech signals to the extent that native English speakers did. Consequently, they were unable to label the speech stimuli appropriately. Thus, a disassociation was again demonstrated between auditory sensitivity for an acoustic property and how that property is weighted in speech perception. Some effect of English experience was found, however, suggesting that adults can modify their weighting strategies for speech.

In the current experiment, sensitivity to the acoustic properties manipulated in the speech stimuli was explored to determine whether it can explain patterns of perceptual weighting for those speech stimuli. Although findings regarding how well listeners can discriminate acoustic cues in nonspeech signals generally cannot predict how well those listeners integrate those cues into phonetic decisions, it still must be the case that sensitivity to a cue is a basic requisite for being able to use that cue. As in earlier studies that addressed this question, nonspeech stimuli were used in the current study because it is extremely difficult to assess sensitivity to acoustic cues in speech signals, if speech signals are used. It is a quintessential characteristic of speech perception that once a cue is integrated into a speechlike percept, listeners can no longer isolate that cue for the purpose of judging its auditory qualities (see, e.g., Mann &Liberman, 1983; Remez, Pardo, Piorkowski, &Rubin, 2001).

The Case for Examining the Weighting of Amplitude Cues

The work on developmental shifts in weighting strategies for speech have thus far examined only temporal and spectral cues, but there is good reason to want to explore potential shifts in the weighting of amplitude cues, as well. Cochlear implants provide a veridical representation of amplitude structure in the speech signal, but degraded spectral structure. Thus, it would be useful to examine whether listeners-both adults and children-attend to amplitude structure when it cues a phonemic contrast. In addition, the possibility has been raised that children with reading problems might be poorer at recovering amplitude structure from the speech signal than their normal-hearing peers (Goswami, Fosker, Huss, Mead, &Szucs, 2011; Goswami et al., 2002), sparking further interest in how strongly typically developing children weight amplitude structure in their phonemic decisions. For these reasons, we selected for study a phonological contrast that involves a distinction in the rate of amplitude change-namely, the stop-glide manner contrast of /ba/ versus /wa/.

For both of these syllables, the vocal tract is initially closed (or tightly constricted) at the lips. As the syllable progresses, that lip constriction need only be opened for the syllable to be produced. Rate of change in lip opening is responsible for the acoustic differences between stops and glides, with two properties primarily affected: (a) the rate of formant change and (b) the rate of amplitude change at syllable onset. The first and second formants increase in frequency as the vocal tract is opened, and the overall amplitude of the signal increases. The spectral cue involving formant transitions is different in this case from that examined in earlier studies of developmental shifts in cue weighting because it does not involve variation in direction of change; instead, it involves variation only in rate of change. In earlier studies, the starting or ending frequencies of formant transitions, as well as direction of change, varied across stimuli as a function of consonant place. For /ba/ and /wa/, formant frequencies are similar at syllable onset and steady-state regions, but the time required to move from one to the other differs. Consequently, the nature of the cue is different than in earlier studies, so it is not possible to predict beforehand whether children will weight this cue more, similarly, or less than adults do. Several studies have already examined adults' weight- ing strategies for this manner contrast. For example, Nittrouer and Studdert-Kennedy (1986) manipulated the amplitude rise time (ART) of natural /ba/ and /wa/

syllables such that tokens of each were given the structure of the other while preserving original formant structures. The results showed that adults based their phonemic decisions almost entirely on the rate of formant change; the effect of ART was small. However, there was one confound in using natural speech samples to examine weighting strategies for these syllables that may have influenced outcomes, and that was fundamental frequency (fO): It also differs at syllable onset for these tokens. Because the vocal tract is completely closed prior to the start of a /ba/ syllable, subglottal pressure is greater at voicing onset in these syllables than in /wa/ syllables, where air continues to flow through the narrow lip constriction. As a result, fO is higher in frequency at constriction release in /ba/ than in /wa/. That factor was not controlled in Nittrouer and Studdert-Kennedy's experiment, but it was in a subsequent experiment. Walsh and Diehl (1991) used synthetic speech tokens in which fO remained consistent and replicated Nittrouer and Studdert-Kennedy's findings, thus minimizing the probability that the outcomes of that earlier study were due to differences in fO. Nonetheless, in the current experiment, we examined potential effects of fO by using both natural and synthetic stimuli. In addition, in the current experiment, we made use of new methods of switching gross amplitude envelopes among natural tokens and of imposing envelope structure on synthetic syllables in order to ensure that these envelopes were what they were described to be.

The Current Experiment

In all, the current experiment had three objectives. The first objective was to examine how adults and children weight ART and rate of formant transitions (hereafter referred to as formant rise time [FRT]) in this stop-manner contrast. To meet this objective, we selected adults and children as participants. The second objective of this study was to determine whether fO influences these decisions. We accom- plished this objective by including two kinds of speech stimuli: (a) natural tokens that retained natural variability in fO and (b) synthetic tokens in which fO was held constant across stimuli. The third objective of this study was to measure sensitivity to ART for nonspeech stimuli for the same listeners from whom the phonemic labeling results were obtained in order to evaluate the extent to which auditory sensitivity to this property accounts for the extent to which it is weighted in the stop-glide decision.

Method

Listeners

Participants were 20 adults between 18 and 40 years of age and 30 children ranging in age from 4;3 (years;months) to 5; 11. The mean age of children was 5;2 (SD = 0;7). None of the listeners (or, in the case of children, their parents) reported any history of hearing or speech disorder. All listeners passed hearing screenings consisting of the pure tones of 0.5, 1, 2, 4, and 6 kHz presented at 25 dB HL to each ear separately. Parents of the 4- and 5-year-olds reported that their children were free from significant histories of otitis media, defined as six or more episodes during the first 3 years of life. Children were given the Goldman Fristoe Test of Articulation-Second Edition (Goldman &Fristoe, 2000) and were required to score at or better than the 30th percentile for their age in order to participate. Children's scores ranged from the 30th percentile to greater than the 87th percentile (M = 59, SD = 18). Adult participants were given the Reading subtest of the Wide Range Achievement Test (4th edition; Wilkinson &Robertson, 2006), and all demonstrated better than a 12th grade reading level.

Equipment and Materials

We recorded stimuli using a Shure KSM studio microphone, a Tube MPStudio V3 amplifier, and an Echo Gina 3G digital audio converter, using Adobe Audition software. All testing took place in a soundproof booth, with the computer that controlled stimulus presentation being located in an adjacent room. Hearing was screened with a Welch Allyn TM262 audiometer using TDH-39 headphones. Stimuli were stored on a computer and presented through a Creative Labs Soundblaster card, a Samson headphone amplifier, and AKG-K141 headphones. This system has a flat frequency response and low noise. Custom-written software controlled the presentation of the stimuli. The experimenter recorded responses with a keyboard connected to the computer.

For the labeling tasks, two drawings (on 8" χ 8" cards) were used to represent each response label: for /ba/, a picture of a baby, and for /wa/, a picture of the ocean (water). When introducing these pictures, the experimenter explained to the listener that the pictures were being used to represent the response labels because babies babble by saying /ba/-/ba/ and babies call water /wa/.

For the discrimination tasks, a 4" χ 14" cardboard response card with a line dividing it into two 7-in. halves was used with all listeners during testing. On one half of the card were two black squares, which represented the "same" response choice; on the other half were one black square and one red circle, which represented the "different" response choice. Ten other cardboard cards (4" χ 14", not divided in half) were used for training with children. On six cards were two simple drawings, each of common objects (e.g., hat, flower, ball). On three of these cards, the same object was drawn twice (identical in size and color), and on the other cards, two different objects were drawn. On four cards were two drawings each of simple geometric shapes: two with the same shape in the same color and two with different shapes in different colors. We used these cards to ensure that all children knew the concepts of "same" and "different."

A game board with 10 steps was also used with children. The children moved a marker to the next number on the board after each block of stimuli (10 blocks in each condition). Cartoon pictures were used as reinforcement and were presented on a color monitor after completion of each block of stimuli. A bell sounded while the pictures were being shown and so served as additional reinforcement for responding.

Stimuli

Five sets of stimuli were created: for labeling tasks, one set of natural speech stimuli and two sets of synthetic speech stimuli; for discrimination tasks, two sets of nonspeech stimuli.

Natural speech stinudi. Three types of stimuli were created from recordings of /ba/ and /wa/ syllables: (a) syllables with original, unprocessed temporal envelopes; (b) syllables with temporal envelopes transposed within the same category of syllable (/ba/ or /wa/); and (c) syllables with temporal envelopes switched between the two types of syllable (/ba/ and /wa/).

Recording and measurements. A male speaker was recorded producing 10 tokens each of /ba/ and /wa/ in random order, and these tokens were digitized at a 44.1-kHz sampling rate with 16-bit resolution directly onto a hard drive. Five tokens of each were selected, matching duration as closely as possible. Acoustic measurements were made of each token, using TF32 software (Milenkovic, 2004). For these measurements, the vowel was defined as the whole vocalic portion of the syllable, from the release of closure for /ba/ or the release of constriction for /wa/. Six measurements were made:

1. FO was measured for the first three pitch periods after vowel onset.
2. Fl, F2, and F3 were measured for the first two pitch periods after vowel onset.
3. Fl, F2, and F3 were measured at the start of vowel steady state, defined as the point where F2 no longer rose more than 10 Hz from one pitch period to the next, and was calculated using 26-pole linear predictive coding (LPC) analysis at each pitch period.
4. Vowel duration was measured from vowel onset to the end of the vowel, which was defined as the zero crossing where energy from the formants higher than Fl was fully attenuated.
5. FRT was measured from vowel onset to the start of the vowel steady state.
6. ART was measured, using the following procedure: The amplitude peak of the syllable was found and root-mean-square (RMS) amplitude was calculated over the five pitch periods with the amplitude peak as the center, using WavEd software (Neely &Peters, 1992). RMS was then computed for individual pitch periods preceding the amplitude peak. The first pitch period with an RMS value >80% of the peak value was labeled as the end of the amplitude rise. ART was calculated as the duration between vowel onset and the end of the amplitude rise.

Table 1 lists the values for each of these measures.

Temporal envelope manipulation. Before the gross temporal envelope (GTE) was interchanged (either transposed or switched) between tokens, prevoicing was removed from the /w/ tokens and the burst was removed

from the /b/ tokens to eliminate those as cues for the stop-glide distinction. These tokens are referred to as "unprocessed" in this article. There were three subsequent steps in the process of interchanging the GTE from a model token onto a target token in order to create transposed and switched stimuli.

First, the GTE was removed from the target token so that a new envelope could be applied without interaction from the envelope of that target. A process of pitch period normalization was used in which every individual sample in one pitch period was scaled by the same amount so the maximum amplitude peak across all pitch periods was uniform. To find the individual pitch periods of the target, autocorrelation functions with 40-ms windows starting at the beginning of each pitch period were used, in a three-step process, as follows: First, measuring from the start of one pitch period, the start of the next pitch period was estimated to be between 5.6 and 14.3 ms later, assuming fO to be between 70 and 180 Hz, which is typical for a male speaker. Second, the peak of the autocorrelation function within that window was used to constrain further where the start of the next pitch period would be. Third, the nearest positive-going zero crossing was identified as the exact start. After every pitch period was identified, each was scaled separately.

The second step in the GTE-interchanging process was extracting the GTE from a second, or model, token. Because of variations of fO and utterance length across tokens, there could be no temporal alignment of individual pitch periods in the separate model tokens. Therefore, the GTE from each model token was measured by half-wave, rectifying the original signal and low-pass filtering using a cutoff frequency of 20 Hz.

The third step in the GTE-interchanging process was overlaying the extracted GTE of the model onto the normalized target using a pointwise multiplication. Prior to the multiplication, the longer of the two signals was truncated at the end to match the length of the shorter signal. Because tokens had been selected to be similar in length, truncation involved only a pitch period or two, when necessary. After doing this, we measured the ART of the target with the new envelope using procedures already described to ensure that the envelopes of the transposed or switched tokens matched those of the tokens that served as models. For two tokens, slight deviations were found. In those cases, individual pitch periods were adjusted so the ART of the target matched the model ART precisely.

The transposed stimuli were created in round-robin fashion: /ba/1 was the model imposed on /ba/ 2 as the target, /ba/ 2 was the model imposed on /ba/ 3 as the target, and so forth. The same procedure was used with the /wa/ stimuli. The switched stimuli were created so that /ba/ 1 was the model and /wa/1 was the target and vice versa, /ba/ 2 was the model and /wa/ 2 was the target and vice versa, and so forth.

These manipulations resulted in a total of 30 stimuli of six types: Five unprocessed /ba/ tokens, five transposed /ba/ tokens (with envelopes from different /ba/ tokens), five switched /ba/ tokens (with /wa/ envelopes), five unprocessed /wa/ tokens, five transposed /wa/ tokens (with envelopes from different /wa/ tokens), and five switched /wa/ tokens (with /ba/ envelopes). During every block of testing, two tokens of each type were played, creating blocks of 12 stimuli. Ten blocks were presented. Each time the software selected a token of a particular type to play, it did so randomly, but it did not replace that token into the pool until each token in the pool had been played. This process resulted in each stimulus being played a total of four times during testing, so 20 responses were collected to each type. In all, 120 stimuli were presented (6 types χ 5 tokens χ 4 repetitions).

Synthetic speech stimuli, two sets. Onset and steady- state formant values averaged across the /ba/ and /wa/ tokens were used to determine parameter settings for a nine-step /ba/-/wa/ continuum using a Klatt synthesizer (Sensyn). The tokens were all 370 ms in duration, with an fO of 100 Hz throughout. Starting and steady-state frequencies of the first two formants were the same for all stimuli, even though the time to reach steady-state frequencies varied. Fl started at 450 Hz and rose to 760 Hz at steady state. F2 started at 800 Hz and rose to 1150 Hz at steady state. F3 was kept constant at 2400 Hz. FRT varied along a nine-step continuum from 30 ms to 110 ms, in 10-ms steps.

Controlling ART required that the signals be pro- cessed in MATLAB because there is no way to reliably control amplitude in Klatt-based speech synthesizers. The amplitude of voicing (AV) parameter is designed to simulate

the amplitude of the voicing source before the signal is filtered by the vocal tract. However, that parameter interacts with filter parameters (i.e., those associated with formants) such that there is no direct correspondence between the AV setting and signal level at output. In this experiment, AV was set to a constant value of 60, and MATLAB was used to overlay ART after synthesis. The envelope created by MATLAB started at 0 dB and rose to the maximum amplitude at the end of the rise time, which varied along a seven-step continuum from 10 ms to 70 ms in 10-ms steps. Still one more adjustment needed to be made because Sensyn imposes a brief rise time of its own, even if AV is set to be constant across the stimulus. That unavoidable rise time would interact with the envelope created in MATLAB, if not corrected. Thus, an extra 10-ms frame was appended to the start of the file with identical parameters to those of the first frame, and then that frame was deleted from each file after stimuli were created.

The procedures described above were combined to make two sets of stimuli, one that varied in FRT and one that varied in ART. For the FRT stimulus set, the most /ba/-like ART (10 ms) and the most /wa/-like ART (70 ms) were applied to each stimulus along the nine-step /ba/-/wa/ FRT continuum, resulting in 18 FRT stimuli (9 FRTs χ 2 ARTs). For the ART stimulus set, stimuli were created with the most /ba/-like FRT (30 ms) and most /wa/-like FRT (110 ms). Then the seven ARTs were applied to each stimulus, resulting in 14 ART stimuli (2 FRTs χ 7 ARTs). Figure 2 shows synthetic stimuli for which FRT and ART signaled phonemic identity in a consistent manner (top panel) and stimuli for which they were set to signal phonemic identity in a contradictory manner. Inspection of the waveforms confirms that ART was implemented as described. During testing, stimuli were played 10 times each in blocks of however many stimuli there were, so that listeners heard a total of 180 FRT and 140 ART stimuli in two separate conditions.

Nonspeech stimuli for discrimination, two sets. For the discrimination task, two types of stimuli were created: (a) one set that was more speechlike in quality and (b) one set that was not speechlike at all, but nonetheless served as an analogue of the first set. As in Miyawaki et al.'s (1975) study, it was considered possible that listeners would be sensitive to ART when it is not heard as part of a speech signal, but fail to attend to it in making the phonemic judgment. Evidence for that position would be obtained if listeners recognized smaller differences in ART with the completely nonspeech signals than they did with the more speechlike signals.

The more speechlike set of stimuli was synthesized with Sensyn, using steady-state formants. The frequencies were 500 Hz for Fl, 1000 Hz for F2, and 1500 Hz for F3. These frequencies are typical values for modeling the resonances of a male vocal tract with a quarter wavelength resonator, although they do not represent any English vowel. The fO was 100 Hz. Total duration was 370 ms. Onset amplitude envelopes (similar to the envelopes used for the other synthetic speech stimuli) were overlaid onto these signals. ART ranged from 0 to 250 ms in 25-ms steps, resulting in 11 stimuli. The other set of stimuli consisted of sine waves synthesized using TONE (Tice &Carrell, 1997), with the same duration, formant frequencies, and ARTs as the formant stimuli, resulting in 11 stimuli. The stimulus with the 0-ms ART was always the standard (A), and every stimulus (including the standard) was played as the comparison (X). During testing, each stimulus was compared to the standard 10 times, so that listeners heard a total of 110 formant stimuli and 110 sine wave stimuli.

Summary. Five sets of stimuli were presented in this experiment, in five separate tasks: one labeling task with natural speech stimuli, two labeling tasks with synthetic speech stimuli (FRT and ART), and two discrimination tasks (one with formant stimuli and one with sine wave stimuli).

Procedure

All procedures were approved by the The Ohio State University Institutional Review Board. Adults were tested in a single session of 45 min, and 4- and 5-year-olds were tested in two sessions of 45 min each over 2 days. The screening procedures (hearing screening and the Wide Range Achievement Test or Goldman Fristoe Test of Articulation) were administered first. The five test conditions were ordered so that one of the synthetic /ba/-/wa/ labeling tasks was first, followed by one of the discrimination tasks. The labeling task with the natural /ba/-/wa/ stimuli was always presented third, followed by the other discrimination task and, finally, the other synthetic

/ba/-/wa/ labeling task. As a result, there were four possible orders of presentation. Adults completed all tasks in the single session, and children completed the first three tasks in the first session and the last two tasks in the second session.

Labeling tasks. For the /ba/-/wa/ labeling tasks, the experimenter introduced each picture separately and told the listener the name of the syllable associated with that picture. Ten live-voice practice trials were presented in which the listener pointed to the picture and named it after the experimenter said a syllable (five times for each syllable). Having listeners both point to the picture and say the syllable ensured that they were correctly associating the syllable and the picture. Then the listener heard the five unprocessed exemplars of /ba/ and /wa/ over headphones and was instructed to respond in the same way. Listeners were required to respond to nine of the 10 exemplars correctly to proceed to testing. For synthetic /ba/-/wa/ stimuli, training was also provided for the endpoints corresponding to the most /ba/-like (30 ms FRT, 10 ms ART) and /wa/-like (110 ms FRT, 70 ms ART) stimuli. Listeners heard five presentations of each endpoint and had to respond to nine out of the 10 correctly in order to proceed to testing. Feedback was provided for up to two rounds of training, and then listeners were given up to two rounds without feedback to reach criterion. If listeners were not able to respond to nine of 10 endpoints correctly by the third round, testing for that condition was not done. During testing in each of the three stimulus conditions, listeners needed to respond with 80% or better accuracy to the endpoints in order to have their data included in the analysis.

Different dependent measures were analyzed for the natural and synthetic stimuli. For natural stimuli, the percentage of stimuli of each type given the label of the original (target) syllable served as the dependent variable. Arcsine transformations were used for statistical analysis because results were close to 100%. For synthetic stimuli, the plan was to use each listener's labeling responses to construct cumulative normal distributions of the proportion of /wa/ responses across each continuum. Lines could then be fit using probit analysis (Finney, 1971). From these probit functions, slopes and distribution means (i.e., phoneme boundaries) can be computed. These procedures were followed for the FRT continua, which showed typical distributions. However, responses to the ART continua did not show the usual cumulative normal distributions. Thus, instead of fitting probit functions, the percentage of /wa/ responses across each continuum served as the dependent variables.

Discrimination tasks. For the discrimination tasks, an AX procedure was used. In this procedure, listeners compare a stimulus, which varies across trials (X), with a constant standard (A). For both the sine wave and formant stimuli, the A stimulus was the one with a 0-ms ART. The interstimulus interval between standard and comparison was 450 ms. The listener responded by (a) pointing to the picture of the two black squares and saying "same" if he or she judged the stimuli as being the same or (b) pointing to the picture of the black square and the red circle and saying "different" if he or she judged the stimuli as being different. Both pointing and verbal responses were used because each served as a check on the reliability of the other.

Before any testing with the acoustic stimuli was done with children, they were shown the drawings of the six same and different objects and were asked to report whether the two objects on each card were the same or different. Then they were shown the cards with drawings of same and different geometric shapes and were asked to report whether the two shapes were the same or different. Finally, children were shown the card with the two squares on one side and a circle and a square on the other side and were asked to point to same and to different. Adults were simply shown the card with the two squares on one side and a circle and a square on the other side and were asked to point to same and to different. Before testing with stimuli in each condition, all listeners were presented with five pairs of stimuli that were identical and five pairs of stimuli that were maximally different, in random order. Listeners were asked to report whether the stimuli were the same or different and were given feedback. Next, these same training stimuli were presented, and listeners were asked to report whether they were the same or different, only without feedback. Listeners needed to respond correctly to nine of the 10 training trials without feedback in order to proceed to testing. During testing in each of the two stimulus

conditions, listeners needed to respond correctly to at least 16 of these physically same and maximally different stimuli (80%) to have their data included in the final analysis.

The discrimination functions of each listener formed cumulative normal distributions, and probit functions were fit to these distributions. From these fitted functions, distribution means were calculated and served as difference thresholds. These thresholds were the 50% points on the discrimination functions.

Results

All 20 adults were able to meet the training and testing criteria to have their data included in the study for all five tasks. All 30 children met the inclusion criteria for the labeling task with natural syllables. For the two labeling tasks with synthetic syllables, 27 of the 30 children met the inclusion criteria for the FRT continua, and 29 of the 30 children met the inclusion criteria for the ART continua. The two discrimination tasks were more difficult for children: Only 12 of the 30 children met the inclusion criteria for the formant stimuli. Those 12 and an additional five children met the inclusion criteria for the sine wave stimuli. These attrition rates suggest that young children have difficulty discerning acoustic stimuli that differ only on amplitude structure, and that is especially true if the stimuli are speechlike.

Labeling Task With Natural Stimuli

Figure 3 shows the percentage of original responses for adults and children for the unprocessed, transposed, and switched /ba/ and /wa/ stimuli. Adults and children responded to the unprocessed and transposed stimuli with the original response (/ba/ for /ba/ and /wa/ for /wa/) 99.33% to 100% of the time. The switched /wa/ stimuli (/wa/ with /ba/ envelopes) were also heard as /wa/ nearly all of the time: 100% for adults and 99% for children. Only one child was affected by the change in ART for the switched /wa/ stimuli, hearing 20% of them as /ba/. Switched /ba/ stimuli (/ba/ with /wa/ envelopes) showed many more /wa/ responses, especially from children. Two of the 20 adults (10%) and 13 of the 30 children (43%) responded to switched /ba/ with more than 10% /wa/ responses.

Table 2 shows results from two-way analyses of variance (ANOVAs), with age as the between-subjects factor and stimulus type (unprocessed, transposed, or switched) as the within-subject factor, for /ba/ and /wa/ stimuli separately. For stimuli created from the original /ba/ syllables, the main effects of stimulus type and age were statistically significant, as was the Stimulus Type χ Age interaction. The largest amount of variance was explained by stimulus type (η2 = .39). Because a significant interaction was found, we conducted one-way ANOVAs with age as the factor for each of the three stimulus types separately to locate the source of that interaction. Only switched /ba/ showed a significant effect, F(1, 48) = 9.14, ρ - .004. These statistical findings support the claim that the only natural stimuli that were not labeled entirely according to formant trajectories were the switched /ba/ syllables. Labeling of these stimuli was influenced slightly by ART, and that influence was greater for children than for adults. Stimuli created from the original /wa/ syllables were labeled entirely according to formant trajectories, by adults and children alike.

Labeling Task With Synthetic Stimuli

Figure 4 shows results for the FRT continua (top panel) and the ART continua (bottom panel) for adults (squares, solid lines) and children (circles, dashed lines). Looking first at results for the FRT continua, on the top panel, it appears that adults and children responded similarly. When these labeling functions are compared with those in Figure 1, which is reprinted from a sibilant-vowel study, responses for both groups resemble those of adults in that earlier study, where functions were steep. This pattern indicates that listeners responded largely on the basis of the cue manipulated along the continuum represented on the x-axis. In this case, that was FRT. However, functions from this experiment were less separated on the basis of the second cue (ART in the current experiment) than were those of the adults in the experiment depicted in Figure 1. This pattern indicates that the second cue in this experiment was not weighted strongly.

To examine results for this FRT continuum more closely, we performed two-way ANOVAs on the slopes and phoneme boundaries, with age and ART as main effects. For slopes, the main effects of age and ART were not

significant, but the Age χ ART interaction was, F(1, 45) = 4.71,/? = .035, η2 = .10. This outcome reflects the fact that adults' labeling functions had similar slopes across ARTs, and children's labeling function for the /wa/ ART had a slope similar to that of adults. However, children's labeling function for the /wa/ ART (filled circles) is slightly shallower, and that likely accounts for the significant interaction. As with natural stimuli, children were slightly affected by the /wa/ ART, even when stimuli had clear /ba/ FRTs. For phoneme boundaries, the effect of ART was significant, F(1, 45) = 17.74,/? <.001, η2 = .28, but neither age nor the Age χ ART interaction was significant. These outcomes mean that listeners responded differently to stimuli with /ba/ and /wo/ ART, but the effect was similar for children and adults. It was not large for either group.

The results for the ART continua (see bottom panel of Figure 4) are striking: Listeners appear to have assigned no weight at all to ART when the formants were /wa/-like (filled symbols). Adults also did not weight ART strongly when the formants were /ba/-like (open symbols), but children did, to a small degree. About 25% of the stimuli with /ba/ FRT and the longest ART were labeled as /wa/ by children. This matches the result found for natural tokens, where some children labeled some switched /bo/ syllables as /wa/, as well as the result found for the FRT continuum with the /wa/ ART, where children's function was shallower than others because some stimuli at the /ba/ FRT endpoint were labeled as /wa/.

Because responses were all so close to 0% and 100% for these synthetic ART stimuli, it was not possible to compute probit functions. Instead, we computed the percentage of /wa/ responses across all steps on the ART continuum for the /ba/ and /wa/ FRT continua separately. We conducted a two-way ANOVA with age as the between-subject s factor and FRT as the within-subject factor. Arcsine transforms were used. The effect of age was significant, F(1, 47) = 6.87, ρ - .012, η2 = .13, as was the effect of FRT, F(1, 47) = 1,591.26,ρ <.001, η2 = .97. The Age χ FRT interaction was also significant, F(1, 47) = 25.93, ρ <.001, η2 = .36. These results confirm that listeners in both groups weighted FRT heavily in their phonemic decisions and that children showed some small weighting of ART, which adults did not do.

From these labeling results, it is clear that all listeners weighted FRT strongly in their stop-glide decisions. Neither adults nor children weighted ART strongly at all. Of course, the question arises as to whether listeners are sensitive to this acoustic structure or not.

Discrimination Tasks

Figure 5 shows discrimination functions for sine wave (filled symbols) and synthetic (open symbols) stimuli for adults (squares) and children (circles). It appears that both adults and children were sensitive to ART. One striking aspect of these results is that children appear to have been more sensitive to changes in ART than adults, but that impression needs to be tempered by the fact that many children were not able to meet criteria to participate at all, indicating they were not able to judge ART in these nonspeech stimuli. Thus, the children included in the data shown here represent only those children who could perform the task with these stimuli and, on average, they appear to have been slightly more sensitive to ART than were adults.

We performed a two-way ANOVA with age as the between-subjects factor and stimulus type as the within-subject factor on distribution means from adults and the 12 children who met criteria for participation with both types of stimuli. We found that the effect of age was significant, F(1, 30) = 4.95, ρ - .034, η2 = .14, as was the effect of stimulus type, F(1, 30) = 48.63, ρ <.001, η2 = .62. The Age χ Stimulus type interaction was not significant. Thus, we can conclude that listeners were more sensitive to ART for sine wave stimuli than for formant stimuli, the more speechlike sounds. The children who met criteria for participating with these nonspeech stimuli were more sensitive to ART than were adults.

Finally, we compared labeling results for children who could and could not meet criteria to participate in the discrimination tasks with nonspeech stimuli to determine whether there were any differences in speech labeling between these groups. We conducted two-way ANOVAs on dependent measures for each set of speech stimuli, with group (children who could or could not meet criteria with the nonspeech stimuli) as the between-subjects factor and stimulus type as the within-subject factor. For no set of speech stimuli was either a

significant effect of group or a Group χ Stimulus type interaction found. Therefore, it may be concluded that children who were unable to perform the discrimination tasks with nonspeech stimuli performed indistinguishably from children who could perform those tasks on speech labeling. Mean scores for the Goldman Fristoe Test of Articulation were also submitted to statistical analysis, and no significant difference was observed.

Discussion

The purpose of this study was to examine the labeling of stimuli differing in manner class (stops vs. glides) by adults and children. This purpose was motivated by three factors: (a) a desire to extend work on developmental changes in perceptual weighting strategies for speech, (b) an interest in constructing a base from which the question can be explored of how listeners with cochlear implants might process the amplitude structure provided by those implants, and (c) suggestions that children with dyslexia might have difficulty processing amplitude structure in the speech signal (Goswami et al., 2002, 2011). Three specific objectives were addressed by the current study. The first objective was to examine whether adults and young children differ in terms of how they weight the acoustic cues to the stop-glide contrast. Outcomes revealed that adults and children alike based their decisions about whether syllables started with stops or glides almost entirely on the rate of formant change. That similarity across age groups matches earlier findings showing that when adults heavily weight formant transitions in phonemic decisions, children demonstrate the same strategies. In general, children weight formant transitions strongly in phonemic decisions, so when adults do the same, their strategies match. However, earlier findings exploring age- related changes in weighting strategies for speech signals typically involved phonemic contrasts in which the direction of formant transitions differed across categories. The current experiment extends those findings by revealing that when the primary acoustic difference is rate of formant change, adults and children alike weight that property greatly.

One age-related difference was observed, however- and that happened when the cues conflicted, as was the case for switched /ba/ syllables. In that case, adults were able to attend to the formant cue only. Children, on the other hand, were slightly affected in their labeling decisions by ART. The suggestion has previously been made that children are obliged to integrate acoustic structure for speech signals, even when that structure provides conflicting information about phonemic identity (Nittrouer &Crowther, 2001). That suggestion may explain outcomes for this current study because the children were deleteriously affected when rate of formant transition and rate of amplitude change cued different phonemic decisions. Even at that, however, the effect was found only if the rate of formant change was rapid; it was not found for the switched /wa/ syllables, where the rate of formant change was gradual. In any event, responses of listeners in both age groups were overwhelmingly based on the rate of formant frequency change.

The second objective of the current study was to determine whether fO in natural stimuli might be used by listeners in making decisions about this manner contrast. This objective was accomplished by using both natural, modified stimuli in which fO retained its original value and synthetic stimuli that shared a consistent fO. Response patterns matched for the two types of stimuli, so no evidence was found to indicate that listeners give any weight at all to fO in this particular phonemic decision.

The third objective was to determine whether sensi- tivity to the acoustic property of ART, as measured for nonspeech sounds, could explain the extent to which listeners weight that property in making the stop-glide distinction. A disassociation between sensitivity and weighting of acoustic properties has been observed in experiments with adults who are second-language learners and in experiments with children. In the current experiment, a similar disassociation was observed: Adults and children-at least, the children who were able to perform the task-showed mean dis- crimination thresholds of less than 50 ms, so they were highly sensitive to variation in ART, yet they did not use this acoustic property in their phonemic decisions. Thus, further evidence was found to support the position that measured sensitivity to acoustic properties reveals little about the role that those properties may play in phonemic decisions. Here, as elsewhere, evidence of separate organi-

zational strategies for speech and nonspeech stimuli is seen. Both kinds of signals require some perceptual organization of sensory elements, but the extent to which that organiza- tion is explained by primitive versus schema-based principles varies for speech and nonspeech signals (Bregman, 1990; Remez, 2008). Furthermore, the specific schémas under- lying perception differ for speech and nonspeech signals (Nittrouer &Tarr, 2011; Remez, Rubin, Berns, Pardo, &Lang, 1994). As a result, the ability to make decisions about the auditory qualities of nonspeech signals predicts little about how the properties of those signals will be used in the perception of speech. In the current study, even more evidence of the disassociation between the perception of nonspeech and speech signals is provided by the fact that the children who could not perform the discrimination task with nonspeech signals showed the same outcomes in their labeling of speech stimuli as the children who could perform the discrimination task. Thus, it may be concluded that a demonstration that a specific property is used in speech perception predicts little about whether listeners will necessarily be able to judge its auditory qualities when it is presented in a nonspeech context.

In sum, the current experiment demonstrates that neither adults nor children use ART in making decisions about whether they heard /ba/ or /wa/. Instead, these listeners weighted FRT strongly in making this decision. Although formant transitions specify this manner distinction differently from the way formant transitions specify place of consonant constrictions (i.e., rate of change vs. direction/ extent of change), it should perhaps not be surprising that adults and children weighted the cue similarly. In either case, formant transitions involve the relatively slowly modulating changes of vocal tract resonances. Evidence from experi- ments with sine wave speech has revealed that adults and children are comparable in their abilities to comprehend those signals, which replicate the slowly modulating changes of vocal tract resonances (Nittrouer &Lowenstein, 2010; Nittrouer, Lowenstein, &Packer, 2009). This evidence is complementary to the idea that it is precisely formant transitions that first capture children's attention when perceiving speech (e.g., Nittrouer, 2006). According to this account, children's perceptual attention gradually shifts away from being highly and almost singly focused on formant transitions in the speech signal and starts to incorporate other phonemically informative kinds of acoustic structure. Where children with dyslexia are concerned, several studies have demonstrated that they depend even more than age- matched control subjects on formant transitions in making phonemic judgments (Boada &Pennington, 2006; Johnson, Pennington, Lowenstein, &Nittrouer, 2011). That outcome is reflected in the results of Goswami et al. (2011), who found that the children with dyslexia placed their /ba/-/wa/ phoneme boundaries at briefer FRTs than did children who read typically. The common interpretation of this sort of finding is that children with dyslexia are delayed in shifting their perceptual weight away from formant transitions and toward other kinds of acoustic structure (see, e.g., Boada &Pennington, 2006; Nittrouer, 1999).

Of course, finding that samples of some listener populations fail to weight ART in making decisions regarding this manner contrast does not necessarily mean that all other populations of listeners will similarly disregard it. The current study demonstrates that adults and children with age-appropriate speech perception failed to attend to ART, and research by Goswami and colleagues (2011) showed that children with dyslexia do not attend to this property either. However, there is one other population of listeners for whom the question needs to be explored of how well amplitude structure supports phonemic decisions: listeners with cochlear implants. The processing strategies of cochlear implants affect the quality of the signal properties delivered. Where formants are concerned, change over time is represented only when frequencies cross channels, so small changes in formant frequencies are missing. Because children typically depend so strongly on the time-varying spectral structure of the speech signal, it is important to determine how well they might be able to use amplitude structure instead when spectral structure is impoverished in this way. Cross-linguistic studies of weighting strategies have revealed that listeners depend on acoustic cues that are most relevant in their native language. For example, adults whose native language is English rely on the length of the vocalic portion before vocal tract closure in decisions regarding the voicing of final obstruents (Chen, 1970; Peterson &Lehiste, 1960; Raphael, 1972). However, listeners whose native language either does not include syllable-final obstruents or does not

make a length distinction based on voicing fail to weight this acoustic property strongly (Crowther &Mann, 1992, 1994; Flege &Wang, 1989). Nonetheless, individuals can modify their weighting strategies as they gain experience with a new, second language (Miyawaki et al, 1975). Thus, the hypotheses could be posed that perhaps adults who receive cochlear implants modify existing weighting strategies once they get those implants, and perhaps children with implants develop strategies that involve weighting ART strongly. Future investigations will need to explore those hypotheses.

In summary, the current study was undertaken to reexamine the acoustic and perceptual bases of labeling decisions for stimuli differing according to a stop-glide manner distinction. The results showed that adults and children alike based these decisions on the rate of formant frequency change, and hardly at all on ART.

A WRITER SEEKS SILENCE IN A NOISY WORLD.

THE CITY'S ROAR

On many visits to Manhattan, I have found myself poking around the city trying to find a moment of quiet. Once I located a hint of it in Central Park during a windless, late-night snowfall. There I stood absolutely still in the lemon glow of the city, a sky full of snow. The city still roared from all sides, a thousand noises combined into one. I counted that distant, mild roar as quiet. It was a welcome relief from the more pressing noises of the daytime city.

During the day, though, heavy traffic tends to run around 85 decibels (dB). Eight straight hours of that noise level could permanently bend the hairs that carry sound through your inner ear. The average subway ride comes to around 112 dB, somewhere between a shouted conversation and a power saw going off near your head.

An audiology researcher in Berkeley, California, tested the sound of his local transit system and found that sound levels were as high as those at a rock concert (around 120 dB). On top ofthat, he noted, many passengers were wearing earbuds. By listening to music loud enough to cover the outside noise, they were going far past the limits on volume and time-exposure that lead to permanent damage and hearing loss.

Hearing is something that, once lost, people cannot get back. Each ear contains about 17,000 "hair cells" that turn vibrations into signals to the brain. Too much noise causes permanent damage to these hairs.

Because of the loud world Americans live in, hearing loss has become an epidemic in the United States. A 2012 study at Johns Hopkins University found that one in three adults has trouble hearing. Loud music, loud workplaces, and loud living environments are all part of the problem. Hearing loss is reported in 8.5 percent of people in their 20s and 17 percent of those in their 30s.

But when it comes to health problems caused by sound, hearing loss is only the tip of the iceberg. Scientists have found that rats that hear a frequent buzzer sound for weeks on end develop high blood pressure. Even after five weeks of buzzing, these rats are still darting back and forth across their cages, while rats in quieter cages have lower blood pressure and don't pace so nervously.

For humans, six hours of exposure to 90-decibel sound significantly raises the heart rate - and leaves it there for up to an hour after the noise is gone. Many studies have found a link between noise exposure and heart attack risk. In 2005 research in Berlin hospitals revealed that people living in loud environments are at a 50 percent greater risk of having a heart attack.

Among school kids, noise may make it harder to learn. In a 2005 study, researchers from the University of London tested children in 89 schools and concluded that kids who are exposed to high levels of aircraft noise have delayed reading skills.

Lorraine Maxwell, a sound researcher at Cornell University, says, "When children are in schools or housing situations where airplanes take off every 30 seconds or truck traffic is going by, those kids are constantly subjected to noise [that] neither they nor their teacher nor their parents can control. For them, long-term memory is interrupted. They stop paying attention. It requires too much energy. We call it cognitive fatigue."

Maxwell has been looking at classrooms for decades, and she believes that learning problems and physical illnesses are tied directly to noise. "We see children's blood pressure rising over time," Maxwell says. "When they are removed from that environment, or if the airport changes its flight pattern, then they recover."

THE COCKTAIL PARTY

Noisiness is subjective - in other words, it's a matter of opinion. It's a combination of decibels, tone, pitch, and annoyance. It ranges from the piercing warning of heavy machinery to a mouse pattering through the wall behind your head when you are trying to sleep. Noise is simply what you do not want to hear.

Quiet - although you can define it as little or no noise - is subjective too.

I was in New York, looking for what I thought was the perfect quiet: no clanking or roaring. I finally chose a rainy Sunday morning on Wall Street, figuring there would be no traffic and no noise. Just to get there, though, I had to hop on a train that was like sticking my head inside a bullhorn. The ride took 20 minutes. After just 10 more

minutes at 110 dB, I would have been at the limits that make the Occupational Safety and Health Administration warn, YOU'RE GOING DEAF!

I got off at an empty station. It was about five o'clock in the morning; there was not a soul to be seen. The train rumbled away, its mechanical racket replaced by a buzz of electricity from the fluorescent lights and tubes in the ceiling.

When clicks and squeals from the next train began coming down the tracks, I pushed my way out through the turnstiles and took the stairs into an early morning rain. There were no cars, no people, just the buildings standing tall and gray. The only sound was a steady fizz of rain on the street. The average rainfall comes in at 50 dB, a volume you could listen to forever without damage or distraction. Relieved by the sound, I snapped open my umbrella and walked into the thin, wet light of dawn.

We often think hearing is less important than sight. But in fact we are hearing just as much as we are seeing, if not more. We just don't always know it.

"Why do we need hearing when we've got vision?" asks Bill Yost, a psychoacoustic researcher at Arizona State University. "If you talk to people who are [born] blind and deaf - never heard or never saw in their lives - and ask them if they could have a sense they would like restored, they usually say hearing."

What the deaf are missing is an "auditory scene," something the hearing brain is constantly paying attention to. With hearing alone, you can tell how far away a garbage truck is, or how close you are to someone who's speaking. Picking up on sound reflections, you can actually listen to shapes and sizes, and whether a space is open or closed.

Your ear turns a flood of incoming sound into a coded message that travels through nerve cells to the brain. Then the brain analyzes this code to create a sound picture of the environment. First, the twists and turns of the outer ear magnify the sound's qualities, setting off the miniature tuning forks of the inner-ear bones. Sound then flows across hair cells in the inner ear like wind through tall grass, and the brain reads this wind. In a way, you see the air with your ears.

The human ear can tell apart 1,500 different pitches. The cells that move information from the ears into the brain are the fastest in the body, making hearing the most real-time sense we have.

Yost says, "The auditory system is always computing information, because what I said just a second ago is gone, so the brain has got to keep track of that over time."

When we throw our sensitive, attentive ears into a loud, modern environment, the result can be maddening. You might think you are tuning out most noise, but the simple fact is you are not. "There's the cocktail party effect," Yost says. "You want to [pay attention] to one voice, but it's difficult because of all the other sounds being generated."

"Listening is not the same as hearing," Yost says. "We get lots of information traveling through the auditory nervous system, but whether we are paying attention to it, listening to it - there's a whole other issue."

THE ANECHOIC CHAMBER

I searched for quiet places from city to city, but kept finding noise. I visited an elevator in Minneapolis (ominous motor sound) and dry sewage tunnels under Tucson (street sounds muffled through manhole covers). It seemed no matter where I went, quiet always came with a "but": quiet but for jet noise, quiet but for a refrigerator hum, quiet but for a distant motor.

I wondered if I would ever find such a thing as silence - not just a lack of noise, but a complete absence of sound. Eventually I arrived at what's called an anechoic ("ann-eh-KO-ick") chamber in the basement of a building at the University of California, Berkeley.

This soundless chamber is overseen by a retired audiologist named Erv Hafter, who took me inside. Hafter carefully explained that an anechoic chamber is not an infinitely silent place. As far as he knows, no such thing exists on Earth. He said there are movements in the ground, vibrations, jackhammers, even distant earthquakes.

The room, covered top to bottom and side to side with foam-core filters, absorbed all noise except for what was aimed directly at me - in this case, Hafter's voice. I could not stop staring at his mouth as he talked. It was as if he were speaking down a tube. I could hear his spit. Between words came a brief and eerie deadness.
Hafter went to the large airlock door. "I'll just shut you in. Take as much time as you need." He closed the door, and I stood in silence, listening for earthquakes in China.
Used for sound experiments, the chamber is lined with speakers and trunks of electrical cables. The floor is a springy net of wire. The wires strained, sounding like violin strings under my feet as I slowly paced the room's edges. Without the usual sound waves bouncing this way and that, I could not hear where I was. My ears were fighting with my other senses: my eyes said I was in a closed space, but my ears said I was floating in an infinite emptiness.
An audiologist doing sound research with babies once told me anechoic chambers always make them cry. He said, "You have a perfectly quiet, normal 10-monthold, happy as álark, maybe even half asleep; you bring them into an anechoic chamber, and they go berserk."
I pulled the chains on four light bulbs, plunging the room into total darkness. It felt like my senses were suddenly cut off, a sensation that would have driven a 10-month-old stark raving mad.
With my vision taken away, I focused on what I could hear, which at first was nothing. The tiny bones in my ears relaxed. I began to hear the soft thrum of my heart. Then came a fainter noise, a hiss. It was not as sharp as the ringing in some people's ears called tinnitus, which is the result of damaged hearing. I thought it was an air duct, but no air comes or goes from an anechoic chamber.
I tilted my head one way and the other, trying to fix on the sound's location. I realized it was in my head. It was, I believe, the sound of blood flow echoing through my skull, like sand pouring across velvet.
I lasted 45 minutes. Then I pulled the chain on each light, popped open the heavy door, and emerged. I took an elevator up, pushed through the outside doors, and stepped onto campus as if coming up for air. It was like getting my senses back, the relief of jet noise and thousands of bustling students.
THE SOUND OF SILENCE
It takes technology to make the quiet of an anechoic chamber. Not even the bottom of a cave is as quiet. This is also the kind of silence that noise-canceling headphones are aiming for.
Walk through an airport, and you will notice people wearing these devices to find their own slice of silence, like portable anechoic chambers. Noise-canceling headphones work by picking up the frequencies of outside sounds and emitting different sound waves that cancel out those frequencies. They essentially put a dome around your head so that you don't have to turn up your music so loud it leaves your ears ringing.
But is masking all outside sounds really the answer to our noisy world? Brent Edwards, head of research for Starkey Laboratories, the largest hearing-aid company in the United States, says no. "Your ears are a constant monitoring system for everything around you," Edwards says.
Even working with top technology, Edwards says, he cannot create a device that breaks down sounds into separate parts, or finds their locations, as well as the human ear does.
"I like the fact I cart hear so much going on," he says. "Our cognitive system has built up an alert mechanism from when mankind had to worry about tigers sneaking up on them in the forest. When there is constant sound around you, that kind of indicates that it is not a threat, nothing you need to pay attention to, and you tend to ignore it. You tend not to even know it's there. When it changes, that is when you are alerted."
Still, I wanted silence. I wanted the anechoic chamber but without the chamber. No walls, no ceiling, no airplanes rumbling by at 30,000 feet, no faroff highway noise, no sound.
In the Gran Desierto of Sonora, Mexico, I searched for this next level of quiet. On the west side of the desert, sand dunes stretch across the horizon. The tallest dunes rise 800 feet, like liquid mountains.
At first, it seemed all I could find in these dunes was a bone-scraping wind. It hardly paused, swirling and scribbling across the sand, a never-ending orchestra of sound. After several straight days it became a bit

maddening. My mouth was salted with blowing sand.
Then one night the wind stopped. It was as if the world suddenly held its breath. I left my camp and climbed to the slender crest of a dune, listening to the last breezes snaking away. I was nearly in the center of 4,000 square miles of sand, with an almostfull moon illuminating the dunes. I clapped my hands and listened for an echo. The sand absorbed most of the sound, reflecting just enough so I could hear the clap riding away. I hooted loud, listened to my voice fleeing across the sand.
And then I was still. I listened.
It sounded perfect enough to finally call it a night.

"Notices"
SUMMARY: We have received an application from the U.S. Marine Corps (Marine Corps) requesting an incidental harassment authorization (Authorization) to take marine mammals incidental to various training exercises at Marine Corps Air Station (MCAS) Cherry Point Range Complex, North Carolina for a period of one year.
The Marine Corps' activities are military readiness activities pursuant to the Marine Mammal Protection Act (MMPA), as amended by the National Defense Authorization Act (NDAA) for Fiscal Year 2004. Per the MMPA, we are requesting comments on our proposal to issue an authorization to the Marine Corps to incidentally harass by Level B harassment only, bottlenose dolphins (Tursiops truncatus), during the training exercises that would occur within the proposed effective period of May 20, 2013 through May 19, 2014. We are also requesting comments on our intent to promulgate regulations governing the take of marine mammals over a 5-year period incidental to the activities described in this notice.
DATES: Comments and information must be received no later than April 29, 2013.
ADDRESSES: Comments on the application should be addressed to P. Michael Payne, Chief, Permits and Conservation Division, Office of Protected Resources, National Marine Fisheries Service, 1315 East-West Highway, Silver Spring, MD 20910-3225. The mailbox address for providing email comments is ITP.Cody@noaa.gov. Please include 0648-XC486 in the subject line. We are not responsible for email comments sent to addresses other than the one provided here. Comments sent via email, including all attachments, must not exceed a 25-megabyte file size.
Instructions: All submitted comments are a part of the public record and we would post to http://www.nmfs.noaa.gov/pr/permits/incidental.htm#applications without change. All Personal Identifying Information (for example, name, address, etc.) voluntarily submitted by the commenter may be publicly accessible. Do not submit confidential business information or otherwise sensitive or protected information.
To obtain an electronic copy of the application, write to the previously mentioned address, telephone the contact listed here (see FOR FURTHER INFORMATION CONTACT), or visit the internet at: http://www.nmfs.noaa.gov/pr/permits/incidental.htm#applications.
The following associated document is also available at the same internet address: The Marine Corps' Environmental Assessment (EA) titled, "Environmental Assessment MCAS Cherry Point Range Operations," for their federal action of supporting and conducting current and emerging training operations. Their EA evaluates the effects of the proposed training operations on the human environment including impacts to marine mammals and their 2009 Finding of No Significant Impact (FONSI) for the activities.
This notice and the referenced document present detailed information on the scope of our federal action and resultant environmental impacts for purposes of the National Environmental Policy Act of 1969 (NEPA; 42 U.S.C. 4321 et seq.) (i.e., potential impacts to marine mammals from issuing the proposed Authorization including measures for mitigation, and monitoring). We solicit and would consider comments submitted in response to this notice when determining whether to prepare additional NEPA analysis. Documents cited in this notice may also be viewed, by appointment, during regular business hours, at the aforementioned address.
FOR FURTHER INFORMATION CONTACT: Jeannine Cody, Office of Protected Resources, NMFS, (301) 427-8401.
SUPPLEMENTARY INFORMATION:
Background
Section 101(a)(5)(D) of the Marine Mammal Protection Act of 1972, as amended (MMPA; 16 U.S.C. 1361 et seq.) directs the Secretary of Commerce to authorize, upon request, the incidental, but not intentional, taking of small numbers of marine mammals of a species or population stock, by United States citizens who engage in a

specified activity (other than commercial fishing) within a specified geographical region if, after notice of a proposed authorization to the public for review and public comment: (1) We make certain findings; and (2) the taking is limited to harassment.

We shall grant authorization for the incidental taking of small numbers of marine mammals if we find that the taking will have a negligible impact on the species or stock(s), and will not have an unmitigable adverse impact on the availability of the species or stock(s) for subsistence uses (where relevant). The authorization must set forth the permissible methods of taking; other means of effecting the least practicable adverse impact on the species or stock and its habitat; and requirements pertaining to the mitigation, monitoring and reporting of such taking. We have defined "negligible impact" in 50 CFR 216.103 as " * * * an impact resulting from the specified activity that cannot be reasonably expected to, and is not reasonably likely to, adversely affect the species or stock through effects on annual rates of recruitment or survival."

Section 101(a)(5)(D) of the MMPA established an expedited process by which citizens of the United States can apply for an authorization to incidentally take small numbers of marine mammals by harassment. Section 101(a)(5)(D) of the MMPA establishes a 45-day time limit for our review of an application followed by a 30-day public notice and comment period on any proposed authorizations for the incidental harassment of small numbers of marine mammals. Within 45 days of the close of the public comment period, we must either issue or deny the authorization and must publish a notice in the Federal Register within 30 days of our determination to issue or deny the authorization.

The National Defense Authorization Act of 2004 (NDAA; (Public Law 108-136)) amended section 101(a)(5)(A) of the MMPA by removing the small numbers and specified geographic region provisions; revising the definition of harassment as it applies to a military readiness activity; and explicitly requiring that our determination of "least practicable adverse impact" include consideration of: (1) Personnel safety; (2) the practicality of implementation; and (3) impact on the effectiveness of the military readiness activity.

The NDAA's definition of harassment as it applies to a military readiness activity is: (i) any act that injures or has the significant potential to injure a marine mammal or marine mammal stock in the wild [Level A Harassment]; or (ii) any act that disturbs or is likely to disturb a marine mammal or marine mammal stock in the wild by causing disruption of natural behavioral patterns, including, but not limited to, migration, surfacing, nursing, breeding, feeding, or sheltering, to a point where such behavioral patterns are abandoned or significantly altered [Level B Harassment].

Summary of Request

We received a request from the Marine Corps on January 28, 2013, requesting that we issue we issue an Incidental Harassment Authorization (Authorization) for the take, by Level B harassment only, of small numbers of Atlantic bottlenose dolphins (Tursiops truncatus) incidental to air-to-surface and surface-to-surface training exercises conducted around two bombing targets within southern Pamlico Sound, North Carolina, at MCAS Cherry Point. We received a complete and adequate application requesting Authorization on March 19, 2013. To date, we have issued two, 1-year Authorizations to the Marine Corps for the conduct of the same activities from 2010 to 2012 (75 FR 72807, November 26, 2010; 77 FR January 3, 2012). This is the Marine Corps' third request for an Authorization. We intend to proceed to rulemaking after a final determination is made on whether or not to issue this Authorization. This document also serves as Notice of Receipt of a request for rulemaking and subsequent Letter of Authorization.

Project Purpose --The Marine Corps plan to conduct weapon delivery training at two bombing targets: Brant Island Target (BT-9) and Piney Island Bombing Range (BT-11). Training at BT-9 would involve air-to-surface (from aircraft to in-water targets) and surface-to-surface (from vessels to in-water targets) warfare training, including bombing, strafing, special (laser systems) weapons; surface fires using non-explosive and explosive ordnance; and mine laying exercises (inert). Training at BT-11 would involve air- to-surface exercises to provide training in the delivery of conventional (non-explosive) and special (laser systems) weapons. Surface-to-surface

training by small military watercraft would also be executed here. The types of ordnances proposed for use at BT-9 and BT-11 include small arms, large arms, bombs, rockets, missiles, and pyrotechnics. All munitions used at BT-11 are inert, practice rounds. No live firing occurs at BT-11. Training for any activity may occur year-round. Active sonar is not a component of these specified training exercises; therefore, we have not included a discussion of marine mammal harassment from active sonar operations within this notice.

Description of the Specified Activity

The Marine Corps is requesting authorization to harass bottlenose dolphins from ammunition firing conducted at two bombing targets within MCAS Cherry Point. The authorization would be valid for a period of one year from the date of issuance. The bombing targets are located at the convergence of the Neuse River and Pamlico Sound, North Carolina.

BT-9 is a water-based target located approximately 52 kilometers (km) (32.3 miles (mi); 28 nautical miles (nm)) northeast of MCAS Cherry Point. The BT-9 target area ranges in depth from 1.2 to 6.1 meters (m) (3.9 to 20 feet (ft)), with the shallow areas concentrated along the Brandt Island Shoal (which runs down the middle of the restricted area in a northwest to southeast orientation). The target itself consists of three ship hulls grounded on Brant Island Shoals, located approximately 4.8 km (3.0 mi) southeast of Goose Creek Island. Inert (non-explosive) ordnance up to 454 kilograms (kg) (1,000 pounds (lbs) and live (explosive) ordnance up to 45.4 kg (100 lbs) trinitrotoluene (TNT) equivalent, including ordnance released during strafing, are authorized for use at this target range. The target is defined by a 6 statute-mile diameter prohibited area designated by the U.S. Army Corps of Engineers, Wilmington District (33 CFR 334.420). Non-military vessels are not permitted within the prohibited area, which is delineated by large signs located on pilings surrounding the perimeter of the BT. BT-9 also provides a mining exercise area; however, all mine exercises are simulation only and do not involve detonations. BT-9 standard operating procedures limit live ordnance deliveries to a maximum explosive weight of 100 lbs TNT equivalent. The USMC estimates that it could conduct up to approximately 1,554 aircraft-based and 322 vessel-based sorties, annually, at BT-9. The standard sortie consists of two aircraft per bombing run or an average of two and maximum of six vessels.

BT-11 is a 50.6 square kilometers (km^2) (19.5 square miles (mi^2)) complex of land- and water-based targets on Piney Island. The BT-11 target area ranges in depth from 0.3 m (1.0 ft) along the shoreline to 3.1 m (10.1 ft) in the center of Rattan Bay (BA, 2001). The in-water stationary targets of BT-11 consist of a barge and patrol (PT) boat located in roughly the center of Rattan Bay. The barge target is approximately 41.1 by 12.2 m (135 by 40 ft) in dimension. The PT boat is approximately 33.5 by 10.7 ft (110 ft by 35 ft) in dimension. Water depths in the center of Rattan Bay are estimated as 2.4 to 3 m (8 to 10 ft) with bottom depths ranging from 0.3 to 1.5 m (1 to 5 ft) adjacent to the shoreline of Piney Island. A shallow ledge, with substrate expected to be hard-packed to hard bottom, surrounds Piney Island. No live firing occurs at BT-11; all munitions used are inert, non-explosive practice rounds. Only 36 percent of all munitions fired at BT-11 occur over water; the remaining munitions are fired to land based targets on Piney Island. The USMC estimates that it could conduct up to approximately 6,727 aircraft-based and 51 vessel-based sorties, annually, at BT-11.

All inert and live-fire exercises at MCAS Cherry Point ranges are conducted so that all ammunition and other ordnances strike and/or fall on the land or water based target or within the existing danger zones or water restricted areas. A danger zone is a defined water area that is closed to the public on an intermittent or full-time basis for use by military forces for hazardous operations such as target practice and ordnance firing. A water restricted area is a defined water area where public access is prohibited or limited in order to provide security for government property and/or to protect the public from the risks of injury or damage that could occur from the government's use of that area (33 CFR 334.2). Surface danger zones are designated areas of rocket firing, target practice, or other hazardous operations (33 CFR 334.420). The surface danger zone (prohibited area) for BT-9 is a 4.8 km (3.0 mi) radius centered on the south side of Brant Island Shoal. The surface danger zone for BT-11 is a 2.9 km (1.8 mi) radius centered on a barge target in Rattan Bay.

According to the application, the Marine Corps is requesting take of marine mammals incidental to specified activities at MCAS Cherry Point Range Complex, located within Pamlico Sound, North Carolina. These activities include gunnery; mine laying; bombing; or rocket exercises and are classified into two categories here based on delivery method: (1) Surface-to-surface gunnery and (2) air-to-surface bombing. Exercises may occur year round, day or night (approximately 15 percent of training occurs at night).

Surface-to-Surface Gunnery Exercises

Surface-to-surface fires are fires from boats at sea to targets at sea. These can be direct (targets are within sight) or indirect (targets are not within sight). Gunnery exercise employing only direct fire is the only category of surface-to-surface activity currently conducted within the MCAS Cherry Point bombing targets. An average of two and maximum of six small boats (7.3-26.0 m; 24-85 ft), or fleet of boats, typically operated by Special Boat Team personnel, use a machine gun to attack and disable or destroy a surface target that simulates another ship, boat, swimmer, floating mine or near shore land targets. Vessels would travel between 0-20 knots (kts) (0-23 miles per hour (mph)) with an average of two vessels actually conducting surface-to-surface firing activities. Typical munitions would be 7.62 millimeter (mm) or .50 caliber (cal) machine guns; and/or 40 mm grenade machine guns. This exercise is usually a live-fire exercise, but at times blanks would be used so that the boat crews could practice their ship handling skills. The goal of training is to hit the targets; however, some munitions may bounce off the targets and land in the water or miss the target entirely. Additionally, the personnel would use G911 concussion hand grenades (inert and live); however, these are not aimed at targets, as the goal is to learn how to throw them into the water.

Table 1 includes the estimated amount of munitions expended at BT-9 and BT-11 in 2011 and 2012. Historically, boat sorties have been conducted at BT-9 and BT-11 year round with equal distribution of training effort throughout the seasons. Live fires constitute approximately 90 percent of all surface-to-surface gunnery events. The majority of sorties originated and practiced at BT-9 as no live fire is conducted at BT-11. The Marine Corps has indicated a comparable number of sorties would occur throughout the IHA timeframe. There is no specific schedule associated with the use of ranges by the small boat teams. However, exercises tend to be scheduled for 5-day blocks with exercises at various times throughout that timeframe. There is no specific time of year or month training occurs as variables such as deployment status, range availability, and completion of crew specific training requirements influence schedules.

Table_1--Aircraft_and_Boat_Sorties,_by_Mission_Type,_Conducted_in_2011_and_2012				
	BT-9		BT-11	
Mission_type	2011	2012	2011	2012
Air-to-Surface	1,554		4,251	
Surface-to-Surface	223	322	105	106
Total	1,777		4,356	

A number of different types of boats are used during surface-to-surface exercises depending on the unit using the boat and their mission and include versions of Small Unit River Craft, Combat Rubber Raiding Craft, Rigid Hull Inflatable Boats, Patrol Craft. They are inboard or outboard, diesel or gasoline engines with either propeller or water jet propulsion. Boat crews approach, at a maximum of 20 kts (23 mph), and engage targets simulating other boats, swimmers, floating mines, or near shore land targets with 7.62 mm or .50 cal machine guns; 40 mm grenade machine guns; or M3A2 concussion hand grenades (approximately 200, 800, 10, and 10 rounds respectively). Vessels typically travel in linear paths and do not operate erratically. Other vessels may be

located within the BTs; however, these are support craft and do not participate in munitions expenditures. The purpose of the support craft is to remotely control High Speed Maneuvering Surface Targets (HSMSTs) or to conduct maintenance on electronic equipment located in the towers at BT-9. Support craft are typically anchored or tied to marker pilings during HSMST operations or tied to equipment towers. When underway, vessels do not typically travel faster than 12-18 kts (13.8-20.7 mph) or in an erratic manner.

Air-to-Surface

Air-to-surface training involves ordnance delivered from aircraft and aimed at targets on the water's surface or on land in the case of BT-11. We provide a description of the types of targets used at MCAS Cherry Point in the previous section. There are four types of air-to-surface activities conducted within the MCAS Cherry Point BTs: mine laying; bombing, gunnery, or rocket exercises which are carried out via fixed- or rotary-wing aircraft.

Mine Laying Exercises

Mine warfare includes the strategic, operational, and tactical use of mines and mine countermine measures. Mine warfare is divided into two basic subdivisions: (a) The laying of mines to degrade the enemy's capabilities to wage land, air, and maritime warfare, and (b) the countering of enemy-laid mines to permit friendly maneuver or use of selected land or sea areas (DoN, 2007). MCAS Cherry Point would only engage in mine laying exercises as described below in the waters around BT-9. No detonations of any mine device are involved with this training.

During mine laying, a fixed-wing or maritime patrol aircraft (P-3 or P-8) typically drops a series of about four inert mine shapes in an offensive or defensive pattern, making multiple passes along a pre-determined flight azimuth, and dropping one or more shapes each time. Mine simulation shapes include MK76, MK80 series, and BDU practice bombs ranging from 25 to 2,000 pounds in weight. There is an attempt to fly undetected to the area where the mines are laid with either a low or high altitude tactic flight. The shapes are scored for accuracy as they enter the water and the aircrew is later debriefed on their performance. The training shapes are inert (no detonations occur) and expendable.

Bombing Exercises

The purpose of bombing exercises is to train pilots in destroying or disabling enemy ships or boats. During training, fixed wing or rotary wing aircraft deliver bombs against surface maritime targets at BT-9 or BT-11,day or night, using either unguided or precision-guided munitions. Unguided munitions include MK-76 and BDU-45 inert training bombs, and MK-80 series of inert bombs (no cluster munitions authorized). Precision-guided munitions consist of laser-guided bombs (inert) and laser-guided training rounds (inert). Typically, two aircraft approach the target (principally BT-9) from an altitude of approximately 914 m (3,000 ft) up to 4,572 m (15,000 ft) and, when on an established range, the aircraft adhere to designated ingress and egress routes. Typical bomb release altitude is 914 m (3,000 ft) for unguided munitions or above 4,572 m (15,000 ft) and in excess of 1.8 km (1 nm) for precision-guided munitions. However, the lowest minimum altitude for ordnance delivery (inert bombs) would be 152 m (500 ft).

Onboard laser designators or laser designators from a support aircraft or ground support personnel are used to illuminate certified targets for use when using laser guided weapons. Due to target maintenance issues, live bombs have not been dropped at the BT-9 targets for the past few years although these munitions are authorized for use. For the effective IHA timeframe, the Marine Corps would not use live bombs. Live rockets and grenades; however, have been expended at BT-9.

Air-to-surface bombing exercises have the potential to occur on a daily basis. The standard sortie consists of two aircraft per bombing run. The frequency of these exercises is dependent on squadron level training requirements, deployment status, and range availability; therefore, there is no set pattern or specific time of year or month when this training occurs. Normal operating hours for the range are 8 a.m. to 11 p.m., Monday through Friday; however, the range is available for use 365 days per year.

Gunnery Exercises

During gunnery training, fixed- and rotary-wing aircraft expend smaller munitions targeted at the bombing targets with the purpose of hitting them. However, some small arms may land in the water. Rotary wing exercises involve either CH-53, UH-1, CH-46, MV-22, or H-60 rotary-wing aircraft with mounted 7.62 mm or .50 cal machine guns. Each gunner expends approximately 800 rounds of 7.62 mm and 200 rounds of .50 cal ammunition in each exercise. These may be live or inert.

Fixed wing gunnery exercises involve the flight of two aircraft that begin to descend to the target from an altitude of approximately 914 m (3,000 ft) while still several miles away. Within a distance of 1,219 m (4,000 ft) from the target, each aircraft fires a burst of approximately 30 rounds before reaching an altitude of 305 m (1,000 ft), then breaks off and repositions for another strafing run until each aircraft expends its exercise ordnance allowance of approximately 250 rounds. In total, about 8-12 passes are made by each aircraft per exercise. Typically these fixed wing exercise events involve an F/A-18 and AH-1 with Vulcan M61A1/A2, 20 mm cannon; AV-8 with GAU-12, 25 mm cannon.

Rocket Exercises

Rocket exercises are carried out similar to bombing exercises. Fixed- and rotary-wing aircraft crews launch rockets at surface maritime targets, day and night, to train for destroying or disabling enemy ships or boats. These operations employ 2.75-inch and 5-inch rockets. Generally, the average number of rockets delivered per sortie is approximately 14. As with the bombing exercise, there is no set level or pattern of amount of sorties conducted.

Munitions Descriptions

We refer the reader to Tables 2 and 3 for a complete list of the ordnance authorized for use at BT-9 and BT-11, respectively. There are several varieties and net explosive weights (for live munition used at BT-9) can vary according to the variety. All practice bombs are inert and used to simulate the same ballistic properties of service type bombs. They are manufactured as either solid cast metal bodies or thin sheet metal containers. Since practice bombs contain no explosive filler, a practice bomb signal cartridge (smoke) is used for visual observation of weapon target impact. Practice bombs provide a low cost training device for pilot and ground handling crews. Due to the relatively small amount of explosive material in practice bombs (small signal charge), the availability of ranges for training is greatly increased.

When a high explosive detonates, it is converted almost instantly into a gas at very high pressure and temperature. Under the pressure of the gases thus generated, the weapon case expands and breaks into fragments. The air surrounding the casing is compressed and shock (blast) wave is transmitted into it. Typical initial values for a high-explosive weapon are 200 kilobars of pressure (1 bar = 1 atmosphere) and 5,000 degrees Celsius (9,032 degrees Fahrenheit). There are five types of explosive sources used at BT-9: 2.75-inch Rocket High Explosives, 5-inch Rocket High Explosives, 30 mm High Explosives, 40 mm High Explosives, and G911 grenades. No live munitions are used at BT-11.

Description of Marine Mammals in the Area of the Specified Activity

Forty marine mammal species occur within the nearshore and offshore waters of North Carolina; however, the majority of these species are solely oceanic in distribution. Only one marine mammal species, the bottlenose dolphin, has been repeatedly sighted in Pamlico Sound, while an additional species, the endangered West Indian manatee (Trichechus manatus), has been sighted rarely (Lefebvre et al, 2001; DoN 2003). The U.S. Fish and Wildlife Service oversees management of the manatee; therefore, we would not include a proposed authorization to harass manatees and we will not discuss this species further in this notice.

No sightings of the endangered North Atlantic right whale (Eubalaena glacialis) or other large whales have been observed within Pamlico Sound or in vicinity of the bombing targets (Kenney, 2006). No suitable habitat exists for these species in the shallow Pamlico Sound or bombing target vicinity; therefore, whales would not be affected by the specified activities. Thus, we will not discuss them further in this notice. Other dolphins, such as Atlantic spotted (Stenella frontalis) and common dolphins (Delphinus delphis), are oceanic in distribution and do not venture into the shallow, brackish waters of southern Pamlico Sound.

The specified activity has the potential to affect only one marine mammal species under our jurisdiction: the bottlenose dolphin. We refer the public to Waring et al. (2011) for general information on this species which is presented below this section. The publication is available at http://www.nmfs.noaa.gov/pr/pdfs/sars/ao2011.pdf. We present a summary of information on the species below this section.

Bottlenose Dolphin

California sea lions are not listed as threatened or endangered under the Endangered Species Act (ESA; 16 U.S.C. 1531 et seq.), however, they are categorized as depleted (and thus strategic) under the MMPA.

Four out of the seven designated coastal stocks for bottlenose dolphins may occur in North Carolina waters at

some part of the year: the Northern Migratory stock (NM; winter); the Southern Migratory stock (SM; winter); the Northern North Carolina Estuarine stock (NNCE; resident, year round); and the more recently identified Southern North Carolina Estuarine stock (SNCE; resident, year round).

Dolphins encountered at the BTs likely belong to the NNCE and SNCE stock; however, this may not always be the case. NMFS' 2011 stock assessment report provides further detail on stock delineation.

NMFS provides abundance estimates for the four aforementioned migratory and resident coastal stocks in its 2011 stock assessment report. The best available abundance estimate for the NNCE stock is the combined abundance from estuarine (Read et al., 2003) and coastal (aerial survey data dating from 2002) waters. This combined estimate is 1,387 (Waring et al., 2011). Similarly, the best available abundance estimate for the SNCE stock is the combined abundance from estuarine and coastal waters. This combined estimate is 2,454 (Waring et al., 2011). The best abundance estimate for the NM stock, resulting from 2002 aerial surveys, is 9,604 (Waring et al., 2011). Using the same information, the resulting best abundance estimate for the SM stock is 12,482 (Waring et al., 2011).

From July 2004 through April 2006, the Services Southeast Fisheries Science Center conducted 41 aerial surveys to document the seasonal distribution and estimated density of sea turtles and dolphins within Core Sound and portions of Pamlico Sound, and coastal waters extending one mile offshore (Goodman et al, 2007). Pamlico Sound was divided into two survey areas: western (encompassing BT-9 and BT-11) and eastern (including Core Sound and the eastern portion of restricted air space R-5306). In total, 281 dolphins were sighted in the western range. To account for animals likely missed during sightings (i.e., those below the surface), Goodman et al. (2007) estimate that, in reality, 415 dolphins were present. Densities for bottlenose dolphins in the western part of Pamlico Sound were calculated to be 0.0272 per square kilometer (km^2) in winter and 0.2158 per km^2 in autumn. Dolphins were sighted throughout the entire range when mean sea surface temperature was 7.60 [degrees] C to 30.82 [degrees] C (45.6 to 87.5 [degrees] F), with fewer dolphins sighted as water temperatures increased. Like in Mayer (2003), dolphins were found in higher numbers around BT-11, a range where no live firing occurs.

In 2000, Duke University Marine Lab (DUML), conducted a boat-based mark-recapture survey throughout the estuaries, bays and sounds of North Carolina (Read et al., 2003). This summer survey yielded a dolphin density of 0.183/km^2 (0.071 mi^2) based on an estimate of 919 dolphins for the northern inshore waters divided by an estimated 5,015 km^2 (1,936 mi^2) survey area. Additionally, from July 2002-June 2003, the USMC supported DUML to conduct dolphin surveys specifically in and around BT-9 and BT-11. During these surveys, one sighting in the restricted area surrounding BT-9 and two sightings in proximity to BT-11 were observed, as well as seven sightings in waters adjacent to the BTs. In total, 276 bottlenose dolphins were sighted ranging in group size from two to 70 animals with mean dolphin density in BT-11 more than twice as large as the density of any of the other areas; however, the daily densities were not significantly different (Maher, 2003). Estimated dolphin density at BT-9 and BT-11 based on these surveys were calculated to be 0.11 dolphins/km^2, and 1.23 dolphins/km^2, respectively, based on boat surveys conducted from July 2002 through June 2003 (excluding April, May, Sept. and Jan.). However, the Marine Corps choose to estimate take of dolphins based on the higher density reported from the summer 2000 surveys (0.183/km^2). Although the aerial surveys were conducted year round and therefore provide for seasonal density estimates, the average year-round density from the aerial surveys is 0.0936, lower than the 0.183/km^2 density chosen to calculate take for purposes of this MMPA authorization. Additionally, Goodman et al. (2007) acknowledged that boat based density estimates may be more accurate than the uncorrected estimates derived from the aerial surveys.

In Pamlico Sound, bottlenose dolphins concentrate in shallow water habitats along shorelines, and few, if any, individuals are present in the central portions of the sounds (Gannon, 2003; Read et al., 2003a, 2003b). The dolphins utilize shallow habitats, such as tributary creeks and the edges of the Neuse River, where the bottom depth is less than 3.5 m (Gannon, 2003). Fine-scale distribution of dolphins seems to relate to the presence of

topography or vertical structure, such as the steeply-sloping bottom near the shore and oyster reefs, which may be used to facilitate prey capture (Gannon, 2003). Results of a passive acoustic monitoring effort conducted from 2006-2007 by Duke University researchers validated this information. Vocalizations of dolphins in the BT-11 vicinity were higher in August and September than vocalization detection at BT-9, an open water area (Read et al., 2007). Additionally, detected vocalizations of dolphins were more frequent at night for the BT-9 area and during early morning hours at BT-11.

Unlike migrating whales which display strong temporal foraging and mating/birthing periods, many bottlenose dolphins in Pamlico Sound are residents and mate year round. However, dolphins in the southeast U.S. do display some reproductive seasonality. Based on neonate stranding records, sighting data, and births by known females, the populations of dolphins that frequent the North Carolina estuarine waters have calving peaks in spring but calving continues throughout the summer and is followed by a smaller number of fall births (Thayer et al., 2003).

Bottlenose dolphins can typically hear within a broad frequency range of 0.04 to 160 kiloHertz (kHz) (Au, 1993; Turl, 1993). Electrophysiological experiments suggest that the bottlenose dolphin brain has a dual analysis system: one specialized for ultrasonic clicks and another for lower-frequency sounds, such as whistles (Ridgway, 2000). Scientists have reported a range of highest sensitivity between 25 and 70 kHz, with peaks in sensitivity at 25 and 50 kHz (Nachtigall et al., 2000). Recent research on the same individuals indicates that auditory thresholds obtained by electrophysiological methods correlate well with those obtained in behavior studies, except at some lower (10 kHz) and higher (80 and 100 kHz) frequencies (Finneran and Houser, 2006).

Sounds emitted by bottlenose dolphins have been classified into two broad categories: pulsed sounds (including clicks and burst-pulses) and narrow-band continuous sounds (whistles), which usually are frequency modulated. Clicks have a dominant frequency range of 110 to 130 kHz and a source level of 218 to 228 decibels (dB) re: 1 [mu]Pa (peak-to-peak) (Au, 1993) and 3.4 to 14.5 kHz at 125 to 173 dB re 1 [mu]Pa (peak-to-peak) (Ketten, 1998). Whistles are primarily associated with communication and can serve to identify specific individuals (i.e., signature whistles) (Caldwell and Caldwell, 1965; Janik et al., 2006). Up to 52 percent of whistles produced by bottlenose dolphin groups with mother-calf pairs can be classified as signature whistles (Cook et al., 2004). Sound production is also influenced by group type (single or multiple individuals), habitat, and behavior (Nowacek, 2005). Bray calls (low-frequency vocalizations; majority of energy below 4 kHz), for example, are used when capturing fish, specifically sea trout (Salmo trutta) and Atlantic salmon (Salmo salar), in some regions (i.e., Moray Firth, Scotland) (Janik, 2000). Additionally, whistle production has been observed to increase while feeding (Acevedo-Gutierrez and Stienessen, 2004; Cook et al., 2004).

Potential Effects on Marine Mammals

As mentioned previously, with respect to military readiness activities, Section 3(18)(B) of the MMPA defines "harassment" as: (i) Any act that injures or has the significant potential to injure a marine mammal or marine mammal stock in the wild [Level A Harassment]; or (ii) any act that disturbs or is likely to disturb a marine mammal or marine mammal stock in the wild by causing disruption of natural behavioral patterns, including, but not limited to, migration, surfacing, nursing, breeding, feeding, or sheltering, to a point where such behavioral patterns are abandoned or significantly altered [Level B Harassment].

The Marine Corps concluded that Level B harassment to marine mammals may occur incidental to munitions firing noise and pressure at the bombing targets. These military readiness activities would result in increased noise levels, explosions, and munitions debris within bottlenose dolphin habitat. In addition, we also considered the potential for harassment from vessel and aircraft operation. Our analysis of potential impacts from these factors, including consideration of the Marine Corps' analysis in its application, is outlined in the following sections.

Anthropogenic Sound

Marine mammals respond to various types of anthropogenic sounds introduced in the ocean environment.

Responses are highly variable and depend on a suite of internal and external factors which in turn results in varying degrees of significance (NRC, 2003; Southall et al., 2007). Internal factors include: (1) Individual hearing sensitivity, activity pattern, and motivational and behavioral state (e.g., feeding, traveling) at the time it receives the stimulus; (2) past exposure of the animal to the noise, which may lead to habituation or sensitization; (3) individual noise tolerance; and (4) demographic factors such as age, sex, and presence of dependent offspring. External factors include: (1) non-acoustic characteristics of the sound source (e.g., if it is moving or stationary); (2) environmental variables (e.g., substrate) which influence sound transmission; and (3) habitat characteristics and location (e.g., open ocean vs. confined area). To determine whether an animal perceives the sound, the received level, frequency, and duration of the sound are compared to ambient noise levels and the species' hearing sensitivity range. That is, if the frequency of an introduced sound is outside of the species' frequency hearing range, it cannot be heard. Similarly, if the frequency is on the upper or lower end of the species hearing range, the sound must be louder in order to be heard.

Marine mammal responses to anthropogenic noise are typically subtle and can include visible and acoustic reactions such as avoidance, altered dive patterns and cessation of pre-exposure activities and vocalization reactions such as increasing or decreasing call rates or shifting call frequency. Responses can also be unobservable, such as stress hormone production and auditory trauma or fatigue. It is not always known how these behavioral and physiological responses relate to significant effects (e.g., long-term effects or individual/population consequences); however, individuals and populations can be monitored to provide some insight into the consequences of exposing marine mammals to noise. For example, Haviland-Howell et al. (2007) compared sighting rates of bottlenose dolphins within the Wilmington, NC stretch of the Atlantic Intracoastal Waterway (ICW) on weekends, when recreational vessel traffic was high, to weekdays, when vessel traffic was relatively minimal. The authors found that dolphins were less often sighted in the ICW during times of increased boat traffic (i.e., on weekends) and theorized that because vessel noise falls within the frequencies of dolphin communication whistles and primary energy of most fish vocalizations, the continuous vessel traffic along that stretch of the ICW could result in social and foraging impacts. However, the extent to which these impacts affect individual health and population structure is unknown.

A full assessment of marine mammal responses and disturbances when exposed to anthropogenic sound can be found in our proposed rulemaking for the Navy Cherry Point Range Complex (74 FR 11057, March 16, 2009). That rulemaking was made final on June 15, 2009 (74 FR 28370). In summary, sound exposure may result in physiological impacts, stress responses, and behavioral responses which could affect proximate or ultimate life functions. Proximate life history functions are the functions that the animal is engaged in at the time of acoustic exposure. The ultimate life functions are those that enable an animal to contribute to the population (or stock, or species, etc.).

I. Physiology-Hearing Threshold Shift

In mammals, high-intensity sound may rupture the eardrum, damage the small bones in the middle ear, or over stimulate the electromechanical hair cells that convert the fluid motions caused by sound into neural impulses that are sent to the brain. Lower level exposures may cause a loss of hearing sensitivity, termed a threshold shift (TS) (Miller, 1974). Incidence of TS may be either permanent, referred to as permanent threshold shift (PTS), or temporary, referred to as temporary threshold shift (TTS). The amplitude, duration, frequency, and temporal pattern, and energy distribution of sound exposure all affect the amount of associated TS and the frequency range in which it occurs. As amplitude and duration of sound exposure increase, generally, so does the amount of TS and recovery time. Human non-impulsive noise exposure guidelines are based on exposures of equal energy (the same SEL) producing equal amounts of hearing impairment regardless of how the sound energy is distributed in time (NIOSH 1998). Until recently, previous marine mammal TTS studies have also generally supported this equal energy relationship (Southall et al., 2007). Three newer studies, two by Mooney et al. (2009a, 2009b) on a single bottlenose dolphin either exposed to playbacks of Navy MFAS or octave-band

noise (4-8 kHz) and one by Kastak et al. (2007) on a single California sea lion exposed to airborne octave-band noise (centered at 2.5 kHz), concluded that for all noise exposure situations the equal energy relationship may not be the best indicator to predict TTS onset levels. Generally, with sound exposures of equal energy, those that were quieter (lower sound pressure level [SPL]) with longer duration were found to induce TTS onset more than those of louder (higher SPL) and shorter duration (more similar to noise from AS Cherry Point exercises). For intermittent sounds, less TS will occur than from a continuous exposure with the same energy (some recovery will occur between exposures) (Kryter et al., 1966; Ward, 1997). Additionally, though TTS is temporary, very prolonged exposure to sound strong enough to elicit TTS, or shorter-term exposure to sound levels well above the TTS threshold, can cause PTS, at least in terrestrial mammals (Kryter, 1985). However, these studies highlight the inherent complexity of predicting TTS onset in marine mammals, as well as the importance of considering exposure duration when assessing potential impacts.

PTS consists of non-recoverable physical damage to the sound receptors in the ear, which can include total or partial deafness, or an impaired ability to hear sounds in specific frequency ranges; PTS is considered Level A harassment. TTS is recoverable and is considered to result from temporary, non-injurious impacts to hearing-related tissues; TTS is considered Level B harassment.

Permanent Threshold Shift

Auditory trauma represents direct mechanical injury to hearing related structures, including tympanic membrane rupture, disarticulation of the middle ear ossicles, and trauma to the inner ear structures such as the organ of Corti and the associated hair cells. Auditory trauma is irreversible and considered to be an injury that could result in PTS. PTS results from exposure to intense sounds that cause a permanent loss of inner or outer cochlear hair cells or exceed the elastic limits of certain tissues and membranes in the middle and inner ears and result in changes in the chemical composition of the inner ear fluids. In some cases, there can be total or partial deafness across all frequencies, whereas in other cases, the animal has an impaired ability to hear sounds in specific frequency ranges. There is no empirical data for onset of PTS in any marine mammal, and therefore, PTS-onset must be estimated from TTS-onset measurements and from the rate of TTS growth with increasing exposure levels above the level eliciting TTS-onset. PTS is presumed to be likely if the hearing threshold is reduced by >/= 40 dB (i.e., 40 dB of TTS). Relationships between TTS and PTS thresholds have not been studied in marine mammals, but are assumed to be similar to those in humans and other terrestrial mammals.

Temporary Threshold Shift

TTS is the mildest form of hearing impairment that can occur during exposure to a loud sound (Kryter, 1985). Southall et al. (2007) indicate that although PTS is a tissue injury, TTS is not because the reduced hearing sensitivity following exposure to intense sound results primarily from fatigue, not loss, of cochlear hair cells and supporting structures and is reversible. Accordingly, NMFS classifies TTS as Level B Harassment, not Level A Harassment (injury); however, NMFS does not consider the onset of TTS to be the lowest level at which Level B Harassment may occur (see III. Behavior section below this section).

Southall et al. (2007) considers a 6 dB TTS (i.e., baseline hearing thresholds are elevated by 6 dB) sufficient to be recognized as an unequivocal deviation and thus a sufficient definition of TTS onset. TTS in bottlenose dolphin hearing have been experimentally induced. For example, Finneran et al. (2002) exposed a trained captive bottlenose dolphin to a seismic watergun simulator with a single acoustic pulse. No TTS was observed in the dolphin at the highest exposure condition (peak: 207 kPa [30psi]; peak-to-peak: 228 dB re: 1 microPa; SEL: 188 dB re 1 microPa ^{2} -s). Schludt et al. (2000) demonstrated temporary shifts in masked hearing thresholds in five bottlenose dolphins occurring generally between 192 and 201 dB rms (192 and 201 dB SEL) after exposure to intense, non-pulse, 1-s tones at, 3kHz, 10kHz, and 20 kHz. TTS onset occurred at mean sound exposure level of 195 dB rms (195 dB SEL). At 0.4 kHz, no subjects exhibited threshold shifts after SPL exposures of 193dB re: 1 microPa (192 dB re: 1 microPa ^{2} -s). In the same study, at 75 kHz, one dolphin

exhibited a TTS after exposure at 182 dB SPL re: 1 microPa but not at higher exposure levels. Another dolphin experienced no threshold shift after exposure to maximum SPL levels of 193 dB re: 1 microPa at the same frequency. Frequencies of explosives used at MCAS Cherry Point range from 1-25 kHz; the range where dolphin TTS onset occurred at 195 dB rms in the Schlundt et al. (2000) study.

Preliminary research indicates that TTS and recovery after noise exposure are frequency dependent and that an inverse relationship exists between exposure time and sound pressure level associated with exposure (Mooney et al., 2005; Mooney, 2006). For example, Nachtigall et al. (2003) measured TTS in a bottlenose dolphin and found an average 11 dB shift following a 30 minute net exposure to OBN at a 7.5 kHz center frequency (max SPL of 179 dB re: 1 microPa; SEL: 212-214 dB re:1 microPa ^{2} -s). No TTS was observed after exposure to the same duration and frequency noise with maximum SPLs of 165 and 171 dB re:1 microPa. After 50 minutes of exposure to the same 7.5 kHz frequency OBN, Natchigall et al. (2004) measured a 4-8 dB shift (max SPL: 160dB re 1microPa; SEL: 193-195 dB re:1 microPa ^{2} -s). Finneran et al. (2005) concluded that a sound exposure level of 195 dB re 1 [mu]Pa2-s is a reasonable threshold for the onset of TTS in bottlenose dolphins exposed to mid-frequency tones.

II. Stress Response

An acoustic source is considered a potential stressor if, by its action on the animal, via auditory or non-auditory means, it may produce a stress response in the animal. Here, the stress response will refer to an increase in energetic expenditure that results from exposure to the stressor and which is predominantly characterized by either the stimulation of the sympathetic nervous system (SNS) or the hypothalamic-pituitary-adrenal (HPA) axis (Reeder and Kramer, 2005). The SNS response to a stressor is immediate and acute and is characterized by the release of the catecholamine neurohormones norepinephrine and epinephrine (i.e., adrenaline). These hormones produce elevations in the heart and respiration rate, increase awareness, and increase the availability of glucose and lipids for energy. The HPA response is ultimately defined by increases in the secretion of the glucocorticoid steroid hormones, predominantly cortisol in mammals. The presence and magnitude of a stress response in an animal depends on a number of factors. These include the animal's life history stage (e.g., neonate, juvenile, adult), the environmental conditions, reproductive or developmental state, and experience with the stressor. Not only will these factors be subject to individual variation, but they will also vary within an individual over time. The stress response may or may not result in a behavioral change, depending on the characteristics of the exposed animal. However, provided a stress response occurs, we assume that some contribution is made to the animal's allostatic load. Any immediate effect of exposure that produces an injury is assumed to also produce a stress response and contribute to the allostatic load. Allostasis is the ability of an animal to maintain stability through change by adjusting its physiology in response to both predictable and unpredictable events (McEwen and Wingfield, 2003). If the acoustic source does not produce tissue effects, is not perceived by the animal, or does not produce a stress response by any other means, we assume that the exposure does not contribute to the allostatic load. Additionally, without a stress response or auditory masking, it is assumed that there can be no behavioral change.

III. Behavior

Changes in marine mammal behavior in response to anthropogenic noise may include altered travel directions, increased swimming speeds, changes in dive, surfacing, respiration and feeding patterns, and changes in vocalizations. As described above, lower level physiological stress responses could also co-occur with altered behavior; however, stress responses are more difficult to detect and fewer data exist relative to specific received levels of sound.

Acoustic Masking

Marine mammals use acoustic signals for a variety of purposes, which differ among species, but include communication between individuals, navigation, foraging, reproduction, and learning about their environment (Erbe and Farmer, 2000; Tyack, 2000). Masking, or auditory interference, generally occurs when sounds in the

environment are louder than, and of a similar frequency as, auditory signals an animal is trying to receive. Masking is a phenomenon that affects animals that are trying to receive acoustic information about their environment, including sounds from other members of their species, predators, prey, and sounds that allow them to orient in their environment. Masking these acoustic signals can disturb the behavior of individual animals, groups of animals, or entire populations.

Southall et al. (2007) defines auditory masking as the partial or complete reduction in the audibility of signals due to the presence of interfering noise with the degree of masking depending on the spectral, temporal, and spatial relationships between signals and masking noise, as well as the respective received levels. Masking of sender communication space can be considered as the amount of change in a sender's communication space caused by the presence of other sounds, relative to a pre-industrial ambient noise condition (Clark et al., 2009). Unlike auditory fatigue, which always results in a stress response because the sensory tissues are being stimulated beyond their normal physiological range, masking may or may not result in a stress response, depending on the degree and duration of the masking effect. Masking may also result in a unique circumstance where an animal's ability to detect other sounds is compromised without the animal's knowledge. This could conceivably result in sensory impairment and subsequent behavior change; in this case, the change in behavior is the lack of a response that would normally be made if sensory impairment did not occur. For this reason, masking also may lead directly to behavior change without first causing a stress response. Projecting noise into the marine environment which causes acoustic masking is considered Level B harassment as it can disrupt natural behavioral patterns by interrupting or limiting the marine mammal's receipt or transmittal of important information or environmental cues. To compensate for masking, marine mammals, including bottlenose dolphins, are known to increase their levels of vocalization as a function of background noise by increasing call repetition and amplitude, shifting calls higher frequencies, and/or changing the structure of call content (Lesage et al., 1999; Scheifele et al., 2005; McIwem, 2006).

While it may occur temporarily, we do not expect auditory masking to result in detrimental impacts to an individual's or population's survival, fitness, or reproductive success. Dolphins are not confined to the BT ranges; allowing for movement out of area to avoid masking impacts. The Marine Corps would also conduct visual sweeps of the area before any training exercise and implement training delay mitigation measures if a dolphin is sighted within designated zones (see Proposed Mitigation Measures section). As discussed previously, the Marine Corps has been working with DUML to collect baseline information on dolphins in Pamlico Sound, specifically dolphin abundance and habitat use around the BTs.

Assessment of Marine Mammal Impacts from Explosive Ordnances

MCAS Cherry Point plans to use five types of explosive sources during its training exercises: 2.75-inch Rocket High Explosives, 5-inch Rocket High Explosives, 30 mm High Explosives, 40 mm High Explosives, and G911 grenades. The underwater explosions from these weapons would send a shock wave and blast noise through the water, release gaseous by-products, create an oscillating bubble, and cause a plume of water to shoot up from the water surface. The shock wave and blast noise are of most concern to marine animals. In general, potential impacts from explosive detonations can range from brief effects (such as short term behavioral disturbance), tactile perception, physical discomfort, slight injury of the internal organs and the auditory system, to death of the animal (Yelverton et al., 1973; O'Keeffe and Young, 1984; DoN, 2001).

Explosives produce significant acoustic energy across several frequency decades of bandwidth (i.e., broadband). Propagation loss is sufficiently sensitive to frequency as to require model estimates at several frequencies over such a wide band. The effects of an underwater explosion on a marine mammal depend on many factors, including the size, type, and depth of both the animal and the explosive charge; the depth of the water column; and the standoff distance between the charge and the animal, as well as the sound propagation properties of the environment. The net explosive weight (or NEW) of an explosive is the weight of TNT required to produce an equivalent explosive power. The detonation depth of an explosive is particularly important due to

a propagation effect known as surface-image interference. For sources located near the sea surface, a distinct interference pattern arises from the coherent sum of the two paths that differ only by a single reflection from the pressure-release surface. As the source depth and/or the source frequency decreases, these two paths increasingly, destructively interfere with each other, reaching total cancellation at the surface (barring surface-reflection scattering loss). Marine Corps conservatively estimates that all explosives would detonate at a 1.2 m (3.9 ft) water depth. This is the worst case scenario as the purpose of training is to hit the target, resulting in an in-air explosion.

The firing sequence for some of the munitions consists of a number of rapid bursts, often lasting a second or less. The maximum firing time is 10-15 second bursts. Due to the tight spacing in time, each burst can be treated as a single detonation. For the energy metrics, the impact area of a burst is computed using a source energy spectrum that is the source spectrum for a single detonation scaled by the number of rounds in a burst. For the pressure metrics, the impact area for a burst is the same as the impact area of a single round. For all metrics, the cumulative impact area of an event consisting of a certain number of bursts is merely the product of the impact area of a single burst and the number of bursts, as would be the case if the bursts are sufficiently spaced in time or location as to insure that each burst is affecting a different set of marine wildlife.

Physical damage of tissues resulting from a shock wave (from an explosive detonation) is classified as an injury. Blast effects are greatest at the gas-liquid interface (Landsberg, 2000) and gas containing organs, particularly the lungs and gastrointestinal tract, are especially susceptible to damage (Goertner, 1982; Hill 1978; Yelverton et al., 1973). Nasal sacs, larynx, pharynx, trachea, and lungs may be damaged by compression/expansion caused by the oscillations of the blast gas bubble (Reidenberg and Laitman, 2003). Severe damage (from the shock wave) to the ears can include tympanic membrane rupture, fracture of the ossicles, damage to the cochlea, hemorrhage, and cerebrospinal fluid leakage into the middle ear.

Non-lethal injury includes slight injury to internal organs and the auditory system; however, delayed lethality can be a result of individual or cumulative sublethal injuries (DoN, 2001). Immediate lethal injury would be a result of massive combined trauma to internal organs as a direct result of proximity to the point of detonation (DoN, 2001). Exposure to distance explosions could result only in behavioral changes. Masked underwater hearing thresholds in two bottlenose dolphins and one beluga whale have been measured before and after exposure to impulsive underwater sounds with waveforms resembling distant signatures of underwater explosions (Finneran et al., 2000). The authors found no temporary shifts in masked-hearing thresholds, defined as a 6-dB or larger increase in threshold over pre-exposure levels, had been observed at the highest impulse level generated (500 kg at 1.7 km, peak pressure 70 kPa); however, disruptions of the animals' trained behaviors began to occur at exposures corresponding to 5 kg at 9.3 km and 5 kg at 1.5 km for the dolphins and 500 kg at 1.9 km for the beluga whale.

Generally, the higher the level of impulse and pressure level exposure, the more severe the impact to an individual. While, in general, dolphins could sustain injury or mortality if within very close proximity to in-water explosion, monitoring and mitigation measures employed by the Marine Corps before and during training exercises, as would be required under any Authorization issued, are designed to avoid any firing if a marine mammal is sighted within designated BT zones (see Proposed Mitigation and Monitoring section). No marine mammal injury or death has been attributed to the specified activities described in the application. As such, and due to implementation of the proposed mitigation and monitoring measures, bottlenose dolphin injury, serious injury or mortality is not anticipated nor would any be authorized.

Inert Ordnances

The potential risk to marine mammals from non-explosive ordnance entails two possible sources of impacts: elevated sound levels or the ordnance physically hitting an animal. The latter is discussed below in the Munition Presence section. The USMC provided information that the noise fields generated in water by the firing of non-explosive ordnance indicate that the energy radiated is about 1 to 2 percent of the total kinetic energy of the

impact. This energy level (and likely peak pressure levels) is well below the TTS-energy threshold, even at 1-m from the impact and is not expected to be audible to marine mammals. As such, the noise generated by the in-water impact of non-explosive ordnance will not result in take of marine mammals.

Training Debris

In addition to behavioral and physiological impacts from live fire and ammunition testing, we have preliminarily analyzed impacts from presence of munition debris in the water, as described in the Marine Corps' application and 2009 EA. These impacts include falling debris, ingestion of expended ordnance, and entanglement in parachute debris.

Ingestion of marine debris by marine mammals can cause digestive tract blockages or damage the digestive system (Gorzelany, 1998; Stamper et al., 2006). Debris could be either the expended ordnance or non-munition related products such as chaff and self protection flares. Expended ordnance would be small and sink to the bottom. Chaff is composed of either aluminum foil or aluminum-coated glass fibers designed to act as a visual smoke screen; hiding the aircraft from enemy radar. Chaff also serves as a decoy for radar detection, allowing aircraft to maneuver or egress from the area. The foil type currently used is no longer manufactured, although it remains in the inventory and is used primarily by B-52 bombers. Both types of chaff are cut into dipoles ranging in length from 0.3 to over 2.0 inches. The aluminum foil dipoles are 0.45 mils (0.00045 inches) thick and 6 to 8 mils wide. The glass fiber dipoles are generally 1 mil (25.4 microns) in diameter, including the aluminum coating. Chaff is packed into about 4-ounce bundles. The major components of chaff are silica, aluminum, and stearic acid; all naturally prevalent in the environment.

Based on the dispersion characteristics of chaff, concentrations around the BTs would be low. For example, Hullar et al. (1999) calculated that a 4.97-mile by 7.46-mile area (37.1 km^2) would be affected by deployment of a single cartridge containing 150 grams of chaff; however, concentration would only be about 5.4 grams per square nautical mile. This corresponds to fewer than 179,000 fibers per square nautical mile or fewer than 0.005 fibers per square foot.

Self-protection flares are deployed to mislead or confuse heat-sensitive or heat-seeking anti-aircraft systems. The flares are magnesium pellets that, when ignited, burn for a short period of time (less than 10 seconds) at 2,000 degrees Fahrenheit. Air-deployed LUU-2 high-intensity illumination flares are used to illuminate targets, enhancing a pilot's ability to see targets while using Night Vision Goggles. The LUU-2B Flare has a light output rating of 1.8 x 10(6) candlepower and at 1,000 feet altitude illuminates a circle on the ground of 500 meters. The LUU-2 is housed in a pod or canister and is deployed by ejection. The mechanism has a timer on it that deploys the parachute and ignites the flare candle. The flare candle burns magnesium at high temperature, emitting an intense bright white light. The LUU-2 has a burn time of approximately 5 minutes while suspended from a parachute. The pyrotechnic candle consumes the flare housing, reducing flare weight, which in turn slows the rate of fall during the last 2 minutes of burn time. At candle burnout an explosive bolt is fired, releasing one parachute support cable, which causes the parachute to collapse.

Ingestion of debris by dolphins is not likely, as dolphins typically eat fish and other moving prey items. We solicited information on evidence of debris ingestion from two marine mammal veterinarians who have performed many necropsies on the protected species of North Carolina's waters. In their experience, no necropsies of bottlenose dolphins have revealed evidence of munition, parachute, or chaff ingestion (pers. comm., Drs. C. Harms and D. Rostein, November 14, 2009). However, it was noted evidence of chaff ingestion would be difficult to detect. In the chance that dolphins do ingest chaff, the filaments are so fine they would likely pass through the digestive system without complication. However, if the chaff is durable enough, it might act as a linear foreign body. In such case, the intestines bunch up on the line restricting movement of the line resulting in an obstruction. The peristalsis on an immovable thin line can cause intestinal lacerations and perforations (pers. comm., C. Harms, November 14, 2009). This is a well-known complication in cats when they ingest thread and which occurs occasionally with sea turtles ingesting fishing line. The longevity of chaff filaments,

based upon dispersion rates, is unclear. Chaff exposed to synthetic seawater and aqueous environments in the pH range of 4-10 exhibited varying levels of degradation suggesting a short lifespan for the outer aluminum coating (Farrell and Siciliano, 1998). The underlying filament is a flexible silica core and composed of primarily silica dioxide. While no studies have been conducted to evaluate the effects of chaff ingestion on marine mammals, the effects are expected to be negligible based upon chaff concentration in the environment, size of fibers, and available toxicity data on fiberglass and aluminum. Given that the size of chaff fibers are no more than 2 inches long, tidal flushing reduces concentration in the environment, and chaff degradation rate, the chance of chaff ingestions is unlikely; however, if swallowed, impacts would be negligible.

Given that there is no evidence that dolphins ingest military debris; dolphins in the Sound forage on moving prey suspended in the water column while expended munition would sink; the property and dispersion characteristics of chaff make potential for ingestion discountable; and that Pamlico Sound is a tidal body of water with continuing flushing, we have preliminarily determined that the presence of training debris would not have an effect on dolphins in Pamlico Sound.

Although sometimes large, expended parachutes (e.g., those from the flares) are flimsy and structurally simple. Thus, we have preliminarily determined that the probability of entanglement with a dolphin is low. There are no known reports of live or stranded dolphins entangled in parachute gear; fishing gear is usually the culprit of reported entanglements. The Service's Marine Mammal Stranding Network (Network) has established protocol for reporting marine mammals in peril. Should any injured, stranded or entangled marine mammal be observed by USMC personnel during training exercises, the sighting would be reported to the Network within 24 hours of the observation.

Vessel and Aircraft Presence

The marine mammals most vulnerable to vessel strikes are slow-moving and/or spend extended periods of time at the surface in order to restore oxygen levels within their tissues after deep dives (e.g., right whales, fin whales (Balaenoptera physalus), and sperm whales (Physeter macrocephalus)). Smaller marine mammals such as bottlenose dolphins (the only marine mammal that would be encountered at the BTs) are agile and move more quickly through the water, making them less susceptible to ship strikes. We are not aware of any vessel strikes of bottlenose dolphins in Pamlico Sound during training operations. Therefore, we do not anticipate that Marine Corps vessels engaged in the specified activity would strike any marine mammals and no take from ship strike would be authorized in the proposed Authorization.

Behaviorally, marine mammals may or may not respond to the operation of vessels and associated noise. Responses to vessels vary widely among marine mammals in general, but also among different species of small cetaceans. Responses may include attraction to the vessel (Richardson et al., 1995); altering travel patterns to avoid vessels (Constantine, 2001; Nowacek et al., 2001; Lusseau, 2003, 2006); relocating to other areas (Allen and Read, 2000); cessation of feeding, resting, and social interaction (Baker et al., 1983; Bauer and Herman, 1986; Hall, 1982; Krieger and Wing, 1984; Lusseau, 2003; Constantine et al., 2004); abandoning feeding, resting, and nursing areas (Jurasz and Jurasz 1979; Dean et al., 1985; Glockner-Ferrari and Ferrari 1985, 1990; Lusseau, 2005; Norris et al., 1985; Salden, 1988; Forest, 2001; Morton and Symonds, 2002; Courbis, 2004; Bejder, 2006); stress (Romano et al., 2004); and changes in acoustic behavior (Van Parijs and Corkeron, 2001). However, in some studies marine mammals display no reaction to vessels (Watkins, 1986; Nowacek et al., 2003) and many odontocetes show considerable tolerance to vessel traffic (Richardson et al., 1995). Dolphins may actually reduce the energetic cost of traveling by riding the bow or stern waves of vessels (Williams et al., 1992; Richardson et al., 1995).

Dolphins within Pamlico Sound are continually exposed to recreational, commercial, and military vessels. Richardson et al. (1995) addresses in detail three responses that marine mammals may experience when exposed to anthropogenic activities: tolerance; habituation; and sensitization. More recent publications provide variations on these themes rather than new data (NRC, 2003). Marine mammals are often seen in regions with

much human activity; thus, certain individuals or populations exhibit some tolerance of anthropogenic noise and other stimuli. Animals will tolerate a stimulus they might otherwise avoid if the benefits in terms of feeding, mating, migrating to traditional habitats, or other factors outweigh the negative aspects of the stimulus (NRC, 2003). In many cases, tolerance develops as a result of habituation. The NRC (2003) defines habituation as a gradual waning of behavioral responsiveness over time as animals learn that a repeated or ongoing stimulus lacks significant consequences for the animals. Contrarily, sensitization occurs when an animal links a stimulus with some degree of negative consequence and as a result increases responsiveness to that human activity over time (Richardson et al., 1995). For example, seals and whales are known to avoid previously encountered vessels involved in subsistence hunts (Walker, 1949; Ash, 1962; Terhune, 1985) and bottlenose dolphins that had previously been captured and released from a 7.3 m boat involved in health studies were documented to flee when that boat approached closer than 400 m, whereas dolphins that had not been involved in the capture did not display signs of avoidance of the vessel (Irvine et al., 1981). Because dolphins in Pamlico Sound are continually exposed to vessel traffic that does not present immediate danger to them, it is likely animals are both tolerant and habituated to vessels.

The specified activities also involve aircraft, which marine mammals are known to react (Richardson et al., 1995). Aircraft produce noise at frequencies that are well within the frequency range of cetacean hearing and also produce visual signals such as the aircraft itself and its shadow (Richardson et al., 1995, Richardson &Wuersig, 1997). A major difference between aircraft noise and noise caused by other anthropogenic sources is that the sound is generated in the air, transmitted through the water surface and then propagates underwater to the receiver, diminishing the received levels to significantly below what is heard above the water's surface. Sound transmission from air to water is greatest in a sound cone 26 degrees directly under the aircraft. Reactions of odontocetes to aircraft have been reported less often than those of pinnipeds. Responses to aircraft include diving, slapping the water with pectoral fins or tail fluke, or swimming away from the track of the aircraft (Richardson et al., 1995). The nature and degree of the response, or the lack thereof, are dependent upon nature of the flight (e.g., type of aircraft, altitude, straight vs. circular flight pattern). Wuersig et al. (1998) assessed the responses of cetaceans to aerial surveys in the northcentral and western Gulf of Mexico using a DeHavilland Twin Otter fixed-wing airplane. The plane flew at an altitude of 229 m at 204 km/hr. A minimum of 305 m straight line distance from the cetaceans was maintained. Water depth was 100-1000m. Bottlenose dolphins most commonly responded by diving (48 percent), while 14 percent responded by moving away. Other species (e.g., beluga whale (Delphinapterus leucas), sperm whale) show considerable variation in reactions to aircraft but diving or swimming away from the aircraft are the most common reactions to low flights (less than 500 m).

Anticipated Effects on Habitat

Detonations of live ordnance would result in temporary modification to water properties. As described above, an underwater explosion from these weapon would send a shock wave and blast noise through the water, release gaseous by-products, create an oscillating bubble, and cause a plume of water to shoot up from the water surface. However, these would be temporary and not expected to last more than a few seconds. Because dolphins are not expected to be in the area during live firing, due to monitoring and mitigation measure implementation, they would not be subject to any short term habitat alterations.

Similarly, no long term impacts with regard to hazardous constituents are expected to occur. MCAS Cherry Point has an active Range Environmental Vulnerability Assessment (REVA) program in place to monitor impacts to habitat from its activities. One goal of REVA is to determine the horizontal and vertical concentration profiles of heavy metals, explosives constituents, perchlorate nutrients, and dissolved salts in the sediment and seawater surrounding BT-9 and BT-11. The preliminary results of the sampling indicate that explosive constituents (e.g., trinitrotoluene (TNT), cyclotrimethylenetrinitramine (RDX), and hexahydro-trinitro-triazine (HMX), as described in Hazardous Constituents [Subchapter 3.2.7.2] of the MCAS Cherry Point Range

Operations EA, were not detected in any sediment or water sample surrounding the BTs. Metals were not present above toxicity screening values. Perchlorate was detected in a few sediment samples above the detection limit (0.21 ppm), but below the reporting limit (0.6 ppm). The ongoing REVA would continue to evaluate potential munitions constituent migration from operational range areas to off-range areas and MCAS Cherry Point.

While it is anticipated that the specified activity may result in marine mammals avoiding certain areas due to temporary ensonification, this impact to habitat and prey resources is temporary and reversible and considered in further detail earlier in this document, as behavioral modification. The main impact associated with the proposed activity would be temporarily elevated noise levels and the associated direct effects on marine mammals, previously discussed in this notice.

Summary of Previous Monitoring

The Marine Corps complied with the mitigation and monitoring required under the previous authorizations (2010-2012). In accordance with the 2010-11 IHA, USMC submitted a final monitoring report, which described the activities conducted and observations made. USMC did not record observations of any marine mammals during training exercises. The only recorded observations--which were of bottlenose dolphins--were on two occasions by maintenance vessels engaged in target maintenance. No marine mammals were observed during range sweeps, air to ground activities, surface to surface activities (small boats), or ad hoc via range cameras. Table 6 details the number of sorties conducted, by air and water, at each target. The number of sorties conducted does not relate to the total amount of munitions expended, as the training requirements for the specific military unit conducting the sortie determine the munitions loading for the air platform or watercraft during each sortie. In addition, munitions expenditures may be determined by the loading specifications of the specific aircraft and vessels used in the training exercise.

Table_6--Sorties_Conducted_at_BT-9_and_BT-11		
Mission_type	BT-9	BT-11
Air-to-surface	1,554	4,251
Surface-to-surface_(water-to-water)	223	105
Total	1,777	4,356

The total amount of ordnance expended at BT-9 and BT-11 under the 2010-11 IHA was 878,625 and 693,612 respectively (Table 7). These amounts represent 98 and 62 percent of the estimated annual maximum ordnance expenditures. The amounts of ordnance expended at the BTs account for all use of the targets. There are five types of explosive sources used at BT-9: 2.75-inc Rocket High Explosives, 5-inch Rocket High Explosives, 30 mm High Explosives, 40 mm High Explosives, and G911 grenades. No explosive munitions are used at BT-11. Based on this information, the Marine Corps did not exceed the authorized level of take.

Table_7--Ordnance_Usage_at_BT-9

The Marine Corps will submit a monitoring report for the 2012 training season which expired on December 31, 2012, to us no later than March 31, 2013.

Proposed Mitigation

In order to issue an incidental take authorization under section 101(a)(5)(D) of the MMPA, we must set forth the permissible methods of taking pursuant to such activity, and other means of effecting the least practicable adverse impact on such species or stock and its habitat, paying particular attention to rookeries, mating grounds, and areas of similar significance, and the availability of such species or stock for taking for certain subsistence uses.

The NDAA of 2004 amended the MMPA as it relates to military-readiness activities and the ITA process such that "least practicable adverse impact" shall include consideration of personnel safety, practicality of implementation, and impact on the effectiveness of the military readiness activity. The training activities described in the Marine Corp's application are considered military readiness activities.

The Marine Corps, in collaboration with us, has worked to identify potential practicable and effective mitigation measures, which include a careful balancing of the likely benefit of any particular measure to the marine mammals with the likely effect of that measure on personnel safety, practicality of implementation, and impact on the "military-readiness activity". These proposed mitigation measures are listed below.

(1) Range Sweeps: The VMR-1 squadron, stationed at MCAS Cherry Point, includes three specially equipped HH-46D helicopters. The primary mission of these aircraft, known as PEDRO, is to provide search and rescue for downed 2^{d} Marine Air Wing aircrews. On-board are a pilot, co-pilot, crew chief, search and rescue swimmer, and a medical corpsman. Each crew member has received extensive training in search and rescue techniques, and is therefore particularly capable at spotting objects floating in the water.

PEDRO crew would conduct a range sweep the morning of each exercise day prior to the commencement of range operations. The primary goal of the pre-exercise sweep is to ensure that the target area is clear of fisherman, other personnel, and protected species. The sweep is flown at 100-300 meters above the water surface, at airspeeds between 60-100 knots. The path of the sweep runs down the western side of BT-11, circles around BT-9 and then continues down the eastern side of BT-9 before leaving. The sweep typically takes 20-30 minutes to complete. The PEDRO crew is able to communicate directly with range personnel and can provide immediate notification to range operators. The PEDRO aircraft would remain in the area of a sighting until clear if possible or as mission requirements dictate.

If marine mammals are sighted during a range sweep, sighting data will be collected and entered into the US Marine Corps sighting database, web-interface, or report generator and this information would be relayed to the

training Commander. Sighting data includes the following (collected to the best of the observer's ability): (1) Species identification; (2) group size; (3) the behavior of marine mammals (e.g., milling, travel, social, foraging); (4) location and relative distance from the BT; (5) date, time and visual conditions (e.g., Beaufort sea state, weather) associated with each observation; (6) direction of travel relative to the BT; and (7) duration of the observation.

(2) Cold Passes: All aircraft participating in an air-to-surface exercise would be required to perform a "cold pass" immediately prior to ordnance delivery at the BTs both day and night. That is, prior to granting a "First Pass Hot" (use of ordnance), pilots would be directed to perform a low, cold (no ordnance delivered) first pass which serves as a visual sweep of the targets prior to ordnance delivery to determine if unauthorized civilian vessels or personnel, or protected species, are present. The cold pass is conducted with the aircraft (helicopter or fixed-winged) flying straight and level at altitudes of 200-3000 feet over the target area. The viewing angle is approximately 15 degrees. A blind spot exists to the immediate rear of the aircraft. Based upon prevailing visibility, a pilot can see more than one mile forward upon approach. The aircrew and range personnel make every attempt to ensure clearance of the area via visual inspection and remotely operated camera operations (see Proposed Monitoring and Reporting section). The Range Controller may deny or approve the First Pass Hot clearance as conditions warrant.

(3) Delay of Exercises: An active range would be considered "fouled" and not available for use if a marine mammal is present within 1000 yards (914 m) of the target area at BT-9 or anywhere within Rattan Bay (BT-11). Therefore, if a marine mammal is sighted within 1000 yards (914 m) of the target at BT-9 or anywhere within Rattan Bay at BT-11 during the cold pass or from range camera detection, training would be delayed until the marine mammal moves beyond and on a path away from 1000 yards (914 m) from the BT-9 target or out of Rattan Bay at BT-11. This mitigation applies to both air-to-surface and surface-to-surface exercises.

(4) Range Camera Use: To increase the safety of persons or property near the targets, Range Operation and Control personnel monitor the target area through tower mounted safety and surveillance cameras. The remotely operated range cameras are high resolution and, according to range personnel, allow a clear visual of a duck floating near the target. The cameras allow viewers to see animals at the surface and breaking the surface, but not underwater.

A new, enhanced camera system has been purchased and will be installed on BT-11 towers 3 and 7, and on both towers at BT-9. The new camera system has night vision capabilities with resolution levels near those during daytime. Lenses on the camera system have focal lengths of 40 mm to 2200 mm (56x), with view angles of 18 [degrees] 10' and 13 [degrees] 41', respectively. The field of view when zoomed in on the Rattan Bay targets will be 23 ft wide by 17 ft high, and on the mouth of Rattan Bay itself 87 ft wide by 66 ft high.

Again, in the event that a marine mammal is sighted within 1000 yards (914 m) of the BT-9 target, or anywhere within Rattan Bay, the target would be declared fouled. Operations may commence in the fouled area after the animal(s) have moved 1000 yards (914 m) from the BT-9 target and/or out of Rattan Bay.

(5) Vessel Operation: All vessels used during training operations would abide by the Service's Southeast Regional Viewing Guidelines designed to prevent harassment to marine mammals (http://www.nmfs.noaa.gov/pr/education/southeast/).

(6) Stranding Network Coordination: The USMC would coordinate with the local NMFS Stranding Coordinator for any unusual marine mammal behavior and any stranding, beached live/dead, or floating marine mammals that may occur at any time during training activities or within 24 hours after completion of training.

Proposed Monitoring and Reporting

In order to issue an ITA for an activity, section 101(a)(5)(D) of the MMPA states that we must set forth "requirements pertaining to the monitoring and reporting of such taking". The MMPA implementing regulations at 50 CFR 216.104 (a)(13) indicate that requests for IHAs must include the suggested means of accomplishing the necessary monitoring and reporting that will result in increased knowledge of the species and of the level of

taking or impacts on populations of marine mammals that are expected to be present.

Proposed Monitoring

The Marine Corps proposes to conduct the following to fulfill the necessary monitoring and reporting that would result in increased knowledge of the species and of the level of taking or impacts on populations of marine mammals expected to be present within the action area:

(1) Protected Species Observer Training: Pilots, operators of small boats, and other personnel monitoring for marine mammals would be required to take the Marine Species Awareness Training (Version 2), maintained and promoted by the Department of the Navy. This training would make personnel knowledgeable of marine mammals, protected species, and visual cues related to the presence of marine mammals and protected species.

(2) Weekly and Post-Exercise Monitoring: Post-exercise monitoring would be conducted concomitant to the next regularly scheduled pre-exercise sweep. Weekly monitoring events would include a maximum of five pre-exercise and four post-exercise sweeps. The maximum number of days that would elapse between pre- and post-exercise monitoring events would be approximately three days, and would normally occur on weekends. If marine mammals are observed during this monitoring, sighting data identical to those collected by PEDRO crew would be recorded.

(3) Long-term Monitoring: The Marine Corps has awarded DUML duties to obtain abundance, group dynamics (e.g., group size, age census), behavior, habitat use, and acoustic data on the bottlenose dolphins which inhabit Pamlico Sound, specifically those around BT-9 and BT-11. DUML began conducting boat-based surveys and passive acoustic monitoring of bottlenose dolphins in Pamlico Sound in 2000 (Read et al., 2003) and specifically at BT-9 and BT-11 in 2003 (Mayer, 2003). To date, boat-based surveys indicate that bottlenose dolphins may be resident to Pamlico Sound and use BT restricted areas on a frequent basis. Passive acoustic monitoring (PAM) is providing more detailed insight into how dolphins use the two ranges, by monitoring for their vocalizations year-round, regardless of weather conditions or darkness. In addition to these surveys, DUML scientists are testing a real-time passive acoustic monitoring system at BT-9 that will allow automated detection of bottlenose dolphin whistles, providing yet another method of detecting dolphins prior to training operations. Although it is unlikely this PAM system would be active for purposes of implementing mitigation measures before an exercise prior to expiration of the proposed Authorization, it could be operational for future MMPA incidental take authorizations and would be evaluated for effectiveness at the appropriate time.

(4) Reporting: The Marine Corps would submit a report to us within 90 days after expiration of the Authorization or, if a subsequent incidental take authorization is requested, within 120 days prior to expiration of the Authorization. The report would summarize the type and amount of training exercises conducted, all marine mammal observations made during monitoring, and if mitigation measures were implemented. The report would also address the effectiveness of the monitoring plan in detecting marine mammals.

General Notification of Injured or Dead Marine Mammals

The Marine Corps would systematically observe training operations for injured or disabled marine mammals. In addition, the Marine Corps would monitor the principal marine mammal stranding networks and other media to correlate analysis of any dolphin strandings that could potentially be associated with MCAS Cherry Point training operations.

Marine Corps personnel would ensure that we are notified immediately or as soon as clearance procedures allow if an injured, stranded, or dead marine mammal is found during or shortly after, and in the vicinity of, any training operations. The Marine Corps would provide us with species or description of the animal(s), the condition of the animal(s) (including carcass condition if the animal is dead), location, time of first discovery, observed behaviors (if alive), and photo or video (if available).

In the event that an injured, stranded, or dead marine mammal is found by Marine Corps personnel that is not in the vicinity of, or found during or shortly after operations, the Marine Corps personnel would report the same

information as listed above as soon as operationally feasible and clearance procedures allow.

General Notification of a Ship Strike

In the event of a vessel strike, at any time or place, the Marine Corps shall do the following:

* Immediately report to us the species identification (if known), location (lat/long) of the animal (or the strike if the animal has disappeared), and whether the animal is alive or dead (or unknown);
* Report to us as soon as operationally feasible the size and length of the animal, an estimate of the injury status (e.g., dead, injured but alive, injured and moving, unknown, etc.), vessel class/type and operational status;
* Report to us the vessel length, speed, and heading as soon as feasible; and
* Provide us a photo or video, if equipment is available.

Estimated Take by Incidental Harassment

The following provides the Marine Corps' model for take of dolphins from explosives (without consideration of mitigation and the conservative assumption that all explosives would land in the water and not on the targets or land) and potential for direct hits and our analysis of potential harassment from small vessel and aircraft operations.

Acoustic Take Criteria

For the purposes of an MMPA incidental take authorization, three levels of take are identified: Level B harassment; Level A harassment; and mortality (or serious injury leading to mortality). The categories of marine mammal responses (physiological and behavioral) that fall into harassment categories were described previously in this notice. A method to estimate the number of individuals that will be taken, pursuant to the MMPA, based on the proposed action has been derived. To this end, we use acoustic criteria that estimate at what received level Level B harassment, Level A harassment, and mortality (or serious injury) of marine mammals would occur. The acoustic criteria for underwater detonations are comprehensively explained in our proposed and final rulemakings for the U.S. Navy's Cherry Point Range Operations (74 FR 11057; 74 FR 28370). We summarize them here:

Criteria and thresholds for estimating the exposures from a single explosive activity on marine mammals were established for the Seawolf Submarine Shock Test Final Environmental Impact Statement (FEIS) ("Seawolf") and subsequently used in the USS Winston S. Churchill (DDG 81) Ship Shock FEIS ("Churchill") (DoN, 1998 and 2001). We adopted these criteria and thresholds in final rule on the unintentional taking of marine animals occurring incidental to the shock testing which involved large explosives (65 FR 77546; December 12, 2000). Because no large explosives (greater than 1000 lbs NEW) would be used at Cherry Point during the specified activities, a revised acoustic criterion for small underwater explosions (i.e., 23 pounds per square inch [psi] instead of previous acoustic criteria of 12 psi for peak pressure over all exposures) has been established to predict onset of TTS.

I.1. Thresholds and Criteria for Injurious Physiological Impacts

I.1.a. Single Explosion

For injury, NMFS uses dual criteria, eardrum rupture (i.e. tympanic-membrane injury) and onset of slight lung injury, to indicate the onset of injury. The threshold for tympanic-membrane (TM) rupture corresponds to a 50 percent rate of rupture (i.e., 50 percent of animals exposed to the level are expected to suffer TM rupture). This value is stated in terms of an Energy Flux Density Level (EL) value of 1.17 inch pounds per square inch (in-lb/in2), approximately 205 dB re 1 microPa ^{2} - sec.

The threshold for onset of slight lung injury is calculated for a small animal (a dolphin calf weighing 26.9 lbs), and is given in terms of the "Goertner modified positive impulse," indexed to 13 psi-msec (DoN, 2001). This threshold is conservative since the positive impulse needed to cause injury is proportional to animal mass, and therefore, larger animals require a higher impulse to cause the onset of injury. This analysis assumed the marine species populations were 100 percent small animals. The criterion with the largest potential impact

range (most conservative), either TM rupture (energy threshold) or onset of slight lung injury (peak pressure), will be used in the analysis to determine Level A exposures for single explosive events.

For mortality and serious injury, we use the criterion corresponding to the onset of extensive lung injury. This is conservative in that it corresponds to a 1 percent chance of mortal injury, and yet any animal experiencing onset severe lung injury is counted as a lethal exposure. For small animals, the threshold is given in terms of the Goertner modified positive impulse, indexed to 30.5 psi-msec. Since the Goertner approach depends on propagation, source/animal depths, and animal mass in a complex way, the actual impulse value corresponding to the 30.5 psi-msec index is a complicated calculation. To be conservative, the analysis used the mass of a calf dolphin (at 26.9 lbs) for 100 percent of the populations.

I.1.b. Multiple Explosions

For multiple explosions, the Churchill approach had to be extended to cover multiple sound events at the same training site. For multiple exposures, accumulated energy over the entire training time is the natural extension for energy thresholds since energy accumulates with each subsequent shot (detonation); this is consistent with the treatment of multiple arrivals in Churchill. For positive impulse, it is consistent with the Churchill final rule to use the maximum value over all impulses received.

I.2. Thresholds and Criteria for Non-Injurious Physiological Effects

To determine the onset of TTS (non-injurious harassment)--a slight, recoverable loss of hearing sensitivity, there are dual criteria: an energy threshold and a peak pressure threshold. The criterion with the largest potential impact range (most conservative), either the energy or peak pressure threshold, will be used in the analysis to determine Level B TTS exposures. We refer the reader to the following sections for descriptions of the thresholds for each criterion.

I.2.a. Single Explosion--TTS-Energy Threshold

The TTS energy threshold for explosives is derived from the Space and Naval Warfare Systems Center (SSC) pure-tone tests for TTS (Schlundt et al., 2000; Finneran and Schlundt, 2004). The pure-tone threshold (192 dB as the lowest value) is modified for explosives by (a) interpreting it as an energy metric, (b) reducing it by 10 dB to account for the time constant of the mammal ear, and (c) measuring the energy in 1/3-octave bands, the natural filter band of the ear. The resulting threshold is 182 dB re 1 microPa ^{2} -sec in any 1/3-octave band.

I.2.b. Single Explosion--TTS-Peak Pressure Threshold

The second threshold applies to all species and is stated in terms of peak pressure at 23 psi (about 225 dB re 1 [mu]Pa). This criterion was adopted for Precision Strike Weapons (PSW) Testing and Training by Eglin Air Force Base in the Gulf of Mexico (NMFS, 2005). It is important to note that for small shots near the surface (such as in this analysis), the 23-psi peak pressure threshold generally will produce longer impact ranges than the 182-dB energy metric. Furthermore, it is not unusual for the TTS impact range for the 23-psi pressure metric to actually exceed the without-TTS (behavioral change without onset of TTS) impact range for the 177-dB energy metric.

I.3. Thresholds and Criteria for Behavioral Effects

I.3.a. Single Explosion

For a single explosion, to be consistent with Churchill, TTS is the criterion for Level B harassment. In other words, because behavioral disturbance for a single explosion is likely to be limited to a short-lived startle reaction, use of the TTS criterion is considered sufficient protection and therefore behavioral effects (Level B behavioral harassment without onset of TTS) are not expected for single explosions.

I.3.b. Multiple Explosions--Without TTS

For multiple explosions, the Churchill approach had to be extended to cover multiple sound events at the same training site. For multiple exposures, accumulated energy over the entire uninterrupted firing time is the natural extension for energy thresholds since energy accumulates with each subsequent shot (detonation); this is consistent with the treatment of multiple arrivals in Churchill. Because multiple explosions could occur within a

discrete time period, a new acoustic criterion-behavioral disturbance without TTS is used to account for behavioral effects significant enough to be judged as harassment, but occurring at lower noise levels than those that may cause TTS.

The threshold is based on test results published in Schlundt et al. (2000), with derivation following the approach of the Churchill FEIS for the energy-based TTS threshold. The original Schlundt et al. (2000) data and the report of Finneran and Schlundt (2004) are the basis for thresholds for behavioral disturbance without TTS. During this study, instances of altered behavior sometimes began at lower exposures than those causing TTS; however, there were many instances when subjects exhibited no altered behavior at levels above the onset-TTS levels. Regardless of reactions at higher or lower levels, all instances of altered behavior were included in the statistical summary. The behavioral disturbance without TTS threshold for tones is derived from the SSC tests, and is found to be 5 dB below the threshold for TTS, or 177 dB re 1 microPa ^{2} -sec maximum energy flux density level in any 1/3-octave band at frequencies above 100 Hz for cetaceans.

II. Summary of Thresholds and Criteria for Impulsive Sounds

The effects, criteria, and thresholds used in the assessment for impulsive sounds are summarized in Table 8. The criteria for behavioral effects without physiological effects used in this analysis are based on use of multiple explosives from live, explosive firing at BT-9 only; no live firing occurs at BT-11.

Take from Explosives

The Marine Corps conservatively modeled that all explosives would detonate at a 1.2 m (3.9 ft) water depth despite the training goal of hitting the target, resulting in an above water or on land explosion. For sources that are detonated at shallow depths, it is frequently the case that the explosion may breech the surface with some of the acoustic energy escaping the water column. The source levels presented in the table above have not been adjusted for possible venting nor does the subsequent analysis take this into account. Properties of explosive sources used at BT-9, including NEW, peak one-third-octave (OTO) source level, the approximate frequency at which the peak occurs, and rounds per burst are described in Table 9. Refer to Table 10 for distances to our harassment threshold levels from these sources.

To calculate take, the distances to which animals may be harassed were considered along with dolphin density. The density estimate from Read et al. (2003) was used to calculate take from munitions firing. As described in the Description of Marine Mammals in the Area of the Specified Activity section, this density, 0.183/km ^{2} , was derived from boat based surveys in 2000 which covered all inland North Carolina waters. Note that estimated density of dolphins at BT-9 and BT-11, specifically, were calculated to be 0.11 dolphins/km^2 , and 1.23 dolphins/km^2 respectively (Maher 2003), based on boat surveys conducted from July 2002 through June 2003 (excluding April, May, Sept. and Jan.). However, the USMC chose to estimate take of dolphins based on the higher density reported from the summer 2000 surveys (0.183/km ^{2}). Additionally, take calculations for munition firing are based on 100 percent water detonation, although the goal of training is to hit the targets, and no pre-exercise monitoring or mitigation. Therefore, take estimates can be considered conservative.

Based on dolphin density and amount of munitions expended, there is very low potential for Level A harassment, serious injury, and mortality and monitoring and mitigation measures are anticipated to further negate this potential. Accordingly, we are not proposing to issue these levels of take. As portrayed in Table 9, the largest harassment zone (Level B) is within 209 m of a detonation in water; however, the Marine Corps has implemented a 1,000 m "foul" zone for BT-9 and anywhere within Raritan Bay for BT-11. In total, from firing of explosive ordnances, the USMC is requesting, and NMFS is proposing to issue, the incidental take of 25 bottlenose dolphins from Level B harassment (Table 11).

Take from Direct Hit

The potential risk of a direct hit to an animal in the target area is estimated to be so low it is discountable. A Range Air Installation Compatible Use Zone (RAICUZ) study generated the surface area or footprints of weapon impact areas associated with air-to-ground ordnance delivery (USMC 2001). Statistically, a weapon safety footprint describes the area needed to contain 99.99 percent of initial and ricochet impacts at the 95-percent confidence interval for each type of aircraft and ordnance utilized on the BTs. At both BT-9 and BT-11 the probability of deployed ordnance landing in the impact footprint is essentially 1.0, since the footprints were designed to contain 99.99 percent of impacts, including ricochets. However, only 36 percent of the weapon footprint for BT-11 is over water in Rattan Bay, so the likelihood of a weapon striking an animal at the BT in Rattan Bay is 64 percent less. Water depths in Rattan Bay range from 3 m (10 ft) in the deepest part of the bay to 0.5 m (1.6 m) close to shore, so that nearly the entire habitat in Rattan Bay is suitable for marine mammal use (or 36 percent of the weapon footprint).

The estimated potential risk of a direct hit to an animal in the target area is extremely low. The probability of hitting a bottlenose dolphin at the BTs can be derived as follows: Probability = dolphin's dorsal surface area * density of dolphins. The estimated dorsal surface area of a bottlenose dolphin is 1.425 m^2 (or the average length of 2.85 m times the average body width of 0.5 m). Thus, using Read et al. (2003)'s density estimate of 0.183 dolphins/km^2 , without consideration of mitigation and monitoring implementation, the probability of a dolphin being hit in the waters of BT-9 is 2.61 x 10^{-7} and of BT-11 is 9.4 x 10^{-8} . Using the proposed levels of ordnance expenditures at each in-water BT (Tables 4 and 5) and taking into account that only 36 percent of the ordnance deployed at BT-11 is over water, as described in the application, the estimated potential number of ordnance strikes on a marine mammal per year is 0.263 at BT-9 and 0.034 at BT-11. It would take approximately three years of ordnance deployment at the BTs before it would be likely or probable that one bottlenose dolphin would be struck by deployed inert ordnance. Again, these estimates are without consideration to proposed monitoring and mitigation measures.

Take from Vessel and Aircraft Presence

Vessel movement is associated with surface-to-surface exercises, as described in the Specified Activities section above, which primarily occurs within BT-11. The USMC is not requesting takes specific to the act of maneuvering small boats within the BTs; however, NMFS has analyzed the potential for take from this activity. The potential impacts from exposure to vessels are described in the Vessel and Aircraft Presence section above. Interactions with vessels are not a new experience for bottlenose dolphins in Pamlico Sound. Pamlico Sound is heavily used by recreational, commercial (fishing, daily ferry service, tugs, etc.), and military (including the Navy, Air Force, and Coast Guard) vessels year-round. The NMFS' Southeast Regional Office has developed marine mammal viewing guidelines to educate the public on how to responsibly view marine

mammals in the wild and avoid causing a take (http://www.nmfs.noaa.gov/pr/education/southeast). The guidelines recommend that vessels should remain a minimum of 50 yards from a dolphin, operate vessels in a predictable manner, avoid excessive speed or sudden changes in speed or direction in the vicinity of animals, and not to pursue, chase, or separate a group of animals. The Marine Corps would abide by these guidelines to the fullest extent practicable. The Marine Corps would not engage in high speed exercises should a marine mammal be detected within the immediate area of the BTs prior to training commencement and would never closely approach, chase, or pursue dolphins. Detection of marine mammals would be facilitated by personnel monitoring on the vessels and those marking success rate of target hits and monitoring of remote camera on the BTs (see Proposed Monitoring and Reporting section).

Based on the description of the action, the other activities regularly occurring in the area, the species that may be exposed to the activity and their observed behaviors in the presence of vessel traffic, and the implementation of measures to avoid vessel strikes, we determined that it is unlikely that the operation of vessels during surface-to-surface maneuvers will result in the take of any marine mammals, in the form of either behavioral harassment, injury, serious injury, or mortality.

Aircraft would move swiftly through the area and would typically fly approximately 914 m from the water's surface before dropping unguided munitions and above 4,572 m for precision-guided munitions bombing. While the aircraft may approach as low as 152 m (500 ft) to drop a bomb this is not the norm and would never be done around marine mammals. Regional whale watching guidelines advise aircraft to maintain a minimum altitude of 300 m (1,000 ft) above all marine mammals, including small odontocetes, and to not circle or hover over the animals to avoid harassment. Our approach regulations limit aircraft from flying below 300 m (1,000 ft) over a humpback whale (Megaptera novaeangliae) in Hawaii, a known calving ground, and limit aircraft from flying over North Atlantic right whales closer than 460 m (1509 ft). Given that Marine Corps aircraft would not fly below 300 m on the approach, would not engage in hovering or circling the animals, and would not drop to the minimal altitude of 152 m if a marine mammal is in the area, we believe it unlikely that the operation of aircraft, as described above, will result in take of bottlenose dolphins in Pamlico Sound in any manner.

Negligible Impact Analysis and Preliminary Determination

Except with respect to certain activities not pertinent here, the MMPA defines "harassment" as: any act of pursuit, torment, or annoyance which (i) has the potential to injure a marine mammal or marine mammal stock in the wild [Level A harassment]; or (ii) has the potential to disturb a marine mammal or marine mammal stock in the wild by causing disruption of behavioral patterns, including, but not limited to, migration, breathing, nursing, breeding, feeding, or sheltering [Level B harassment].

The NDAA's definition of harassment as it applies to a military readiness activity is: (i) any act that injures or has the significant potential to injure a marine mammal or marine mammal stock in the wild [Level A Harassment]; or (ii) any act that disturbs or is likely to disturb a marine mammal or marine mammal stock in the wild by causing disruption of natural behavioral patterns, including, but not limited to, migration, surfacing, nursing, breeding, feeding, or sheltering, to a point where such behavioral patterns are abandoned or significantly altered [Level B Harassment].

We propose to authorize take by Level B harassment for the proposed training operations. Acoustic stimuli generated during training operations may have the potential to result in the behavioral disturbance of some marine mammals. There is no evidence that planned activities could result in injury, serious injury, or mortality within the specified geographic area for the requested authorization. The required mitigation and monitoring measures would minimize any potential risk for serious injury or mortality.

Pursuant to our regulations implementing the MMPA, an applicant is required to estimate the number of animals that will be "taken" by the specified activities (i.e., takes by harassment only, or takes by harassment, injury, and/or death). This estimate informs the analysis that we must perform to determine whether the activity will have a "negligible impact" on the species or stock. We have defined "negligible impact" in 50 CFR 216.103 as:

"an impact resulting from the specified activity that cannot be reasonably expected to, and is not reasonably likely to, adversely affect the species or stock through effects on annual rates of recruitment or survival." A negligible impact finding is based on the lack of likely adverse effects on annual rates of recruitment or survival (i.e., population-level effects). An estimate of the number and manner of takes, alone, is not enough information on which to base a negligible impact determination. We must also consider other factors, such as the likely nature of any responses (their intensity, duration, etc.), the context of any responses (critical reproductive time or location, migration, etc.), or any of the other variables mentioned in the first paragraph (if known), as well as the number and nature of estimated Level A takes, the number of estimated mortalities, and effects on habitat.
The Marine Corps has been conducting gunnery and bombing training exercises at BT-9 and BT-11 for several years and, to date, no dolphin injury, serious injury, or mortality has been attributed these military training exercises. The Marine Corps has a history of notifying the NMFS stranding network when any injured or stranded animal comes ashore or is spotted by personnel on the water. Therefore, stranded animals have been examined by stranding responders, further confirming that it is unlikely training contributes to marine mammal injuries or deaths. Due to the implementation of the aforementioned proposed mitigation measures, no take by Level A harassment or serious injury or mortality is anticipated nor would any be authorized in the IHA. We are proposing; however, to authorize 25 Level B harassment takes associated with training exercises.
The Marine Corps has proposed a 1000 yard (914 m) safety zone around BT-9 despite the fact that the distance to NMFS explosive Level B harassment threshold is 228 yards (209 m). They also would consider an area fouled if any dolphins are spotted within Raritan Bay (where BT-11 is located). The Level B harassment takes allowed for in the IHA would be of very low intensity and would likely result in dolphins being temporarily behaviorally affected by bombing or gunnery exercises. In addition, takes may be attributed to animals not using the area when exercises are occurring; however, this is difficult to calculate. Instead, we look if the specified activities occur during and within habitat important to vital life functions to better inform its negligible impact determination.
Read et al. (2003) concluded that dolphins rarely occur in open waters in the middle of North Carolina sounds and large estuaries, but instead are concentrated in shallow water habitats along shorelines. However, no specific areas have been identified as vital reproduction or foraging habitat. Scientific boat based surveys conducted throughout Pamlico Sound conclude that dolphins use the areas around the BTs more frequently than other portions of Pamlico Sound (Maher, 2003) despite the Marine Corps actively training in a manner identical to the specified activities described here for years.
As described in the Affected Species section of this notice, bottlenose dolphin stock segregation is complex with stocks overlapping throughout the coastal and estuarine waters of North Carolina. It is not possible for the Marine Corps to determine to which stock any individual dolphin taken during training activities belong as this can only be accomplished through genetic testing. However, it is likely that many of the dolphins encountered would belong to the NNCE or SNCE stock. These stocks have a population estimate of 1,387 and 2,454, respectively. We are proposing to authorize 25 takes of bottlenose dolphins in total; therefore, this number represents 1.8 and 1.0 percent, respectively, of those populations. This species is not listed as threatened or endangered under the ESA
Based on the analysis contained herein of the likely effects of the specified activity on marine mammals and their habitat, and taking into consideration the implementation of the mitigation and monitoring measures, we preliminarily find that the specified USMC AS Cherry Point BT-9 and BT-11 training activities will result in the incidental take of marine mammals, by Level B harassment only, and that the total taking from will have a negligible impact on the affected species or stocks.
Subsistence Harvest of Marine Mammals
Marine mammals are not taken for subsistence uses within Pamlico Sound; therefore, issuance of an IHA to the USMC for MCAS Cherry Point training exercises would not have an unmitigable adverse impact on the

availability of the affected species or stocks for subsistence use.
Endangered Species Act (ESA)
No ESA-listed marine mammals are known to occur within the action area. Therefore, there is no requirement for NMFS to consult under Section 7 of the ESA on the issuance of an Authorization under section 101(a)(5)(D) of the MMPA. However, ESA-listed sea turtles may be present within the action area.
On September 27, 2002, NMFS issued a Biological Opinion (BiOp) on Ongoing Ordnance Delivery at Bombing Target 9 (BT-9) and Bombing Target 11 (BT-11) at Marine Corps Air Station, Cherry Point, North Carolina. The BiOp, which is still in effect, concluded that that the USMC's proposed action will not result in adverse impacts to any ESA-listed marine mammals and is not likely to jeopardize the continued existence of the endangered green turtle (Chelonia mydas), leatherback turtle (Dermochelys coriacea), Kemp's ridley turtle (Lepidochelys kempii), or threatened loggerhead turtle (Caretta caretta). The proposed IHA will not result in effects beyond those considered in the 2002 BiOp and NMFS does not anticipate the need for further Section 7 consultation for the Authorization or the underlying activities proposed by the Marines. No critical habitat has been designated for these species in the action area; therefore, none will be affected.
National Environmental Policy Act (NEPA)
On February 11, 2009, the Marine Corps issued a Finding of No Significant Impact for its Environmental Assessment (EA) on MCAS Cherry Point Range Operations. Based on the analysis of the EA, the Marine Corps determined that the proposed action will not have a significant impact on the human environment. We adopted the Marine Corps' EA and signed a Finding of No Significant Impact on August 31, 2010. We have again reviewed the proposed application and preliminarily determined that there are no substantial changes to the proposed action or new environmental impacts or concerns. Therefore, we have determined that a new or supplemental EA or Environmental Impact Statement is likely unnecessary. Before making a final determination in this regard, we will review public comments and information submitted by the public and others in response to this notice. The EA referenced above is available for review at http://www.nmfs.noaa.gov/pr/permits/incidental.htm.
Dated: March 26, 2013.

Full text: W ith the start of university and international cricket happening in Dunedin in the past two weeks, a lot of partying has made the news. One of the things that has always amazed me about parties is how we can tune-in to a single conversation, while filtering out the music, clinking of glasses and other conversations.
But this ability is surprisingly difficult for people with hearing impairments, even if they have hearing aids. They

often find it difficult to pay attention to a single sound and filter out the noise. My father complains that his hearing aids actually seem to make it worse, because he can hear even more irrelevant noise. His solution is to take his hearing aids out, but that just removes him from the conversation. And that doesn't sound very nice to me.
The "cocktail party problem" is the name scientists have given to our ability to tune-in to just one speaker at a noisy gathering, and it has puzzled scientists for more than 60 years. Exciting new neuroscience research suggests that the brain is able to recognise and filter out irrelevant noise, even before it comes to our attention.
Study participants simultaneously watched two videos of people telling a story and were asked to concentrate on only one of them. While participants were doing this, the researchers recorded their brain activity. With the assistance of some sophisticated kit and clever mathematical computation, researchers were able to track the information from the two videos as it travelled through the subjects' brains. They found evidence that both stories were heard. That is, the actual sounds of each story entered the brain in the same way.
This makes sense because we can hear all the sounds at a party, but only pay attention to some of them.
Researchers then looked at regions of the brain that are known to be involved with "higher order" functions. These are the things that we sometimes think of as uniquely human, such as using and understanding language. These areas of the brain showed only the activity patterns of the story that the subjects were asked to pay attention to. The brain activity patterns coming from the irrelevant story simply did not exist at these higher levels. This is the first-ever evidence that we may be able to direct the flow of information into our brains.
Now that scientists know the places in the brain that only the important information gets to, they can map the pathway that it takes. More importantly, they can now ask what happens to the unimportant information. Why doesn't it get to the same place? How is it filtered out? And why is the filter broken in some people? Design and evaluation of tinnitus synthesis methods: From spectral to spatial matching

Author: Bertet, Stéphanie;Baskind, Alexis;Londero, Alain;Bonfils, Laure;Viaud-Delmon, Isabelle;Warusfel, Olivier

Publication info: American Journal of Otolaryngology 34.2 (2013): 121-32.
ProQuest document link

Abstract: Purpose
This study was designed to investigate methods to help patients suffering from unilateral tinnitus synthesizing an auditory replica of their tinnitus.
Materials and methods
Two semi-automatic methods (A and B) derived from the auditory threshold of the patient and a method (C) combining a pure tone and a narrow band-pass noise centred on an adjustable frequency were devised and rated on their likeness over two test sessions. A third test evaluated the stability over time of the synthesized tinnitus replica built with method C, and its proneness to merge with the patient's tinnitus. Patients were then asked to try and control the lateralisation of this single percept through the adjustment of the tinnitus replica level.
Results
The first two tests showed that seven out of ten patients chose the tinnitus replica built with method C as their

preferred one. The third test, performed on twelve patients, revealed pitch tuning was rather stable over a week interval. It showed that eight patients were able to consistently match the central frequency of the synthesized tinnitus (presented to the contralateral ear) to their own tinnitus, which leaded to a unique tinnitus percept. The lateralisation displacement was consistent across patients and revealed an average range of 29dB to obtain a full lateral shift from the ipsilateral to the contralateral side.

Conclusions

Although spectrally simpler than the semi-automatic methods, method C could replicate patients' tinnitus, to some extent. When a unique percept between synthesized tinnitus and patients' tinnitus arose, lateralisation of this percept was achieved.

Full text: 1 Introduction

Subjective tinnitus (i.e. perception of a sound without any external or internal auditory stimulation [1]) is a highly prevalent otoneurological symptom for which there is currently no causally oriented treatment [2] . In the USA up to 16 % of the general population has been found to suffer from frequent tinnitus [3] . Although most people can become accustomed to a tinnitus percept, clinical subjective tinnitus can significantly alter one's quality of life [4] . In the most recent pathophysiological models, tinnitus was no longer considered to originate in the cochlea but was rather seen to be a consequence of neuroplastic changes in the central auditory and non auditory pathways occurring as a consequence of sensory deprivation after cochlear damage [5,6] . Indeed, the clinical patterns of tinnitus were similar to those observed in chronic pain following amputation [7,8] , where conditioning techniques using virtual reality (VR) have been shown both to be theoretically interesting and effectively useful [9] . Hypothetically, if the patients manage to transfer their subjective auditory perception to a real sound similar to their tinnitus percept, it could allow them to take control of the tinnitus-like percept they manipulate, see and hear.

The aim of the presented study was to build a tinnitus avatar that would be further exploited in a therapeutic protocol, where the patient would be invited to manipulate his/her tinnitus avatar in a virtual reality environment [10] . This implies creating a "virtual tinnitus" that could be manipulated in the virtual environment. In order to reproduce a realistic sensation, the virtual tinnitus needs to "imitate" the patient's tinnitus behaviour. Although tinnitus can be perceived inside or outside the head, the majority of tinnitus is unilateral (with a predominance for the left ear) or bilateral [11,12] . To limit the number of different factors, only patients with an unilateral tinnitus were recruited in the presented study.

In headphone listening conditions, a sound source played over headphones can be externalized using head related transfer function (HRTF) but can also move "inside the head" by an action of source lateralisation. In normal headphone listening conditions, diotic signals give rise to a unique auditory event located in the centre of the head. Increasing the gain of one of the signals "pushes" the sound image towards the corresponding ear. If dichotic signals, differing in pitch, are presented, then the fusion does not occur any more and two separate auditory events are heard respectively in the right and left ear. Lackner [13] conducted an experiment on six patients that were suffering from tinnitus resulting from cortical and peripheral damages. The central frequency of their tinnitus was matched with an external sound played in the contralateral ear (opposite ear of the ear where the tinnitus is located - stated as ipsilateral ear). For four of them, the internal and the external signals fused and therefore resulted in a unique percept. Changing the gain of the external signal changed the perceived position of this percept. This experiment was done using only one pure frequency tone that reproduced part of the tinnitus spectrum.

The tinnitus sensation is complex to characterize because only the patient suffering from tinnitus can recreate a similar sound with synthetic signals that do not necessarily "sound" like his/her sensation. The tools can only help him/her in this recreation. Nageris et al. [12] reported judiciously that the variability of the measured tinnitus

pitch was dependent on different factors such as: test procedure, homogeneity of the population sample and origin of the tinnitus. Indeed, different signals and methods have been carried out to characterize tinnitus dominant pitch. Although the repeated within-session pitch matching was shown to be comparable with that of external tones matching, tinnitus pitch matching was shown to vary significantly across sessions [14-16] . In most studies, tinnitus characterisation would consist of adjusting a pure tone frequency to match the dominant pitch of the perceived tinnitus [12-15,17-20] . Different procedures have been used to help the patient to create a replica of their tinnitus, avoid octave error and work on the reliability of their results. In [13] , patients used a method of adjustment where the frequency of the external tone was swept by the experimenter. Tyler and Conrad-Armes [14] advised to use either method of adjustment or adaptive method by "bracketing" the tinnitus pitch. Mitchell et al. [19] and Penner and Klafter [18] worked on pure tone matching using a frequency adaptive forced-choice-double-staircase procedure. Moore et al. [20] used a bracketing method centred on a previously defined frequency. Most of these methods are time-consuming therefore tiring for the patient (Tyler suggested repeating the procedure at least seven times to have a final result) and, most of the time, needs an external examiner to manage the frequency change. Furthermore, the reliability of tinnitus matching with a single pure tone might be inappropriate to represent the timbre of tinnitus [21] . In order to better portray the complex tinnitus sensation, Norena [16] then Roberts [22] proposed a method to estimate the various components contributing to the global tinnitus sensation. In [16] , ten subjects were asked to rate successively the similarity of their tinnitus against a collection of pure tones ranging from 500 Hz to 14 kHz. A combination of these tones weighted by their respective ratings forms what the authors named "the internal spectrum of perceived tinnitus". It was observed that this estimated internal spectrum roughly followed the frequency profile of the auditory threshold with the main components falling into the hearing loss area. Using a similar approach, Roberts et al. [22] proposed to characterize the tinnitus spectrum using eleven sound clips with a central frequency ranging from 0.5 kHz to 12 kHz. For each subject, the bandwidth of these eleven sound clips (pure tone, 5 % of the centre frequency (CF) at ?10 dB, 15 % of CF at ?10 dB) was chosen according to a self-described tinnitus timbre as being respectively "tonal", "ringing" or "hissing". The tinnitus spectrum was modelled through the individual rating of these eleven sounds with the tinnitus as the comparison using the Borg CR100 scale [23] . Conducted with 32 subjects, the study also revealed that the tinnitus spectrum spanned the region of the hearing loss [22] . In these two methods the patients had to adjust manually defined frequency tones. Conclusions from Norena et al. and Roberts et al. suggest that an automatic or semi-automatic tinnitus synthesis method could be derived from the measurement of the subject's auditory threshold shift. The tinnitus matching process could then be simplified and reliable, if the tinnitus sensation is stable.

In the presented study, three methods of creating a credible auditory image (tinnitus avatar) of the patient's perceived tinnitus were investigated. The reliability was then investigated by a test-retest of the synthesized tinnitus built with one of the methods. Finally, if the combination of synthesized tinnitus and the patient's tinnitus gave rise to a unique percept, then the apparent lateralisation of this percept was investigated.

2 Materials and methods

In the following section, the three methods as well as the three subjective test procedures are presented. The study received the approval of the local ethical committee (Comité de Protections des Personnes Ile de France VIII, Boulogne Billancourt, France).

2.1 Tinnitus synthesis methods

Three adaptive subject-driven methods have been devised to create an acoustic replica of the patient's tinnitus. The devised methods were based on a combination of two complex stimuli respectively composed of a sinusoidal component and a filtered noise component. This combination was meant to allow the patient to tune between different tinnitus sensations, often reported in the literature as sounding "tonal" or "ringing", "hissing", "whooshing", etc.

All tinnitus synthesis methods presented below used the contralateral ear to drive the tinnitus matching. This

choice was in line with the CIBA recommendation that advocates the use of the contralateral ear for pitch matching if the tinnitus is unilateral [15] .

2.1.1 Auditory threshold measurement

The tinnitus synthesis methods A and B described below were based on the estimated auditory threshold curve of the patient. Consequently, audiograms of the patients have been systematically measured for both ears before inviting them to tune their respective avatar with the different methods.

An audiogram program has been designed to estimate the hearing curve of the patient using an ascendant method. Sequences of one-second fixed-frequency pure tone separated by one second of silence were presented to the patient with a step increase of 3 dB until he/she indicated hearing the sound by pressing the space-bar of the keyboard. The stimulated ear and the frequency were randomly chosen. Once the sound was detected, another tone was presented to the patient until all the measurements were done. The hearing threshold was measured from 125 Hz to 16 kHz. Measured frequencies corresponded to the frequency distribution defined in ISO 389-1 [24] complemented with the frequency distribution defined in ISO 389-5 [25] norms in order to cover the range from 125 Hz to 16 kHz. From 125 Hz to 8 kHz, frequencies were roughly distributed in 1/3 octave band. From 8 kHz to 16 kHz, frequencies were distributed in 1/6 octave band.

2.1.2 Semi automatic methods A and B

The assumption behind the design of method A and B was based on Norena's conclusion that the tinnitus' internal spectrum mirrors the frequency profile of the auditory loss of the ipsilateral ear, i.e. the ear where the tinnitus was located. For both methods, the synthetic tinnitus was a combination of two complex stimuli. The first stimulus was composed of a series of sinusoids and the second was a broadband filtered noise. The frequency content of the tinnitus was automatically built and the only task of the patient was to determine the relative gain of the sinusoid aggregate stimulus and of the noise stimulus (one slider controlling the balance between both components). A global gain slider allowed for the matching of the overall signal level to the tinnitus loudness.

2.1.2.1 Method A

The two components were sculpted in frequency to follow the auditory threshold curve (in dB SPL) of the ipsilateral ear. The frequencies of the sinusoids were those used in the auditory threshold measurement procedure. Their relative gains fitted the corresponding auditory thresholds. The frequency envelope of the filter applied to the noise stimulus component was derived from the same auditory threshold curve using linear interpolation between the different measured frequencies. Method A took the ipsilateral auditory threshold curve as the basis of the tinnitus reproduction. Different typologies of hearing loss were equally considered. Indeed, method A weighted equivalently a unilateral notch present on the ipsilateral ear, and a symmetrical hearing impairment.

2.1.2.2 Method B

In method B, it was hypothesized that the analysis of the auditory threshold asymmetry between the two ears may be used as an indicator of the tinnitus' internal spectrum. Accordingly, the tinnitus avatar spectrum built with method B aimed at mirroring this asymmetry. The relative weight of the sinusoids and the noise filter envelope were built upon the auditory thresholds difference (in dB) between the ipsilateral and the contralateral ears. As for method A, the frequency profile was fixed and the patients were only asked to adjust a slider controlling the level balance between the two components and a global gain slider to match the overall signal level to the loudness of the tinnitus.

2.1.3 "Manual method" C

Method C was close to single pitch matching. Pitch matching has often been based on adaptive procedure or bracketing, with fixed discretized frequency, sometimes managed by instructor. In this case, the patients were asked to span the frequency range to find the matching frequency. The synthetic tinnitus was composed of two stimuli: a pure tone and a 1/6 octave band noise centred on a single and adjustable frequency. The band-pass filter was either implemented using a bi-quadratic parametric filter or in the Fourier domain, using a 1/6 octave

band rectangular window. Patients were invited to synthesize the tinnitus avatar by adjusting the central frequency common to both components, their relative gains and a global level.

2.2 Test session 1

This first test session was intended to gather preliminary observations about the different tinnitus synthesis methods. Objective data was collected about the different control parameters tuned by the patients together with their spontaneous comments about the task, the overall similarity of the created tinnitus avatars and the preferred tinnitus avatar (i.e. the one that sounds the most like their tinnitus). The whole session lasted from forty-five minutes to one hour.

2.2.1 Patients

Ten patients (two females, eight males) aged between 26 and 60 (mean 41) and reporting tonal and stable unilateral tinnitus (five left and five right) were involved in a tinnitus avatar synthesis session where they could create their tinnitus avatar using the three methods A, B and C successively.

2.2.2 Apparatus

Both the audiogram and tinnitus matching procedures were performed on a Mac Book Pro equipped with an external RME Fireface 400 sound card set at 44.1 kHz sampling rate. The methods were implemented using MAX/MSP software. Audiogram measurements and test session 1 were performed with Koss R80 headphones. The total electro-acoustic chain comprising the computer, the sound card and the headphones was calibrated using a B&K artificial ear in order to derive the dB FS to dB SPL conversion curve.

For each synthesis method, a simple graphical user interface (GUI) was designed to help the patient to tune the different method parameters. The GUI consisted of different virtual sliders represented on the screen, which the patient controlled with the mouse.

Once the patient was satisfied with the tinnitus matching, an excerpt of 10 seconds was saved in an audio sound file in order to allow for its subjective evaluation in the different test sessions. Sound files were encoded with 24 bits dynamic range and 44.1 kHz sampling rate. In order to better exploit the dynamic of the sound files, signals were amplified before being recorded so as to approach an RMS level of ?10 dB FS. The corresponding gain was saved and compensated for when playing back the sound file, in order to restore the tinnitus avatar to its original level.

2.2.3 Procedure

The session started with the measurement of the auditory threshold curve of the patient on both ears using the procedure described in Section 2.1.1 . Immediately after, the patient proceeded with the creation of his/her tinnitus avatars using the three tinnitus synthesis methods A, B and C (described in Section 2.1.2 and Section 2.1.3) successively. For all patients, the order of the methods was kept the same. Before starting a given method, the patient received explanations about the GUI and the significance of each tuning parameter (virtual sliders controlled with the mouse). Once the tinnitus matching was accomplished, a short sound file excerpt of the tinnitus avatar was automatically recorded. The patient was invited to have a short debriefing with the experimenter, to give oral feedback or any free comments about the task itself or about the global or detailed resemblance between his/her tinnitus and the recently created avatar.

As a last step, after having accomplished the matching using the three creation methods, the patient was invited to compare the three tinnitus avatars and to indicate which was the most similar to his/her tinnitus. To do so, the patient listened alternatively to the three avatar sound files, and was free to switch from one to the other. As during the matching process, the avatars were played back on the contralateral ear. However the patient could not change the playback level, which was set according to what he/she had tuned during the matching step. Once the most resembling tinnitus avatar was chosen, the patient was asked to comment on his/her choice.

2.3 Test session 2

The time interval between the first and second sessions was between two and five months.

The second session was dedicated to the subjective assessment of the tinnitus avatars synthesized during the

first session. As exposed in Section 2.1 , the different synthesis methods were devised to portray individual specificities of the tinnitus spectrum. In order to verify whether these methods actually succeeded in their goals, the patients were invited to compare the likeness of their own tinnitus avatars with that of non-individual avatars such as those that were created by the other patients. Although necessarily based on subjective judgements, and despite a small number of patients, the goal was to obtain some objective quantification of the suitability of the different proposed tinnitus synthesis methods.

2.3.1 Patients

This session involved a subset of five patients who participated in the first session (two females, three males, mean age = 46, age range 34-60) reporting tonal and stable unilateral tinnitus (three left and two right).

2.3.2 Apparatus

The equipment was the same that the one used in test session 1, described in 2.2.2 .

2.3.3 Procedure

Two different tests were organised within the same session, the total duration of which was about thirty minutes. For both tests, twelve stimuli including individual and non-individual tinnitus avatars were presented to each patient. They consisted of a subset of the tinnitus sound files collected during the first session. Three of these stimuli were the individual avatars that the patient had built during the first session with methods A, B and C. The nine others were non-individual, and corresponded to the tinnitus avatars that were respectively built and selected as their best by the other nine patients of the first session. It should be noted that the stimuli corpus presented was different for each patient. Ten stimuli were common to all (the ten best avatars including the patient's own best). Accordingly, they did not necessarily originate from the same synthesis method. Two stimuli were patient specific, i.e. they corresponded to the two other individual avatars that the patient built during the first session but did not select as his/her best.

2.3.3.1 Visual Analogue scale (VAS)

Each stimulus was played back in loop in the contralateral ear and the patient was free to listen to it as long as he/she wanted. The patient was first asked to adjust the level of the tinnitus avatar in accordance to his/her tinnitus. The level was initialized to ?150 dB and the patient could adjust it with a vertical slider represented on a GUI. In order to avoid sound distortion of the avatar and hearing injury, the level was constrained to stay below an upper limit of 0 dB FS (107 dB SPL at 1 kHz) otherwise the tinnitus avatar was simply muted. This precaution was especially important when a patient was adjusting the level of a non-individual tinnitus avatar as his/her hearing threshold may differ from that of the patient who designed it. After matching its level, the patient was asked to rate the level of resemblance of the tinnitus avatar with his/her tinnitus on a VAS (from 0 = completely different to 100 = identical). The adjustment of the signal level and the similarity judgment were made using two vertical faders represented on a GUI. The twelve tinnitus avatars were successively scored using the same procedure. The three avatars created by the patient were presented first followed by the non-individual tinnitus avatars. The patient was not aware of the identity and origin of the tinnitus avatars.

2.3.3.2 Pairwise Comparison test

The twelve stimuli were used in a forced choice pairwise comparison. All stimuli were played back in loop in the contralateral ear using the level tuned by the patient during the VAS test. For each pair the patient could switch freely at any time between both stimuli, but was no longer allowed to modify the level. The patient was invited to select which stimulus from the pair was the most similar to his/her tinnitus. As a full pairwise comparison method with twelve stimuli would have led to a rather tedious task (66 pairs), we restricted the number of pairs. For each patient the three individual avatars were compared to each other (3 pairs), and the three individual avatars were also compared to the other nine non-individual tinnitus avatars (27 pairs), which led to a total of 30 pairs. For each patient the global "preference" score of the different stimuli was obtained by adding the number of times it was chosen, divided by the number of times it was involved in a pairwise comparison (11 times for individual avatars and 3 times for the non-individual ones).

2.4 Test session 3

A third test session investigated, on the one hand, the reproducibility and stability of the tinnitus avatar over a one-week interval and, on the other hand, whether the patient's tinnitus and the tinnitus avatar merged together and gave rise to a unique percept. Based on the observations and results of the first two test sessions (see section 3.1 and 3.2 for details), the preferred method was chosen to be method C. Only this method was used in this third test session.

2.4.1 Patients

A new set of twelve patients (six females and six males) aged from 24 to 69 (mean 45 years) were involved in this third test session. They all reported unilateral tinnitus (six right and six left).

2.4.2 Apparatus

The equipment was similar to the test sessions 1 and 2, apart from the headphones. Test session 3 was performed using BeyerDynamic 990 open headphones which were used during the therapeutic application [10] . The calibration was adapted accordingly.

2.4.3 Procedure

The procedure was conducted in two phases, separated by a one-week interval.

2.4.3.1 First phase

The auditory threshold curve of the patients was first measured on both ears using the audiogram method described in Section 2.1.1 . The patients were then invited to a training task where they had to match two sinusoidal tones in pitch and loudness. A reference tone of fixed frequency was played in the ipsilateral ear. A variable frequency tone was played in the contralateral ear. The task of the patients was to match the pitch and loudness of the variable tone to that of the reference tone by moving sliders integrated in a graphical user interface situated in front of them. The training was repeated for five tones with increasing frequency (500 Hz, 1000 Hz, 2000 Hz, 4000 Hz and 8000 Hz). Once the training was completed, the patients were invited to create a tinnitus avatar (hereafter called C1) with method C as described in Section 2.1.3 .

2.4.3.2 Second phase

One week later, the patients were asked to create a new version (hereafter called C2) of their tinnitus avatar following the same procedure as in the first phase. This was also preceded by a frequency-matching training phase. After creating the new tinnitus avatar, the patients were invited to evaluate the similarity of the C1 and C2 tinnitus avatar versions with their tinnitus. Each avatar was presented to the contralateral ear, and the patients were not allowed to modify its level. The evaluation was performed with two methods.

In the first evaluation method, the patients had to evaluate the similarity of each tinnitus avatar version with their tinnitus using a VAS from 0 ("very different") to 100 ("identical").

In the second evaluation method, the two avatars were compared to each other. The patient could freely switch from one tinnitus avatar version to the other as many times as they wanted. The two versions were denoted "A" and "B" and the patients were not aware of their respective identity. Using a 7-point horizontal scale (from left to right: "A much more similar to the tinnitus than B", "A more similar to the tinnitus than B", "A and B are equivalent", "B more similar to the tinnitus than A", "B much more similar to the tinnitus than A"), the patients were asked to judge the similarity according to three criteria: "global similarity", "pitch similarity", "loudness similarity".

A final test was performed in which the patients were asked to choose their preferred tinnitus avatar version (C1 or C2) and check if the combination of the tinnitus avatar with their tinnitus was merging into a unique percept. The patients were then successively invited to tune the tinnitus avatar gain in order to localize the tinnitus image at five different lateral directions (an apparent direction towards the contralateral side, an apparent position in between the median plane and the contralateral ear - approximately on the same sagittal plane as the eye, an apparent direction in the median plane, an apparent position in between the median plane and the ipsilateral ear and, an apparent direction towards the ipsilateral side). Each direction tuning was repeated twice.

3 Analysis

Results from the three test sessions are shown in the following sub-sections. Characteristics of the avatars are analysed in pitch and loudness. The scores of the different avatar ratings are displayed in cumulated distributions. For the test sessions 1 and 2, cumulative distribution values were calculated for each method and compared to each other. A cumulative distribution "smaller" than another means that the distribution is concentrated on higher scores and thus indicates a better merit of the corresponding method. A non-parametric statistical analysis, the Kolmogorov-Smirnov unilateral test was conducted on score distributions.

3.1 Characteristic of the avatars

From the results of test session 1, spectral parameters of the avatars synthesized by the patient with each method are described in Table 1 . The last row of the table displays the tinnitus considered as preferred by the patient after matching the three avatars.

Fig. 1 shows the spectral profiles of the three different tinnitus avatars synthesized by two patients together with the respective auditory threshold frequency curves of their ipsilateral and contralateral ears. The avatar built with method C had its central frequency defined by the patient. Its central frequency often reached very high values. This observation is in line with previous studies showing that tinnitus matched high frequency tones in up to 88% of subjects in a population displaying high frequency sensorineural hearing loss [26] . For three patients (P4, P9, P10) this frequency was even over 12 kHz. Indeed, in contrast with previous studies [22,27] , the frequency range was not capped at a maximum of 12 kHz in order to stay coherent with the automatic methods A and B, which have built a tinnitus avatar spectrum encompassing the whole frequency range. When comparing the central frequency of the synthesized tinnitus avatars that were built with method C by the ten patients, it was seen that all but one stayed within the same octave band and five out of seven even stayed within an interval of more or less one sixth of an octave. For methods A and B, the avatar spectra were derived from the patient's auditory thresholds. The avatar built with method A followed the hearing loss of the ipsilateral ear; a greater loss implies a higher signal amplitude. As the patient's hearing loss arose mostly at high frequency, method A built stimuli with a spectral profile strongly predominant at high frequencies. Apart from patient P10, all patients exhibited quasi symmetrical loss between ispilateral and contralateral ears. Therefore this high frequency predominance vanished in method B due to the fact that its frequency profile was based on the difference between the ipsilateral ear and the contralateral ear auditory thresholds. Consequently, the tinnitus profile built upon method B tended to emerge at mid frequencies, while the high frequencies remained below the auditory threshold. This tendency was corroborated by the comments of the patients who often judge the tinnitus avatar A as being higher in pitch, or even harsher than tinnitus avatar B. Interestingly, the only patient who selected the tinnitus avatar synthesized with the differential method B exhibited a pronounced auditory threshold asymmetry (cf. patient P10 in Fig. 1).

To evaluate the loudness of the tinnitus sensation, the level of the avatar is expressed in dB SL with respect to the auditory threshold of the contralateral ear (where the avatar was played). As seen in Table 1 , on average, the tinnitus avatar was tuned so that its spectral profile emerged only a few dB (<10 dB) above the contralateral auditory threshold (method A: mean 6 dB (±9.74), method B: mean 6 dB (±7.16), method C: mean 9 dB (±17.62)), as found in [14,20] . However, Table 1 shows that for some avatars, especially those built with method C, the level was much higher or even sometimes lower than the auditory threshold of the contralateral ear. This may come from the fact that the auditory threshold has been sampled only on a limited set of frequencies (every 1/6 octave). In method C, the pitch could be continuously tuned over the entire frequency range. Thus, the correction applied to convert dB FS into dB SL could be inaccurate for the frequencies in between the measured ones, especially in the interpolated frequency regions exhibiting a steep slope. The same phenomenon could have occurred with the noise component of the avatars built with method A and B.

Although the averaged level ratio between the sinusoid component and the noise component was almost balanced for method A and for method B, important variability was observed among patients (method A: mean

?1 dB (±32.38), method B: mean 14 dB (±33.80)). For method C, the noise component was maintained at a very low level, or even muted, especially for the five first patients P1 to P5 (see [Table 1]), that described the noise component with too much low frequency content, and for whom the mean S/N was +48 dB (±33.28). It was suspected that the bi-quadratic filter used to create the band-pass noise was not sharp enough, which could have led to a high risk of the emergence of low frequencies over their contralateral auditory threshold. As a consequence, for the five next patients P6 to P10, the filter was then replaced by a 1/6 octave band rectangular window centred on the same frequency as the sinusoidal component. For patients P6 to P10, who used this more selective band-pass filter, the mean level difference between the sinusoidal and the noise component was reduced to 18 dB (±6.65).

3.2 Choice of the avatar

At the end of session 1, the patients had to choose the avatar that matched best their tinnitus. Out of ten patients, seven selected the tinnitus avatar synthesized with method C as the best matching one, whilst two selected the method A and one selected the method B ([Table 1]).

In session 2, five patients who participated in the first session had to rate individual and non-individual avatars on a VAS and, comparatively by pairs. The idea behind the inclusion of non-individual avatars was to check whether the patients would actually rank higher their own avatars compared to non-individual ones. The global score obtained for the individual tinnitus avatars built with method A, B and C was averaged over five individual judgments, whereas the score for the non-individual avatars was averaged over forty-five (9 ×5). [Fig. 2] displays the distribution of the VAS scores obtained for the different individual avatars A, B and C and the non-individual avatars. In the forced choice pairwise comparison procedure, a preference score was derived by scoring each stimulus of a given pair with '1' if preferred and '0' if not. A global score was obtained for each synthesis method by adding the scores over all pairs and normalising this value by the number of pairs in which it was presented. For both, VAS and pairwise comparison test results, method C obtained better scores than method B (see [Fig. 2]). The cumulative distribution of method C scores was "smaller" than that of method B (Kolmogorov-Smirnov test, $P < .002$), which reflects a better ranking. The cumulative distribution of individual tinnitus avatars built with method C was significantly smaller than that of individual tinnitus avatars built with method A ($P < .02$) for the pairwise comparison test. In contrast, the score distributions of method A and C were not significantly different for the VAS test. However, the cumulative distribution of method C was smaller than that of non-individual tinnitus avatars ($P < .01$), which was not the case of method A ($P = .15$). In other words, when patients judged method C, they preferred their individual tinnitus avatar to non-individual avatars, which was not the case for the other methods A or B.

The non-individual tinnitus avatars included in the test session 2 were the best matching tinnitus avatars chosen by the ten patients of the first test, which means that seven of them belonged to method C (see [Table 1]). The cumulative distribution of the VAS score for individual tinnitus avatars built with method C was compared with the one for non-individual tinnitus avatars restricted to those built with method C. The Kolmogorov-Smirnov unilateral test concluded that the cumulative distribution of the tinnitus avatars C was still smaller than the cumulative distribution of the non-individual tinnitus avatars ($P = .04$). In the pairwise comparison test, the cumulative distribution of the tinnitus avatars built with method C was only marginally smaller than that of non-individual avatars ($P = .08$). As observed before with the analysis of the VAS scores, this tendency was likely to come from the fact that non-individual avatars were mainly built with method C (seven out of ten), and that all these tinnitus avatars were homogeneously tuned in frequency.

With both evaluation methods, the scores of the individual tinnitus avatars synthesized with method C were shown significantly higher than the scores obtained with non-individual avatars. This revealed a superior ability of method C to preserve the individual characteristics of the patient's tinnitus. However, when the non-individual avatars were restricted to those built with method C, this difference tended to vanish (only significant in the VAS test), and may have resulted from the homogeneous frequency tuning observed among all tinnitus avatars built

by the patients involved in these test sessions.

3.3 Stability over time

Test session 3 concentrated on evaluating the likeness of avatars created with method C over two sessions. Two ratings were used: absolute scale (VAS) and comparison of the two created avatars.

3.3.1 VAS judgements of C1 and C2

Fig. 3 displays the individual VAS scores of the two tinnitus avatar versions created by each patient within a one week interval. The distribution of the individual scoring differences between the first and the second tinnitus avatars was also compared to a normal distribution to investigate the patient's consistency in tuning his/her tinnitus.

The Kolmogorov-Smirnov test showed that the distribution of individual score differences was significantly lower than would be expected with a normal distribution (P <.02), which indicates that each patient showed a preference for the most recently tuned tinnitus avatar, rating it higher than that tuned a week earlier.

3.3.2 Preference judgement of C1 and C2

In order to gain a better insight into the perceptual dimensions that could explain the scoring, the patients were invited to rate their preference by comparing C1 and C2 (i.e. the tinnitus avatars that matched their tinnitus better) on a 7-point scale (from "A much more similar to the tinnitus than B" to "B much more similar to the tinnitus than A"). The test was repeated three times, each time with a different instruction, judging the similarity to their tinnitus according to a "global likeness", a "spectral likeness", or an "intensity likeness". From this data, a preference score was derived on a scale ranging from ?3 (first avatar much more similar) to +3 (second avatar much more similar). The cumulative distribution of these preference scores was then compared to a normal distribution. Fig. 4 displays the individual responses of the patients together with the cumulative distribution curves of the preference scores derived from the test. According to the Kolmogorov-Smirnov test, the distribution of the preference score for the global likeness was not significantly different from a normal distribution (P = .48), the distribution of the preference score for the spectral likeness was marginally smaller than the normal distribution (P = .04), and the preference score for the intensity likeness was significantly smaller than the normal distribution (P = .003). There was no significant global preference towards the most recent avatar, however, when orienting the judgment on the spectral matching and on the intensity matching there was a significant preference towards the most recent tinnitus avatar, especially for the intensity matching.

3.3.3 Frequency tuning consistency between the two tinnitus avatars

The objective consistency of the patients' frequency tuning between the two tinnitus avatars were then compared. Fig. 5 displays the histogram of the central frequency ratio between the second and the first avatars, expressed on a 1/6 octave band logarithmic scale. Values are mainly clustered around 0, corresponding to a ratio of 1 between the two central frequencies (+/? 1/6 octave), and 6 corresponding to a central frequency of the second avatar one octave above the central frequency of the first avatar (+/? 1/6 octave). This means that most of the patients tuned the second avatar either very close to the first one (+/? 1/6 octave) or one octave above (+/? 1/6 octave). This tendency suggests that patients were relatively consistent in their frequency tuning, although they may have been confused with octave interval difference.

3.4 Spatial fusion and percept lateralisation

Out of twelve patients in the test session 3, eight reported that their tinnitus and the avatar were actually merging into a unique percept, while the remaining four patients reported that the tinnitus avatar and the tinnitus were always heard as separate entities whatever the level of the tinnitus avatar.

Fig. 6 displays the results of the lateralisation test in which the patients were invited to tune the gain of the tinnitus avatar to control the apparent spatial location of their tinnitus. The gain was expressed relative to the level tuned to match the perceived loudness of their tinnitus.

Interestingly, the four patients for whom no merging percept could be found all showed large inconsistency in the pitch tuning between their two avatars (one octave or more difference). This could either indicate that they

did not succeed in matching the dominant pitch of their tinnitus or that the method C did not allow them to convincingly portray their tinnitus spectrum. For the eight other patients, the slope of the lateralisation displacement as a function of the tinnitus avatar level was shown to be close to linear and was consistent over the different patients. A linear fit across the individual curves revealed that a range of 29 dB was required to obtain a full lateral shift from the ipsilateral to the contralateral side. It was also interesting to observe the negative intercept: ?6.3 dB (±3.6 dB for 95 % confidence interval). In other words, when the patients were asked to tune the tinnitus avatar level so as to obtain an auditory image in the median plane (0°), this level was significantly below the level they had tuned for the equal loudness judgment.

4 Discussion

The first part of the study intended to determine whether a tinnitus avatar synthesis method based on an automatic spectrum profile reconstruction would succeed in faithfully portraying the internal spectrum of the perceived tinnitus. Method A and B were inspired by previous studies conducted on the internal characterization of tinnitus spectra. In [16,22] , patients were invited to match the loudness and rate the likeness of a series of elementary sound clips to their tinnitus. These sound clips were either pure tones or narrow band-pass noises centred on frequencies regularly spanning the region from 500 Hz to 14 kHz. In both studies, the subjective likeness of these sound clips was shown to roughly follow the auditory threshold of the subject. Methods A and B, devised so as to avoid any frequency-tuning task from the patient, systematised the relationship between the auditory threshold and the tinnitus spectrum. Unfortunately, from the scores collected in both test sessions 1 and 2, it can be concluded that, in their current state, methods A and B did not succeed in convincingly portraying the tinnitus' internal spectrum of the ten patients that have tried them. The attempt of method B to build the tinnitus avatar upon the asymmetry of the hearing threshold profiles did not show any evidence of merit. Method C which proposed a simpler stimulus profile centred on a single frequency, performed comparatively better. Although the stimulus proposed by method C was often judged to lack of complexity and to match only the dominant pitch of the tinnitus, the stimuli built by methods A and B did not automatically render a timbre comparable to the internal tinnitus spectrum.

However, a different approach may improve their behaviour. In the study of Roberts et al. [22] , for instance, it was observed that the likeness matches of pure tones or band-pass noise centred on increasing frequencies show a roll-off above 12 kHz. This property could be taken into account to weight the spectral profile of the sinusoid aggregate and the filtered noise components accordingly. Furthermore, methods A and B were using the defined frequency tones chosen for the audiogram to build the avatar. These predominant frequencies might not match the tinnitus frequency. The frequency steps of method C were not continuous but they were much smaller than one sixth of an octave (from 1 Hz step at 250 Hz to 80 Hz step at 17 kHz, with 5 Hz step at 1 kHz and 25 Hz step at 4 kHz), which allowed the patient to adjust the tone frequency with precision.

Methods A and B were derived from the hearing loss profile of the ipsilateral ear. In some studies, it has been a matter of debate whether the tinnitus' internal spectrum extends over the region of the auditory loss, or if it shows preponderance at or near its edges [20,27-29] . In Sereda's study, the hearing loss profile was determined by regression of the audiometric data. The edge of the hearing loss was defined as the break point of the regression where the audiometric data passed from clinically normal (< 20 dB HL) to impaired (> 20 dB HL). In the presented study, although some of the avatars were falling in the hearing loss (considering Sereda's definition) of the ipsilateral ear of the patient, others had their central frequency at the edge of near the edge of hearing loss. An alternative method could then propose to build the auditory profile according to the frequency derivative of the auditory threshold, in order to focus on the edges of the region of auditory loss. Such a method was implemented during this study but too few patients could test it to allow for its evaluation. However, this method would not have satisfied all patients as four of the patients had normal hearing threshold and no edge or slope or hearing loss could be established.

Test session 3 provided information on the consistency and stability of the tinnitus avatars tuned with method C,

within a one week interval. It was shown that the frequency tuning was fairly consistent between the two sessions, although the pitch of the second session was often tuned one octave (+/? 1/6 octave) above. Several studies [12,14,15,20] pointed out that procedure is important for pitch reproduction stability and octave error, especially because tinnitus matching often involves high pitch matching. Indeed, the human ability to recognize pitch interval was generally considered to degrade rapidly for pure tones above 4-5 kHz, although recent studies have shown that robust pitch information could be conveyed by complex sounds composed of harmonics that are all above 6 kHz [30] . To avoid octave error, Moore proposed a procedure that directed the patient close to the frequency region of the tinnitus. In [20] , the patient listened to defined tones from 0.25 to 8 kHz with one-octave interval and had to indicate the closest tone to his/her tinnitus. The matching task was starting from the selected frequency. However, even with this precaution, octave errors have been listed. In Moore's study, an external administrator was adjusting the frequency to carry out the characterisation of the tinnitus pitch. In our procedure, the patient was allowed and invited to freely span the all frequency range before starting to concentrate on one particular region. Even though a training task was introduced asking the patient to match two external tones in pitch (one tone had fixed frequency), it was not sufficient. The patient should be invited to check whether a pitch one octave higher would match his/her tinnitus' dominant pitch better. Then, the frequency region where the patient searches his/her tinnitus pitch should be limited.

Method C also seemed a good candidate to allow fusion between the tinnitus avatar and the tinnitus. Lackner demonstrated this phenomenon for four patients using pure tones, suggesting that the tinnitus reacted like an external sound [13] . In our study, such merging was observed for the majority of the patients (eight patient out of twelve) using a complex sound, provided that they were consistent in pitch matching. For those patients, it was also possible to steer the lateralisation of this percept by controlling the level of the tinnitus avatar only displayed in the contralateral ear. If confirmed, this would mean that the sub-cortical localisation process is preserved. For instance, the average slope of the lateralisation displacement as a function of the tinnitus avatar level was similar to that reported for the lateral displacement as a function of interaural level difference for normal hearing in dichotic conditions, i.e. 24 dB for a full lateral displacement from left to right [31] .

More intriguing was the significant negative offset of the lateralisation curve (?6.3 dB). Indeed, on average, the median position was obtained with a tinnitus avatar level significantly lower than the equal loudness level. One hypothesis is that this comes from the loudness interaction principle for interaural interaction between the two ears. It has been shown that when an intermittent sound (here the avatar) matches the loudness of a continuous sound (the tinnitus), the loudness of the continuous sound decreases [32] . Although further studies are needed to confirm this observation, it suggests a new approach to characterize the subjective intensity of the tinnitus, where its value would be obtained indirectly from a localisation task rather than a direct loudness evaluation might be relevant. Indeed, a task directly focusing on the tinnitus loudness may bring a general over-estimation as the subjective intensity may be emphasized through an attentional process [33] .

5 Conclusion

The present study aimed at synthesizing an auditory replica of a patient's tinnitus. The attempt to design methods that automatically build the tinnitus' spectral content upon the frequency profile of the patient's auditory threshold did not succeed in convincingly portraying the patient's tinnitus. At least, in their current state, these methods performed less well than a more conventional method based on the combination of a pure tone and a band-pass noise centred at an adjustable single frequency. Although lacking spectral complexity, such a simple tinnitus avatar already shows interesting perceptual properties, provided that the patient is able to match the central frequency consistently. Indeed, a consistent spectral matching, between the patient's tinnitus and the tinnitus avatar played back into the contralateral ear, elicits the spatial fusion between the subjective tinnitus and the external stimulus. Furthermore, adjusting the level of the tinnitus avatar in the contralateral ear can control the apparent lateralisation of this unique percept.

Abstract
In order to improve the efficiency of hearing-aids arithmetic research, a method for hearing loss simulation is proposed. This method is divided into three main steps: frequency shaping, amplitude compression and full phase low-pass filtering. According to the patient's audiogram, frequency shaping can change the amplitude-frequency characteristics of speech, and then form the speech which is audible for hearing loss patients. Amplitude compression is used to compress the dynamic range of patients with sensorineural hearing loss. According to the hearing and pain threshold of hearing impaired subjects, the speech is piecewisely compressed. Especially, patients with hearing loss greater than 70dB may have total loss of their inner hair cell function. For this case, a method which passed the speech through the full phase low-pass filter is adopted. In the comparison test with hearingimpaired subjects, the method for hearing loss simulation has precisely simulated the characteristic of hearing loss for these patients. So this method can be used as an auxiliary method for hearing aids arithmetic research.

Keywords: Hearing Aids, Hearing Loss Simulation, Frequency Shaping, Full Phase Filter

(ProQuest: ... denotes formulae omitted.)

1. Introduction

Simulation technology is widely used in various fields[1,2,3]. Now it is rapidly growing in healthcare professions generally, both for teaching and conveying understanding of disability and disease conditions[4]. The necessary components for the development of such simulations in hearing healthcare-a sufficient understanding of the functional consequences of hearing loss and the technical capability to simulate them-are currently available for improved patient and family counseling, hearing conservation, and professional training.

Firstly, an effective simulation system can provide a realistic demonstration of both the communicative and psychosocial effects of hearing impairment. By listening to speech through the simulated loss, family members would immediately appreciate the importance of lip-reading and speaking clearly in assisting with and improving communication. They would also gain an understanding of the benefits that come with various hearing aid options. Such counseling would enable family members to partake more directly in hearing health decisions. Secondly, one mission of hearing conservation is to educate people about the risks of hearing damage and the protective measures available for minimizing that risk. An accurate and credible demonstration of hearing loss could be an effective motivator in industrial and military hearing conservation as well as public education programs. In these applications, a suitably designed and flexible hearing loss simulator would allow users to switch instantly between normal hearing and any degree of hearing loss. Thirdly, using simulations, students in audiology and deaf-education programs could gain valuable understanding by experiencing the disabilities with which they will work as clinicians and teachers. They would have the opportunity to explore different degrees

and types of hearing loss and to experience the effects of hearing aid options, either in the controlled conditions of a teaching laboratory or in the world outside the lab. Mainstream classroom teachers with deaf or hard-of-hearing students could likewise benefit from demonstrations of difficulties in communication and ways to improve it.

On both psychoacoustic discrimination tasks and speech-reception tests, results from impaired listeners are reasonably well-matched by normal-hearing subjects listening through a simulation that includes only threshold shiftand recruitment[5,6]. In 2006, Sensimetrics Corporation has developed HeLPS (the Hearing Loss and Prosthesis Simulator), a flexible and powerful nonimmersive simulation system designed specifically for audiologic use[7].

Although various hearing loss simulations have been developed over the years, none considers the dead regions at high frequencies as a defining characteristic for hearing loss simulation. Based on researches above mentioned, a method for the simulation of hearing loss is proposed. This method is divided into three main steps: frequency shaping, amplitude compression and full phase low-pass filtering. After the comparison test with hearing-impaired subjects, the method for hearing loss simulation can be used as an auxiliary method for hearing aids arithmetic research.

2. Method for Hearing Loss Simulation

The test speech was processed by three steps: frequency shaping, amplitude compression and low-pass filtering. Frequency shaping was used to simulate the hearing loss of patients according to the real patient's pure tone testing. Amplitude compression was used to restrict the patient's test speech energy according to the dynamic range of patient. Finally, low-pass filtering was used. Before the speech was given to patients, the full phase low-pass filter was adopted. The CF (Cut-offfrequency, CF) of the low-pass filter is set according to the edges of dead regions for hearing-impaired subjects, which ensured that there was no component above the CF within the test signals. This setting was only provided for patients who had dead regions in the high frequency region.

2.1 Frequency shaping

Loudness recruitment is the necessary characteristic for many hearing losses. For those losses that exhibit abnormal loudness growth, loudness recruitment must be included in the simulation. In the paper, frequency shaper is adopted. The principle of frequency shaping is to change the amplitude-frequency characteristics of speech, and then form the speech which is audible for hearing loss patients according to the patient's audiogram. Generally, the audiogram is tested according to 11 frequency points, so this experiment supposed that the hearing level between these frequency points varies linearly. The detailed steps are:

(1) According to the audiogram, the hearing levels $G(f)$ between two testing frequency point are set linearly.

(2) Then the FFT $X (f)$ of the original signal $x(n)$ is calculated, and the hearing levels within the corresponding frequency regions is subtracted from $X (f)$ to obtain $Y(f)$.

(3) Finally, the IFFT is performed on $Y(f)$ to get the frequency-shaped signal $y(n)$.

2.2 Amplitude compression

Many hearing impaired people with sensorineural hearing loss have a reduced dynamic range. Sometimes, the loud speech is acceptable for normal-hearing people, but for some hearingimpaired subjects it is too noisy and uncomfortable. So for high intensity speeches, it does not need to be amplified but to be limited. The hearing range of normal people is about 0~120 dB. Here, 0dB denotes the hearing threshold, while 120dB denotes the paint threshold. Normally, speech pressure level of 90dB makes people uncomfortable.

The typical linear amplitude compression curve is shown in Figure 1. From the figure, when the input signal energy Pin is lower than the threshold Pth, the output signal energy is the same as the input signal energy. The amplitude compression only acts when the input signal energy is higher than Pth. When it exceeds the paint threshold, the output signal energy will remain unchanged. Suppose g is the output gain, the relationship between the output signal $y(n)$ and the input signal $x(n)$ is:

... (1)
The relationship between the output energy and the input energy is F
... (2)
The calculation method for the output gain g is:
... (3)
2.3 Full phase digital filter
High-frequency hearing loss is the most common clinical hearing impairment, which may result from cochlear anatomy, auditory physiology, noise, ototoxic drugs, and age[8,9]. The hearing loss in about 90% children and young people is related with high frequency between 4 kHz and 8 kHz. When hearing losses in one region are higher than 70 dB, this region is called as 'dead region' which means a certain region of the cochlea with nonfunctioning inner hair cells[10]. For this issue, the full phase low-pass filter is adopted. Individuals with no dead regions should obtain a benefit from high-frequency amplification, whereas individuals with dead regions may show no benefit from high-frequency amplification[11,12]. Full phase filter can effectively improve the degradation performance caused by the data truncation. Full phase filter considers all data truncation problem, and then process them respectively. Finally, the processing results are synthesized to obtain the output signal. This method effectively suppresses the spectral leakage problem caused by the data truncation, which make the filter process more continuous. So comparing with traditional filter design method, the full phase low-passing filter has the steep transition zone, big stop-band attenuation and good pass-band ripple. Especially, the full phase characteristic makes each channel signal have no phase distortion after filtering, and then more accurately maintain the amplitude and phase information of the original signal in each channel. Furthermore, the design process is easy to realize.
Similar to traditional method, full phase DFT is also based on frequency sampling. But this design method can more precisely control the frequency response of sampling points. The design steps are[13]:
(1) According to the design requirement, the ideal frequency response ( ) g H w of the zerophase FIR is selected. By zero-phase conditions, its amplitude frequency characteristics are even symmetry with ω=0, π, 2π.

(2) According to the requirements of the CF accuracy and implementation complexity, the length M =2N-1 of full phase DFT digital filter ( ) N h n is set.
(3) ( ) g H w is equally spaced sampled between the interval of [0 ,2π]. Here, the frequency sampling point ω is equal to 2πk/ N (k =0,1,...,N-1) , so the filtering response is:
... (4)
(4) The zero-phase filter ( ) N h n is:
... (5)
3.Simulations
3.1 Subjects
Six hearing-impaired adults, one woman and five men (age: 18-64 years), participate in the study. They were experienced hearing aid users and recruited from the Medical School of Southeast University. Relevant information about all the subjects is provided in Table 1. Their hearing threshold levels, measured via the Interacoustics AD226 audiometer, are shown in Table 1. In addition, six normal-hearing students, two woman and four men (age:20-30 years), also participate in the study. Subjects are not paid for their participation in the experiments. The participation of the subjects in these experiments is in accordance with the 'Guiding principles for research involving human or animal subjects'.
Although there were only six patients in the test, their causes for hearing loss were representative. As shown in Table 1, subject 1 and subject 5 were presbycusis, so their hearing level was gradually decreasing in both ears. The cause for subject 3 was the near constant exposure to the high noise levels, so his level had a V-notch at 6000Hz. The hearing level of drug-induced deafness had a steep drop for both ears, which was in accordance

with that of subject 2. The curve of hearing-impaired patients with congenital or hereditary hearing loss was relatively flat, which was suitable for subject 4 and subject 6. Furthermore, subject 2 and subject 3 had steeply sloping hearing losses.

3.2 Simulations for signal processing

The content of the test speech is "na shi li zh.ng shang y.u d. y. zh.ng shu, b. zh. d. zh., b. zh. d. gan". Every process procedure which simulates the hearing loss of the subject 3 is shown in Figure 2.

3.3 Pure-tone test

Figure 3 shows thresholds for the 6 hearing-impaired subjects for 11 pure-tone signals between 125 and 8000 Hz. Each subject has moderate-to-severe high-frequency hearing loss, with varying degrees of hearing impairment in the low and middle frequencies. Six normal hearing subjects' broadband thresholds were matched to each of the six hearing-impaired subjects' quiet thresholds. To illustrate the precision of the threshold matching, comparisons between normal-hearing listeners and hearing-impaired listeners are shown in Figure 3. The root mean square errors between the normal listener's 11 broadband thresholds and the corresponding hearing-impaired listener's quiet thresholds are also included in each panel.

4.Conclusion

The paper was designed to improve client/family understanding of both hearing loss and available treatment options. The method is divided into three main steps: frequency shaping, amplitude compression and full phase low-pass filtering. Results in pure tone test between normal hearing subjects and hearing-impaired subjects are almost the same. So this method can be a valuable demonstration tool for audiologists working in family counseling, aural rehabilitation, hearing conservation, or professional education.

The use of fractal tones in tinnitus patient management

Author: Sweetow, Robert.

Publication info: Noise & Health 15.63 (Mar 2013): 96-100.
ProQuest document link

Abstract: A variety of noises have been employed for decades in an effort to facilitate habituation, mask, or suppress tinnitus. Many of these sounds have reportedly provided benefit, but success has not been universal. More recently, musical stimuli have been added as a sound therapy component. The potential advantages of using such stimuli, in particular fractal tones, in combination with amplification are discussed in this paper.

Full text: Introduction
Knowledge of tinnitus has progressed over the past two decades from considering tinnitus as a symptom of an ear disorder to the current belief that the generation of tinnitus perception and tinnitus distress, is a function of the brain. This concept has been validated not only by the fact that surgical destruction of the auditory nerve does not necessarily remove the perception of tinnitus, [1],[2],[3] but also by an increasing number of neuroimaging investigations [4],[5],[6] demonstrating widespread activation of neural structures. It is also believed that a key factor in many, if not most, instances of tinnitus is reorganization (neural plasticity) and an increase in central nervous system activity (gain) as a consequence of peripheral attenuation. [7],[8] In fact, the vast majority of individuals with chronic tinnitus show at least some degree of hearing loss. [9] Several investigations have demonstrated hyperactivity within auditory pathway structures such as the dorsal cochlear nucleus and the inferior colliculus. [10],[11],[12]
Attempts have been made to restore this missing acoustic stimulation, at least partially, via amplification,

filtering, or other means in order to overcome the lack of appropriate stimulation from the ear to the damaged frequency regions in the auditory cortex. Numerous studies have demonstrated various degrees of benefit provided by amplification. [13],[14],[15] There are a number of reasons why hearing aids might be effective in providing relief from tinnitus. Among them are the beliefs that greater neural activity may allow the brain to correct for abnormal reduced inhibition due to outer hair cell damage; an enriched sound environment provided by amplification may minimize maladaptive cortical reorganization; amplification of ambient noise may partially mask tinnitus and is likely to reduce the contrast from tinnitus perception to quiet; and fatigue and stress created by the requirement of extra listening effort may be reduced thus allowing more resources to be allocated to tinnitus coping mechanisms. All of these may facilitate habituation. Furthermore, since the majority of tinnitus sufferers have at least some degree of hearing loss and advances in digital technology allowing for open fittings have expanded the lower range of amplification candidates, hearing aids are frequently a common choice for relief. In the recent Kochkin et al., 2011 study, [16] of nine tinnitus treatment methods assessed (hearing aids, music, medication, relaxation exercises, counseling, non-wearable sound generators, herbs and dietary supplements, wearable sound generators, and psychological counseling), the most substantial tinnitus amelioration was achieved with hearing aids (34%), followed by the use of music (30%). None of the other treatments achieved an efficacy rating of more than 10%.

There are three distinct goals for sound therapy. The ultimate objective is to completely suppress the tinnitus, while a less gratifying, but still effective (and realistic) goal is to facilitate habituation (the process of adapting to a stimulus thorough repeated exposure). With habituation, either the perception of the tinnitus, or the reaction to the tinnitus is greatly, if not fully, diminished. [17] The third option is to provide total or partial masking. [18] Total masking occurs when an external sound is perceived as being louder than the tinnitus, rendering it inaudible when in the presence of the masking stimuli. Partial masking occurs when the loudness of the tinnitus is reduced, but not eliminated by the masker. In addition, masking may divert the patient's attention. Masking employs a narrow band of noise centered around the perceived pitch of the tinnitus in an attempt to provide relief by either completely or partially obscuring the patient's perception of the tinnitus. However, many advocates of behavioral retraining therapies consider full masking of tinnitus to be counterproductive, since for long-term habituation to occur, the stimulus has to be perceived during training. [17] In addition, masking can interfere with hearing or produce too much distraction. Furthermore, it may only work for a tonal type tinnitus, because if a noise is employed, either broadband or narrow band (in order to limit the overall loudness), it may sound too similar to a "hissing" tinnitus. However, perhaps the greatest limitation of masking is that it typically cannot be constantly or permanently sustained. Therefore, while noise was once considered the most common form of acoustic tinnitus management, other auditory stimuli that can mask or mingle with tinnitus are now being increasingly recommended, utilized, and researched for their long-term benefits.

Sound therapy is not universally effective. However, the actual benefit from sound therapy remains somewhat elusive. Meta analyses have been conducted on the use of sound therapy. In the Cochrane review [19] six trials (553 participants) were analyzed. They concluded that no significant change was seen in the change in loudness or the overall severity of tinnitus following the use of sound therapy compared to other interventions such as patient education, relaxation techniques, tinnitus coping strategies, counseling, tinnitus retraining and exposure to environmental sounds. The authors stated that "the lack of quality research in this area, in addition to the common use of combined approaches (hearing therapy plus counseling) in the management of tinnitus are, in part, responsible for the lack of conclusive evidence." Other studies. [20],[21] (primarily from the psychology literature) have indicated a small, but significant benefit from the addition of sound therapy to other approaches. At least one author [22] has indicated that "virtually all sound therapies are combined with some form of counseling." Thus, differences in the benefits reported from sound therapies may relate, at least in part, to the effectiveness of counseling, and it is certainly possible that personality characteristics of the patient and perceived psychoacoustic characteristics of the tinnitus may play a yet undefined role.

The purpose of this paper is to propose the use of music, and specifically, unfamiliar music in the form of fractal tones, as a sound therapy tool and to analyze the rationale and considerations that one might contemplate in selecting specific musical stimuli for sound therapy.

Music is considered a reasonable acoustic stimulus for sound therapy since many of the most commonly reported problems occurring as a consequence of tinnitus relate to increased stress and difficulties relaxing, concentrating, and sleeping. [23] A recent study was conducted examining the relative impact of stress and noise exposure (one of the most frequent causes of tinnitus) on the probability of having tinnitus. The authors reviewed over 2,000 tinnitus patients and concluded that while exposure to both noise and stress were important for the probability and level of tinnitus discomfort, stress was the more important factor in determining whether a patient would transition from being mild or severely impacted. [24] It has also been reported that long-term stress and coping strategies were the strongest predictors of tinnitus, even stronger than traditional risk factors such as hearing loss, age, gender, and hyperacusis. [25]

The use of music for setting and altering moods, arousing, and relaxing, is certainly not new. Music is commonly employed in homes, work environments, celebrations, advertisements, romances, movies, athletic locker rooms, shopping malls, and hospitals to soothe, relax, energize and engage. Additionally, music has been actively, and increasingly, employed as a therapeutic treatment for a number of physical and psychological ailments. [26] Advances in neuroscience and neural imaging have provided a greater understanding of the effects of musical stimuli on the brain and human behavior, including stress. Knowledge about the site of stimulation, neural interactions, and transfer of neural transmitters help explain the behavioral consequences, both positive and negative, of exposure to music. Listening to music can result in physiological changes correlated with relaxation and stress relief. [27] One reason music is believed to be helpful in reducing stress is because of the wide range of neural structures that are activated including the cerebellum, frontal lobe, limbic system, and auditory cortex. Each of the areas has been identified as being involved in tinnitus perception. [28],[29]

Moreover, music is an easy stimulus to alter and certain "rules" have been established about patterns of musical elements, such as slow onset, slower tempo, lower pitch, degree of repetition, and lack of emotional content that, if followed, can produce a desired calming, rather than alerting, effect. [30],[31],[32] Studies have shown that listening to certain types of musical stimuli induces relaxation and heightened concentration in some individuals, but not in others. [33] Active listening tends to arouse, passive listening tends to soothe. Active listening may distract, passive listening may allow for increased relaxation. It has been recommended that music used for tinnitus management should evoke positive feelings, should be void of vocals, should not contain pronounced bass beats, should be pleasant, but not too interesting or compelling (though for short-term relief attention capturing music can be beneficial), should induce relaxation while reducing tinnitus audibility (best for long-term relief), and should be played at low levels where music blends with tinnitus. [34],[35] Other suggestions indicate that if music is to be relaxing, it should have a tempo near or below resting heart rate (60-72 beats/min); have a fluid melodic movement, contain a variety of pitches, be self-selected, not have rapid amplitude changes, [36] and contain an element of uncertainty. [37] In addition, the fact that sounds (including music) affects people in different ways, due to inherent, learned (and cultural) preferences, should be taken into consideration.

While music was identified as a preferred "masker" for tinnitus in 1988, [38] perhaps the first widespread employment of music for tinnitus relief was proposed by Davis, et al., [39],[40],[41] and commercialized by Neuromonics. This approach incorporates a counseling component and a sound therapy component consisting of four pre-recorded music passages that are filtered in accordance with the individuals' hearing loss and delivered via an MP3 player coupled to high fidelity, non-occluding earphones. Many of the principles mentioned above (for example, a relatively slow tempo with no sudden changes in amplitude) to induce relaxation have been utilized in the selection of the pre-recorded musical passages. More recently, Okamoto et al., [42]

proposed a very different music therapy. It differs from the Neuromonics approach in that it removes (notches) the music out of the frequency regions associated with the tinnitus rather than increasing the intensity in accordance with the hearing loss. In addition, rather than using pre-selected music, it allows the listeners to select music based on their own preference.

While success has been reported success for both approaches, there are potential limitations. In the Neuromonics approach, the patient has only limited choices in the stimuli. This may become a liability if the patient becomes bored or bothered by the repetition of the music. For both therapies, the use of previously recorded music may have an undesired impact on stress reduction because familiar music could evoke memories and potentially negative emotions [34] or create unwanted distraction. From a practical perspective, since somewhat visually obtrusive headphones (including cords) are currently used in these approaches, some individuals may not be able to use the processor at times where headphones may be considered inappropriate, such as during work. This restriction could perhaps be resolved with the future use of wireless technology.

Another potential limitation is that while the Neuromonics processor modifies the musical signal to compensate for hearing loss, it only provides this stimulation during the limited time it is worn each day (2-4 h is suggested). It does not provide amplification of external stimuli to compensate for the hearing impairment. As stated earlier, current theories suggest that tinnitus generation may result from the peripheral attenuation of auditory input. [11] This attenuation provokes an increase in central auditory system activity from the dorsal cochlear nucleus through the auditory cortex, as well as a coupling with the limbic system (particularly the hippocampus and amygdala) via collateral connections from the thalamus and other structures. [4] Stimulation of the thalamus results in release of neurotransmitters, including adrenaline, to produce an autonomic nervous system response associated with stress. [43]

An alternative approach that incorporates the benefits and rules of music but avoids these potential limitations is the use of fractal tones. Auditory fractal tones utilize harmonic, but not predictable relationships, and are generated by a recursive process where an algorithm is applied multiple times to process its previous output. [44] The tones (which sound somewhat like wind chimes) are pleasant, but are not associated with music that the listener may hold in memory. They create a melodic chain of tones that repeat enough to sound familiar and follow appropriate musical rules, but vary enough to not be predictable. In addition, the algorithm ensures that no sudden changes appear in tonality or tempo.

The potential application of fractal tones delivered via high-fidelity hearing aids was explored in an experiment to determine if the presence of various acoustic stimuli, including fractal tones, would (1) be perceived as relaxing to tinnitus patients, (2) reduce short term tinnitus annoyance, and (3) lower subjective tinnitus handicap and reaction scores in a 6 month field trial. [45] The experimental protocol allowed for a comparison of fractal tones alone, fractal tones combined with amplification, broadband (white) noise alone, white noise mixed with amplification, and fractal tones along with amplification and white noise.

Results indicated that fractal tones were effective in promoting relaxation and reducing annoyance from tinnitus. Similar results were also reported by others. [46],[47] Both fractal tones and white noise reduced tinnitus annoyance (white noise to a greater degree than the fractal tones, likely due to greater masking effects), but the fractal tones were preferred by subjects for longer term use for reasons discussed below. In addition, while the majority of subjects selected slower tempos for relaxation and long-term wear, this choice was not unanimous. This underscores the benefit of providing the individual listener with choices. [48] Individual preferences for certain types of acoustic stimuli were also emphasized in the Henry et al., [49] study in which they reported most, but not all, of their participants clearly preferred certain stimuli over others.

The Sweetow and Sabes results [45] agreed with the Henry et al., [49] data in that their subjects showed a preference for stimuli that were modulated in both the spectral and temporal domains. In the latter study, subjects were presented with a variety of noises and environmental sounds that were filtered and modulated. They found that most, but not all, of their subjects had clear preferences for certain stimuli over others, and

most preferred were those that were modulated or temporally varying as opposed to steady state (i.e., pure tones, or filtered or broad band-noise) signals. Modulated signals are characteristic of fractal and other musical stimuli. Reavis, et al., [50] indicated that electrical and acoustic suppression was achieved most effectively using dynamically modulated signals. Their results confirmed the conclusions of others. [51],[52] that temporally patterned sounds such as amplitude and frequency modulated signals may produce highly synchronized and robust cortical responses as opposed to steady state sounds, which produce mostly onset and offset responses in the cortex, and thus may be a more attractive stimulus for this cortical effect. Zeng et al. [53] also suggested that the temporal characteristics of an electrically generated signal are critical to suppression. Sounds that are too slow produce bursts of activity and those that are too fast show no synchronization, but within a specific range the neurons fire synchronously to the sound stimulus and can produce synchronized, robust neural activity in the auditory cortex. It is possible that there are also optimal properties for an acoustical signal designed for tinnitus relief, though this has yet to be verified.

Preferences for modulated stimuli (as opposed to steady-state signals) for tinnitus relief, may be part of the reason why noise masking has fallen out of favor among some practitioners as an acoustic tinnitus treatment, in addition to the fact that noise does not have the inherent value of inducing relaxation. Interestingly, in the Sweetow and Henderson-Sabes study, noise (similar to the faster tempo fractal tones) reduced short-term annoyance more than other stimuli. The likely cause for this finding was that the steady state noise and faster rhythm provided for more masking because of the shortening (or complete lack) of inter-stimulus intervals. However, only two of the participants opted to have the noise only as a program during the 6 month wearing of the hearing aids, and none of them selected the noise only condition as their preferred setting. This too, may be related to the belief that noise may lack the inherent stress-reducing and relaxation inducing characteristics of music. Thus, the combination of tinnitus annoyance reduction and increased relaxation may be an important factor in long-term acceptance.

Although fractal music differs from conventional music in terms of its familiarity, similar preferences for using music for relaxation and tinnitus sound therapy appear to apply. This includes the finding that sudden variations in amplitude can be disconcerting and counterproductive for sound therapy, lower pitches were found to be more relaxing than higher pitches, and slower tempos were preferred over faster tempos. In addition, subjects preferred major chords rather than minor chords. [45] Subjects in the Hann, et al., [34] investigation compared four well-known baroque musical passages, Bach's Air in G, which is also one of the pre-recorded musical passages contained in the Neuromonics protocol, Albinoni's Adagio, and two of Vivaldi's Four Seasons. Their conclusion was that the major mode was the common musical element for preference. This is consistent with the elements of music most associated with a positive emotional response. [30],[31]

Presenting musical stimuli via hearing devices offer some obvious advantages. For example, the hearing deficit can be compensated for by applying the algorithm of the hearing aids to the fractal tones, a potential advantage over pre-recorded CDs. In addition, modern hearing aids are less conspicuous than wearing headphones, particularly those requiring a wired connection to a MP3 player. However, if musical, or other acoustical stimuli are going to be incorporated into hearing aids (so-called combination devices) one must consider whether the limitations of the devices themselves, in particular, bandwidth and dynamic range, create restrictions. Previous investigations [49] may shed some light on this question. In this study, the majority of subjects preferred the amplitude modulated sounds over the filtered white noise sounds even though the latter stimuli contained several tracks extending to 14 KHz, well beyond the capability of modern hearing aids. Thus, the bandwidth limitations of current hearing aids may not be a critical drawback. Hearing aids have inherent restrictions on dynamic range since their primary purpose is amplifying speech (as opposed to MP3 players or other recording devices). Rather than producing a potential decrement to sound therapy for tinnitus, Hann et al., [34] suggest that minimizing the dynamic range is actually a desirable component of sound therapy for tinnitus patients. Considering the fact that hearing impaired patients have loudness recruitment, and many further suffer from

hyperacusis, it makes sense that certain tinnitus patients do not wish to be exposed to high intensities. The use of hearing aids with low compression knee points may be of benefit because they will provide additional amplification for very quiet environments, while still offering separate regulation for gain and output for high input intensities.

Conclusions

Musical stimuli may provide a different, and in some cases, superior option for sound therapies. The use of amplification, combined with flexible music-like signals containing relaxation inducing properties may be a further asset to tinnitus management procedures.

No cochlear dead regions detected in non-pulsatile tinnitus patients: An assessment with the threshold equalizing noise (sound pressure level) test

Author: Gilles, Annick; De Ridder, Dirk; Van de Heyning, Paul.

Publication info: Noise & Health 15.63 (Mar 2013): 129-33.
ProQuest document link

Abstract: One of the hypotheses on the etiology of non-pulsatile tinnitus in normal or hearing impaired patients is the existence of sharp edged cochlear dead regions (DR) flanking normal functioning hair cells. The lack of inhibition of DR on the neighboring neurons may lead to hyperactivity. Currently the Threshold Equalizing Noise test (TEN test) is the reference test to clinically assess cochlear DR. To identify cochlear DR in patients with non-pulsatile tinnitus with and without hearing loss using the TEN (sound pressure level)-test. Data were obtained from adult patients with non-pulsatile tinnitus visiting the Tinnitus Clinic of the University Hospital Antwerp. The TEN (SPL)-test was performed to assess the presence of cochlear DR for test frequencies ranging from 0.5 to 8 kHz. A total of 55 ears of 33 subjects (15 male; 18 female) with non-pulsatile tinnitus were included in the study. Subjects were divided into subgroups based on the audiometric configuration of hearing loss: Flat configuration (N = 23), high-frequency gently sloping (N = 10) and high-frequency steeply sloping (N = 22). In forty-eight ears there was no evidence of cochlear DR. In seven ears the results were inconclusive. This occurred in patients with high-frequency steeply sloping audiogram configurations. The present study does not support the TEN (SPL) test as a reliable tool for the detection of cochlear DR in a tinnitus population.

Full text: Introduction
A dead region (DR) can be defined as a region in the cochlea where the inner hair cells (IHCs) along the basilar membrane and/or neurons are non-functioning or missing, resulting in the absence of basilar membrane vibration transduction to the brain at those places. [1],[2] This does not mean that a particular tone is not audible. A tone producing peak vibration at a particular place on the basilar membrane can be detected by off-place or off-frequency listening provided that the stimulus is sufficiently loud. The tone will not be detected at its usual place on the basilar membrane but at an adjacent place where the IHCs are functioning more effectively. [2],[3] The extent of a DR can be defined in 2 manners: Either by distance along the basilar membrane,

described by the characteristic frequencies related to this place (e.g., a DR extending from 4000 to 10 000 Hz), or by the characteristic frequency (CF) of IHCs or neurons adjacent to the DR. [2] The presence of a DR can result in several problems such as abnormal pitch perception, [4] rapid loudness growth, [5] and distorted perception of pure tones. [6] In order to diagnose cochlear DRs, the Threshold Equalizing Noise (TEN) test was developed. [7] In this test a broadband masking noise (the TEN) is used which is spectrally shaped so that all auditory output filters contain an equal noise power. This means that, for subjects with normal hearing thresholds, the masked threshold for a pure tone is the same for all frequencies over the range of 250-10 000 Hz. More specifically, the TEN level is specified as the level in a one-Equivalent Rectangular Bandwidth N (ERB N) (132 Hz) wide band centered at 1000 Hz, where ERB N stands for the average of the auditory filter as determined for young normal-hearing subjects at moderate sound levels. [2] For example, if the TEN noise is presented at a dial level of 70 (corresponding to 70 dB/ERB), then thresholds, for normal hearing subjects, across a wide frequency range, measured in this noise should also be 70 dB SPL. [Figure 1] [2] illustrates the principle of the TEN test. Looking at the top panel, the solid curve represents the basilar membrane vibration pattern for a pure tone with a CF of. [1] 5 kHz, expressed by the maximum vibration at that frequency. The shaded area reflects the presence of a high-frequency DR starting at approximately 1.07 kHz. To measure absolute thresholds for frequencies below 1.07 kHz, 40 dB of basilar membrane vibration is needed (long-dashed line). As indicated by the short-dashed line, the absolute threshold value of a 1.5 kHz tone (which falls within the DR) is 67 dB. A threshold is measurable because of the intact IHC's adjacent to the DR (= off-frequency listening). In the bottom panel a TEN of 70 dB/ERB N is added masking the 1.5 kHz tone at 67 dB. To make the tone audible again the level has to be increased so that basilar vibration just below the 1.07 kHz DR slightly exceeds 70 dB. A level of 97 dB is required in order to achieve audibility of the tone again. A normal hearing subject with no DR would have a masked threshold of approximately 70 dB. This figure shows that for the person with a DR, the masked threshold was 30 dB higher than the unmasked threshold (97 dB vs. 67 dB) and that the masked threshold was 27 dB higher than in the case where there was no DR (97 dB vs. 70 dB). This last remark demonstrates the two criteria that need to be fulfilled to determine a DR: (1) at least 10 dB of masking is required and (2) the masked threshold should be at least 10 dB higher than normal. [2] There are currently two commercially available TEN test versions: the TEN sound pressure level test (TEN-SPL) and the TEN hearing loss level test (TEN-HL). [2] They differ in 3 ways: Frequency range tested, amplitude characteristics of the TEN noise and the calibration. The TEN (SPL) test is calibrated in dB SPL and covers a frequency range of 250-10 000 Hz. The TEN (HL) test is the modified version of the TEN (SPL), calibrated in dB HL which is easier to interpret as the audiometer is also calibrated in dB HL. The frequency range of the TEN (HL) is narrowed to 250-4000 Hz and the TEN noise contains a lower crest factor. The present study aims to investigate whether cochlear DRs are more prevalent in patients suffering from tinnitus. Tinnitus, the perception of sound in the absence of an external acoustic sound source, poses a clinical problem for millions of people around the world. [8] The understanding of the pathological mechanism of tinnitus generation remains in the stage of hypothesis and conjecture. One of the hypotheses on the etiology of non-pulsatile tinnitus is the existence of sharp edged cochlear DRs flanking normal functioning hair cells. The lack of inhibition of DRs on the neighboring neurons may lead to hyperactivity. Previous studies showed that tinnitus in the absence of measurable hearing loss at all frequencies or at the tinnitus frequency does not exclude cochlear/neural damage. [9] Previously the detection of DRs was reported in eight out of eleven subjects with normal hearing and non-pulsatile tinnitus, [10] providing evidence for the theory that deafferentiation is also possible in tinnitus subjects with audiometrically normal hearing thresholds. In the present study we used the TEN (SPL) test in order to assess cochlear DRs in an adult population with non-pulsatile tinnitus and various audiometric configurations.{Figure 1}

Methods

Subjects

Thirty-three patients presenting with non-pulsatile tinnitus in the University Hospital Antwerp (UZA) underwent the standard otorhinolaryngologic (ORL) and audiometric protocol for tinnitus. In addition, the TEN (SPL) test was performed in tinnitus ears only. The group consisted of fifteen male and eighteen female patients with a mean age of 51.7 +- 16.2-years-old (range 20-73). Twenty-two patients suffered from bilateral tinnitus while eleven patients perceived a unilateral tinnitus in either the right or left ear.

Pure-tone audiometry

All patients received visual inspection of the eardrum by an ORL-specialist. In addition, tympanometry was normal in all subjects so middle ear pathologies were excluded. According to current clinical standards (ISO 8253-1, 1989), air conduction threshold were measured at 125, 250, 500, 1000, 2000, 3000, 4000, 6000 and 8000 Hz using a 2-channel Interacoustics AC-40 audiometer in a soundproof booth. Bone conduction thresholds were measured at 250, 500, 1000, 2000, 3000 and 4000 Hz. All the patients included in this study had a normal hearing or a sensorineural hearing loss (SNHL) as the air-bone gap never exceeded 10 dB HL. For all the analyses only those ears in which tinnitus was perceived were included in this study. Tinnitus ears were divided into 3 categories in accordance with Demeester et al., (2009): A flat configuration, a high-frequent gently sloping (HFGS) configuration and a high-frequent steeply sloping (HFSS) configuration. To be categorized as a flat configuration, the difference between the mean thresholds of 250/500 Hz, the mean of 1 kHz/2 kHz thresholds, and the mean of 4 kHz/8 kHz should be less than or equal to 15 dB. A HFGS configuration is defined as an audiogram where the difference between the mean of 500 Hz/1 kHz thresholds and the mean of 4 kHz/8 kHz thresholds is greater than 15 dB but less than 29 dB. Finally, a HFSS configuration is present when the difference between the mean of 500 Hz/1 kHz thresholds and the mean of 4 kHz/8 kHz is 30 dB or more. [11] Of all tinnitus ears, 24 were categorized with a flat, 10 with a HFGS, and 21 with a HFSS configuration.

Tinnitus analysis

A Dutch validated version of the Tinnitus Questionnaire (TQ), [12] was completed by the majority of patients (four patients did not complete the questionnaire). The TQ was originally published by Goebel and Hiller. [13] who described the TQ as a global index of tinnitus-related distress. Based on the total score on the TQ, patients are assigned to a distress category: Slight (0-30 points: Grade 1), moderate (31-46 points: Grade 2), severe (47-59 points, grade 3) and very severe (60-84 points, grade 4).

Secondly, patients had to score their tinnitus loudness on a Visual Analogue Scale (VAS) going from 0 (no tinnitus) to 10 (tinnitus extremely loud). Finally, tinnitus pitch and intensity were determined through tinnitus analysis using pitch matching and loudness matching procedures.

Threshold equalizing noise (SPL) procedure

The TEN (SPL) test was performed in all fifty-five tinnitus ears using an original TEN (SPL) CD played by a CD player (Sony CDP-XE270) and presented through a TDH-39 supra-aural earphone. First, the audiometer was connected to the CD player output plug. Input channel 1 on the audiometer was selected on the left side, and channel 2 was selected on the right side. The first track on the CD, a calibrating tone, was played continuously and both volume unit (VU) meters were adjusted to read 0 dB. Absolute thresholds were measured using a final 2 dB-step size to determine the threshold. Subsequently, the TEN was presented with a level of 70 dB and the masked thresholds were measured in a similar way. In case the absolute thresholds of a patient were 60 dB SPL or worse, the level of the TEN was raised. Therefore, the TEN provided at least 10 dB of masking at all times. A DR was considered present if the following criteria were both met. [7]

The masked threshold is at least 10 dB worse than the absolute thresholdThe masked threshold is at least 10 dB worse than the masking noise (TEN)The results were categorized as positive (DRs present), negative (no DRs present) or inconclusive. Several situations can cause inconclusive results. Firstly, it may be impossible to produce 10 dB of masking in patients with severe or profound SNHL because the maximum output of the audiometer is reached. Therefore, the intensity of the TEN will not cause sufficient masking. Secondly, when the

TEN level was considered as too loud by the patient, the level was lowered and did not provide sufficient masking, leading to inconclusive results. Finally, absolute and/or masked thresholds could not be measured in some patients with profound hearing loss at certain frequencies because of output limitations of the audiometer.

Results

The audiometric results are represented graphically in [Figure 2] where mean absolute hearing thresholds of patients with a flat (N = 24), a HFGS (N = 10) and HGSS (N = 21) are shown. A full tinnitus analysis was performed on 31 ears of 21 patients (10 with bilaterally tinnitus, 11 with unilateral tinnitus). [Table 1] shows the results of the tinnitus analysis after pitch matching as well as the tinnitus type (pure tone or noise-like). In addition, [Table 2] shows the scores for VAS and TQ. The majority of patients experienced a high-pitched tinnitus and mostly a noise-like character. The tinnitus loudness was scored on a VAS by nineteen of the thirty-three patients (of which in 11 patients with bilateral tinnitus, the VAS was also scored bilaterally). Tinnitus intensity was measured in 26 patients and 29 patients completed the TQ of which eight patients were categorized with a degree 1, 10 with a 2 nd degree, 9 with a 3 rd and 2 with a 4 th degree. Because of time shortcomings in the daily clinical practice, all (TQ, VAS and tinnitus analysis) were not always done completely. Therefore, [Table 1] and [Table 2] do not contain data of all ears of all patients on which the TEN (SPL) was applied. In patients suffering from bilateral tinnitus, the TEN (SPL) test was performed in both ears. In patients with unilateral tinnitus, TEN (SPL) was performed in the affected ear only. [Figure 3] shows the mean masked threshold per frequency in 70 dB SPL of TEN (or more in subjects where the unmasked threshold exceeded 60 dB SPL). The mean masked thresholds were 10 dB SPL or more better than the 'normal' masked threshold (which would be 70 dB SPL in 70 dB TEN) for all frequencies meaning that the tone was audible even at a level much lower than the TEN level. As one of the criteria for a DR states that the masked threshold should be at least 10 dB worse than the unmasked threshold, no DRs were found in these patients. Therefore, the outcome of most TEN (SPL) tests were negative. Nevertheless, four patients showed inconclusive results at certain frequencies. In one patient with a symmetric HFSS audiogram configuration and bilateral non-pulsatile tinnitus, the unmasked threshold could not be measured bilaterally upwards from 2 kHz because of audiometer output limitation as the unmasked threshold exceeded 120 dB HL. In three other patients with a HFSS configuration (two patients with bilateral tinnitus and one with unilateral tinnitus), the unmasked threshold were measured but the TEN noise could not be set loud enough to provide sufficient masking. Therefore the results in these patients remained inconclusive for a DR located in the high frequencies. An oversight of inconclusive results along with the reason of inconclusiveness is given in [Table 3].{Figure 2}{Figure 3}{Table 1}{Table 2}{Table 3}

Discussion

It has been suggested that tinnitus is often accompanied by severe (IHCs damage in certain cochlear regions, even in the absence of measurable hearing loss. [9],[10] Severe IHC damage causes deafferentiation and therefore DRs in the cochlea. In the present study tinnitus patients with different audiometric configurations and hearing thresholds (going from normal hearing to profound hearing loss) were tested for DRs by use of the TEN (SPL) test. In the study of Weisz et al., (2006) a normal hearing student population suffering from tinnitus was tested of which eight out of eleven subjects were identified with a DR. [10] In another study, in which the TEN (HL) test was applied, 15% of tinnitus patients with normal hearing sensitivity had positive TEN results, indicative for a DR. [14] In our normal hearing subjects with tinnitus (N = 16 ears), no DRs were identified. It has been reported earlier that it is more likely that IHC damage/loss is involved in subjects where the hearing loss exceeds 55 to 60 dB. [15] Furthermore, it has been found that a DR is more prevalent in subjects with a hearing loss exceeding 55 to 60 dB SPL. [3],[14] In addition, severe high-frequency hearing loss or high frequency steeply sloping audiograms are more associated with DRs and positive TEN findings. Several studies found a greater prevalence of DRs in subjects with a steep slope. [3],[16] The present study was not able to confirm these findings as also those ears with a HFSS audiogram configuration (N = 22) showed negative TEN results.

However, as mentioned earlier and elucidated in [Table 3], in four patients with a HFSS configuration, unmasked or masked thresholds could not be obtained in seven tinnitus ears because of audiometer output limitations. Here the TEN findings remained inconclusive. The problem of the amount of inconclusive results of the TEN (SPL) test has been previously reported by Hornsby and Dundas (2009) where in 80% of the ears inconclusive results were found for at least one frequency and 30% at three frequencies or more. [3] Vinay and Moore (2007) also noted that it is more likely to have inconclusive results when the audiometric thresholds exceed 85 dB HL. [14] The TEN (HL) test can be presented at higher levels without distortion and might therefore reduce the amount of inconclusive results. [2] Nevertheless, in the present study, the TEN (SPL) was deliberately chosen over the TEN (HL) because of the wider frequency range. Furthermore, as tinnitus analysis showed that most patients included in this study, perceived a high pitched tinnitus, we were especially interested in the cochlear preservation at those frequencies. Thirty-two ears of the patients included in the present study, were characterized as a HFGS (N = 10) or a HFSS (N = 22) configuration. As mentioned before, patients with high-frequency steeply sloping audiometric configurations are more likely to have a DR in that area. Such results were not found by the current study. As the present study aimed to assess the TEN (SPL) as a clinical tool for the explanation of tinnitus, the question arises whether cochlear DRs are necessary for a tinnitus percept. It has been shown that immediately after acute (impulse) noise trauma in military personnel, 88% of the soldiers perceived a noise-induced tinnitus. [16] The presence of cochlear DRs was determined by the use of psychophysical tuning curves (PTCs), which is considered as a more reliable tool by some authors. [17] It has been shown that immediately after acute impulse noise trauma in military personnel 70% of the soldiers had DRs, 50% of which recovered partially or completely (narrowing or disappearing of the DR zone) after some time. The high prevalence of DRs after noise trauma may be involved in noise-induced tinnitus. However, the fact that some patients with tinnitus had no DRs and some patients with DRs had no tinnitus supports the hypothesis that the presence of a DR is neither necessary nor sufficient to induce tinnitus. [16] These findings fit the suggestion that OHCs might be of more importance than IHCs in the generation of tinnitus as in a previous study in a group of normal hearing tinnitus patients 85% demonstrated abnormal transient otoacoustic emissions, of which only 15% abnormal TEN (HL) findings. [18] In conclusion, tinnitus is a common phenomenon in modern society. While the etiology of tinnitus remains elusive in many cases, research is needed in order to identify a possible causative factor. One of the hypotheses on non-pulsatile tinnitus is the presence of cochlear DR leading to central hyperactivity. If DR can be identified by use of the TEN test, the present study does not support the concept that DR are necessary for tinnitus. Therefore, the use of the TEN test as a diagnostic tool in a tinnitus population might be of limited value. The authors would like to point out that the present study does not designate the TEN test to be unreliable as a whole but as a result of the present findings the TEN test does not provide a useful tool in the diagnostics of tinnitus patients. Further research with the TEN test in tinnitus patients is necessary in order to confirm these findings.

Noisy Classroom Simulation Aids Comprehension in Hearing-Impaired Children

Publication info: Targeted News Service [Washington, D.C] 11 Feb 2013.
ProQuest document link

Full text: The University of Washington issued the following news release:
Children with hearing loss struggle to hear in noisy school classrooms, even with the help of hearing aids and other devices to amplify their teacher's voice. Training the brain to filter out background noise and thus understand spoken words could help the academic performance and quality of life for children who struggle to hear, but there's been little evidence that such noise training works in youngsters.

A new report (asadl.org/jasa/resource/1/jasman/v133/i1/p495_s1) showed about a 50 percent increase in speech comprehension in background noise when children with hearing impairments followed a three-week auditory training regimen. The effect was still evident when the children were tested three months after the training ended.

The findings are among the first to demonstrate that auditory training with noise can work in children. Other studies show that similar regimens help hearing-impaired adults.

The training involves repeated exposure to speech masked by noise, and is intended to teach the brain how to receive information and process it more efficiently. This could help hearing-impaired children who struggle to keep up in noisy classrooms.

"It's not a fair playing field with their normal-hearing peers," said Jessica Sullivan (https://sites.google.com/a/uw.edu/pahlab/home/bio), lead author and a University of Washington assistant professor of speech and hearing sciences. "They have the best technology, but it's not enough - they still miss things."

People with normal hearing usually filter out background noise seamlessly. If a loud truck rumbles by, they can still understand a conversation because their brains work quickly to fill in sounds that they might have missed. But people with hearing loss take in sound more slowly, and brain regions that process hearing aren't as adept at filling in muffled information.

In Sullivan's study, published in the January issue of the Journal of the Acoustical Society of America (http://asadl.org/jasa/), hearing-impaired youngsters ages 6 to 17 attended seven one-hour sessions spread across three weeks. They listened to a series of sentences, such as "We saw two brown bears" or "Grandmother gave Bob red beans," masked by staticky background noise intended to simulate a clattering classroom scene.

During the sessions, Sullivan gradually made the regimen more demanding by ratcheting up the number of words in the sentences, the noise volume and the time between hearing the sentence and identifying what words were said. The children had to give correct answers 80 percent of the time before advancing to the next level of difficulty.

Three months after the training, the participants still showed improvements in word recognition over the noise. Sullivan also found that auditory training with a crackling noise - called "interrupted" because white noise was interspersed with fleeting five- to 95-millisecond silences - increased hearing comprehension more than using continuous white noise. Children in the interrupted noise group showed about a 50 percent increase in speech intelligibility compared with their hearing at the beginning of the experiment.

"The maintenance of the improvement is a truly significant finding," Sullivan said. "It indicates that new hearing and listening strategies have been developed to detect speech despite noise."

The next step in the research is to see how the regimen works for other people, such as adults and cochlear-implant users, and to other types of noise, including real-world settings.

Co-authors are Linda Thibodeau and Peter Assmann of the University of Texas at Dallas, where the study was conducted. The study was funded by the National Institute on Deafness and Other Communication Disorders (http://www.nidcd.nih.gov/Pages/default.aspx).

Speech Perception in Noise by Children With Cochlear Implants

Author: Caldwell, Amanda; Nittrouer, Susan.

Publication info: Journal of Speech, Language and Hearing Research (Online) 56.1 (Feb 2013): 13-30.
ProQuest document link

Abstract: Common wisdom suggests that listening in noise poses disproportionately greater difficulty for listeners with cochlear implants (CIs) than for peerswith normal hearing (NH). The purpose of this studywas to examine phonological, language, and cognitive skills that might help explain speech-in-noise abilities for children with CIs. Three groups of kindergartners (NH, hearing aid wearers, and CI users) were tested on speech recognition in quiet and noise and on tasks thought to underlie the abilities that fit into the domains of phonological awareness, general language, and cognitive skills. These last measures were used as predictor variables in regression analyses with speech-in-noise scores as dependent variables. Compared to children with NH, children with CIs did not perform as well on speech recognition in noise or on most other measures, including recognition in quiet. Two surprising results were that (a) noise effects were consistent across groups and (b) scores on other measures did not explain any group differences in speech recognition. Limitations of implant processing take their primary toll on recognition in quiet and account for poor speech recognition and language/phonological deficits in childrenwithCIs. Implications are that teachers/clinicians need to teach language/phonology directly and maximize signal-to-noise levels in the classroom.

Full text: Headnote

Purpose: Common wisdom suggests that listening in noise poses disproportionately greater difficulty for listeners with cochlear implants (CIs) than for peerswith normal hearing (NH). The purpose of this studywas to examine phonological, language, and cognitive skills that might help explain speech-in-noise abilities for children with CIs.

Method: Three groups of kindergartners (NH, hearing aid wearers, and CI users) were tested on speech recognition in quiet and noise and on tasks thought to underlie the abilities that fit into the domains of phonological awareness, general language, and cognitive skills. These last measures were used as predictor variables in regression analyses with speech-in-noise scores as dependent variables.

Results: Compared to children with NH, children with CIs did not perform as well on speech recognition in noise or on most other measures, including recognition in quiet. Two surprising results were that (a) noise effects were consistent across groups and (b) scores on other measures did not explain any group differences in speech recognition.

Conclusions: Limitations of implant processing take their primary toll on recognition in quiet and account for poor speech recognition and language/phonological deficits in childrenwithCIs. Implications are that teachers/clinicians need to teach language/phonology directly and maximize signal-to-noise levels in the classroom.

Key Words: cochlear implants, speech perception, children, speech recognition in noise and quiet

(ProQuest: ... denotes formulae omitted.)

Recognizing speech in noisy conditions has always been viewed as presenting special difficulty for listeners with hearing loss. Before cochlear implants (CIs), when hearing aids (HAs) were the only means of amplification, this difficulty could be explained largely by the fact that abnormal cochlear function is associated with broadened auditory filters (e.g., Glasberg &Moore, 1986; Leek,Dorman,&Summerfield, 1987). Phonemically relevant spectral structure, such as formant frequencies, is poorly represented with broadened filters (e.g., Revoile, Pickett, &Kozma-Spytek, 1991). As a result, perceptual segregation of that spectral structure from background noise is difficult (Baer, Moore, &Gatehouse, 1993; Bernstein&Brungart, 2011; Boothroyd,Mulhearn, Gong, &Ostroff, 1996; Fu, Shannon, &Wang, 1998). The development of CIs as a treatment for severe to profound hearing loss has done nothing to improve this particular problem because processing strategies in these devices are designed to deliver only spectrally broad signals to the auditory system (e.g., Rubinstein,

2004).

CIs have, however, improved speech recognition in quiet for listeners with severe to profound hearing loss, with average isolated word recognition scores for adults of 40% to 50% correct (Firszt et al., 2004) and some individual implant users scoring much higher; however, listeners using CIs continue to struggle in noisy situations (e.g., Zeng &Galvin, 1999). In addition to the problems introduced by processing strategies that provide only a broad representation of phonemically relevant spectral structure, a lack of temporal fine structure contributes to the difficulty these listeners experience segregating a target signal from background noise (Lorenzi, Gilbert, Carn, Garnier, &Moore, 2006). From these constraints on the kinds of signal structure available through implants, it is easy to appreciate why listeners with CIs might struggle to recognize speech in noisy environments. There are, however, factors other than the constraints on signal structure affecting bottom-up auditory processes that influence how well listeners recognize speech in noisy backgrounds.

Top-Down Linguistic Effects

A listener's knowledge of linguistic structure and the ability to bring that knowledge to bear on speech perception affect how well one recognizes speech in noise. Several metrics have been developed to quantify the contributionmade by these top-down influences. In particular, Boothroyd (Boothroyd, 1968;Boothroyd&Nittrouer, 1988) developed such a metric, known as the j factor, and it has been used on data for listeners fromage 4 years to elderly (Nittrouer &Boothroyd, 1990). When it comes to word recognition, this metric is built on the principle that the probability of recognizing a word is related to the probabilities of recognizing the separate constituents of that word, a relationship that can be represented by this equation:

... (1)

where pw is the probability of recognizing the word; pp is the probability of recognizing each part, or phoneme; and n is the number of phonemes in the word. Of course, a listener's lexical knowledge influences word recognition such that the probability of recognizing a word does not depend on the recognition of each phoneme separately, as would be the case for nonsense items. Therefore, Equation 1 can be changed as follows:

... (2)

where j is the number of independent channels of information required for recognition and is between 1 and n.Equation 2 can now be rewritten to provide the metric of the effective number of information channels needed to recognize a word:

... (3)

According to this formula, j is a dimensionless factor that serves as an index of how strongly lexicality influences word recognition. The smaller j is, the greater the effect of lexicality on recognition. This effect is the combination of having the requisite lexical knowledge and of being able to bring that knowledge to bear on recognition. Nonetheless, early investigations of top-down linguistic constraints on speech perception typically assumed normal language knowledge and instead focused on measuring the extent towhich listeners use that knowledge in perception (Hirsh, Reynolds, &Joseph, 1954; Miller, Heise, &Lichten, 1951; Pollack, Rubenstein,&Decker, 1959). Studies with other populations, however, are reminders that the first component of the effect cannot be assumed. Listeners such as second-language learners are perfectly capable of using linguistic constraints during perception, if functioning intheir first language, but lack adequate familiarity with linguistic and phonological structure in their second language. As a result, speech perception under difficult listening conditions, such as noisy environments, is hard for these listeners (Bradlow&Pisoni, 1999; Cutler, Garcia Lecumberri, &Cooke, 2008; Flege, MacKay, &Meador, 1999; Pinet &Iverson, 2010; Rogers, Lister, Febo, Besing, &Abrams, 2006; von Hapsburg, Champlin, &Shetty, 2004). When evaluating speech perception in noise for clinical populations, it is possible that a lack of linguistic knowledge might similarly explain some part of any observed deficit that is found for those listeners.

Lessons From Individuals With Dyslexia

One population other than listeners with hearing loss that demonstrates particular difficulty recognizing speech

in noise consists of individuals with reading problems. In 1983, Brady, Shankweiler, and Mann showed that children with dyslexia recognized words in noise more poorly than their peers with normal hearing (NH), even though recognition scores in quiet were comparable across groups. This finding was attributed to poor phonological category formation on the part of the childrenwith dyslexia, and work since then has supported that suggestion (e.g., Serniclaes, Ventura, Morais, &Kolinsky, 2005; Vance &Martindale, 2011). Other studies have found that individuals with reading problems have difficulty creating categories from sensory inputs, regardless of whether they are related to speech (Ahissar, Lubin, Putter-Katz, &Banai, 2006; Nittrouer, Shune, &Lowenstein, 2011). In turn, this problem has been identified as a source of the speech-perception-in-noise difficulties exhibited by this group. The ability to make strong predictions about what kinds of structures to expect makes perception resistant to noisemasking (Ahissar, 2007). Fromthis perspective, the problems dyslexic children encounter listening to speech in noise could be described as strictly top-down effects: Because of their weakly defined phonological categories, they are ill equipped to predict the structures that would be in the noise. This explanation could similarly explain the finding that second-language learners have greater difficulty recognizing speech in noise than first-language learners: Because second-language listeners have more weakly specified phonological categories as well, they would also be less capable of predicting phonological form through the interfering noise. In any event, it is unlikely that the deficits that listeners with dyslexia exhibit when it comes to listening to speech in noise are due to problems at the auditory periphery.

Ziegler and colleagues (Ziegler, Pech-Georgel, George, Alario, &Lorenzi, 2005; Ziegler, Pech-Georgel, George,&Lorenzi, 2011) conducted two studies with a slightly different population (individuals with specific language impairments) and found that these listeners did indeed have more difficulty than typically developing children understanding speech in a variety of noises. However, the children with language impairment showed masking release for fluctuating, rather than stationary, noise comparable in magnitude to that of typically developing children. Because that kind of masking release is a peripheral effect, their enhancedmasking per se is unlikely due to auditory deficits at the periphery.

Another deficit often attributed to children with dyslexia is one described as a temporal processing deficit (Gaab, Gabrieli, Deutsch, Tallal, &Temple, 2007; Merzenich et al., 1996; Tallal, 1980; Tallal, Miller, &Fitch, 1993; Tallal &Piercy, 1973, 1974). This proposed deficit is commonly viewed as a problem in how the auditory system handles rapidly changing acoustic structure, and the proposed effect is that it hinders the ability of children with dyslexia to develop highly refined phonological categories. Consequently, it could be a source of their problems in understanding speech in noise. One kind of phonetic contrast that has been used to demonstrate temporal processing deficits in children with dyslexia is voice onset time (VOT): Children with reading problems have exhibited shallower labeling functions for stimuli along VOT continua than children without such deficits (Breier et al., 2001; Godfrey, Syrdal-Lasky, Millay, &Knox, 1981; Manis et al., 1997). VOT is a particularly good property to use in investigations of whether children with hearing loss who use CIs have difficulty forming phonemic categories, similar to the problems found for children with dyslexia. This temporal structure should be well represented in implants because processing strategies recover envelopes in a number of channels and code this information onto the electrodes. Thus, this acoustic cue of VOT could offer a test of whether there is an underlying problem with category formation for children with CIs.

Children Who Use CIs

Given all that is known about what it takes to recognize speech in noisy backgrounds, it comes as no surprise to find that children with CIs have been found to have more trouble than other children doing so (Davidson, Geers, Blamey, Tobey,&Brenner, 2011). Peripheral processes that allow listeners with normal cochlear function to separate target signals from background noise are impaired in these children, because of the signal-processing limitations of the devices. Some of the perceptual and cognitive processes that seemto influence speech recognition in noisy environments from a top-down direction are also impaired, likely adding to these listeners' problems understanding in noise. Children with CIs do not have phonemic categories that are as well formed as

their peers with NH (Geers &Hayes, 2011; Johnson &Goswami, 2010), a factor that could inhibit their abilities to predict the signal. Although implants are associated with tremendous improvements in spoken language abilities for children with hearing loss over what they are capable of without them (Tomblin, Spencer, Flock, Tyler, &Gantz, 1999), these children continue to show impaired abilities. Compared to their peers with NH, children with CIs continue to struggle at recognizing language structure in general (Niparko et al., 2010; Nittrouer, 2010) and at building vocabularies (Hayes, Geers, Treiman, &Moog, 2009; James, Rajput, Brinton, &Goswami, 2009; Nittrouer, 2010). These broader language deficits would reasonably be expected to affect the abilities of children with CIs to recognize speech in noise. Finally, children with CIs have demonstrated impaired abilities in processes fitting under the heading of cognitive skills, in particular working memory (Burkholder &Pisoni, 2003; Cleary, Pisoni, &Geers, 2001; Pisoni, Kronenberger, Roman, &Geers, 2011). Deficits in cognitive skills have not specifically been implicated in problems recognizing speech in noise.However, it can be assumed that difficulties forming and retaining amemory of what was heard could influence outcomes.

The Current Study

Before this study was conducted, it was anticipated that children with CIs would show poorer speech perception in noise than children with NH, or even children with enough residual hearing to use HAs. The study we report here was undertaken mainly to examine factors that might account for variability among children with CIs in theirabilities to recognize speech innoise, thus improving researchers' collective understanding of this deficit. In particular, three measures of phonological awareness were obtained, along with a measure of speech perception in noise. The three measures of phonological awareness spanned a range of developmental aptitude, thus increasing the likelihood that maximum variability among participants would be found. Such variability is necessary for performing powerful regression analyses. Other factors examined as potential predictors of children's abilities to recognize speech in noise included their abilities to form phonemic categories based on a temporal property (VOT). Examining children's labeling of stimuli along aVOTcontinuumprovided an estimate of howwell these children can use rapidly changing acoustic structure of a sort likely to be available through an implant. It also permitted insight into how well deaf children with CIs can form categories when given access to the sensory information on which those categories are based. Also evaluated in the current study were children's language comprehension, vocabulary size, short-term memory, and speed of perceptual processing. All participants with hearing loss, and most with NH, in this study were part of a longitudinal investigation and had been tested repeatedly at regular intervals since infancy. This fact made them a particularly good sample to study, because no evidence to suspect secondary handicaps that might interfere with the development of spoken language has been found for any child in the longitudinal study.

Method

Participants

Fifty-four children who had just completed kindergarten came to The Ohio State University during the summer of 2010 to participate in this study. Of these, 35 had permanent sensorineural hearing loss with three-frequency pure-tone averages greater than 50 dB hearing level in the better ear. Twenty-seven of those children had severe to profound sensorineural hearing loss and wore one or two CIs. Eight had moderate hearing loss and wore bilateral HAs. Another 19 children had NH. Pure-tone audiometric measurements made at the time of testing confirmed these category descriptions. All children except for four in the NH group had participated in a longitudinal study from 12 to 48 months of age (Nittrouer, 2010). All children with hearing loss in the study received intervention services focused on spoken language development starting shortly after their hearing loss was identified.

Demographic Measures

Demographic information for the three groups is provided in Table 1. Range of age at the time of testing was 73-85 months for children with NH, 72-83 months for children with HAs, and 73-94 months for children with CIs. One child with CIs had to repeat kindergarten, which explains the greater age range for that group.

Socioeconomic status was indexed using a two-factor scale on which both the highest educational level and the occupational status of the primary income earner in the home are considered (Nittrouer &Burton, 2005). Scores for each of these factors range from 1 to 8, with 1 being the lowest and 8 being the highest. Values for the two factors are multiplied together, resulting in a range of possible scores from1 to 64. In general, a score of 30 represents a household in which the primary income earner has a 4-year university degree and a job such as a midlevel manager or a teacher. Scores of 20 represent households in which the primary income earner has a high school diploma and works in a service industry, in construction, or as a skilled craftsman. The scores obtained for these children suggest they all had reasonably rich language environments in the home.

The bottom four rows of Table 1 show demographic information for the children with hearing loss. All children with hearing loss had been identified before 2 years of age, and most had been identified before 1 year. The childrenwith CIs had received those implants early, which for 21 of the 27 children meant before age 2. Consequently, these children had considerable experience using their implants. Eighteen of the children with implants wore two. Thirteen children with implants had worn an HA on the opposite ear (i.e., bimodal experience) for a period of a year or more.

Equipment

All testing took place in sound-attenuated rooms. All stimuli used in testing were presented via a computer with a Creative Labs Soundblaster digital-to-analog card using a 44.1-kHz sampling rate with 16-bit digitization and a RolandMA-12C-powered speaker for audio presentation, placed 1min front of the child at a 0° azimuth. The phonological awareness tasks were presented in audiovisual format using a 1,500-kbps data rate and 24-bit digitization for video presentation. Presentation for speech recognition in noise was audio only.

All test sessions were video-recorded using a Sony HDR-XR550V video recorder so that scoring could be done later. Children wore Sony FM transmitters in specially designed vests that transmitted speech signals to the receivers. Those receivers provided direct line input to the hard drives of the cameras to ensure good sound quality for all recordings.

General Procedure

Children arrived in Columbus, Ohio, the night before testing started. Four to six children attended each camp. They were tested individually in six separate sessions over a 2-day period. Each test session consisted of several tasks that lasted no longer than 1 hr. Children had a minimum of 1 hr between test sessions. Several kinds of measures were collected to assess children's abilities to recognize words and constituent phonemes in noise and to evaluate the factors that likely affect those recognition abilities. All procedureswere approved by the institutional review board of The Ohio State University.

Stimuli and Task-Specific Procedures

Speech in noise. Eighteen word lists from Mackersie, Boothroyd, and Minniear (2001) were used. Each list consisted of 10 phonetically balanced CVC words. Noise with a flat spectrum was generated using a randomnoise generator. Six word lists were presented at each of three signal-to-noise ratios (SNRs): -3 dB, 0 dB, and +3 dB. These levels were chosen because they have been used often in earlier work investigating speech recognition in noise by children, both typically developing and with dyslexia (Brady et al., 1983; Nittrouer et al., 2011; Nittrouer &Boothroyd, 1990). Although the same 18 lists were presented to all children, the SNR at which each list was presented varied randomly across children. The order of presentation of lists, and so ofSNRs, also varied randomly, with the stipulation that two lists could not be presented at the same SNR consecutively. During presentation, the level of the words was held constant at 68 dB SPL, and the level of noise varied. After testing in noise was completed with these 18 word lists, the same words were presented in quiet for recognition. Dependent measures were the percentages of correct words and phonemes.

The j factor (Boothroyd &Nittrouer, 1988) was used to index the contribution of lexical effects to word recognition. The j factor is not reliable when percentages of phonemes or words recognized correctly are below 5% or above 95%. In this study, these factors were not available for some children with HAs or CIs in some

SNRs because they scored below 5% correct on either phonemes or words. Using the j factor permitted the examination of whether any potential group differences observed for recognition scores might be due to differences in the extent to which children made use of lexical effects during speech perception.

In a separate session, the CIDW-22 word lists (Hirsh et al., 1954) were presented in quiet. These lists consist of 50 words each and are commonly administered in clinical settings. There are four lists, and the lists presented to individual children varied. These additional materials were used to gauge how ecologically valid the Mackersie et al. (2001) materials are for use with children.

Phonological awareness. Three tasks assessing phonological awareness were used in order to cover a broad range of developmental skill levels. The syllable counting task required children to count the number of syllables in each word. Because this task assesses sensitivity to syllable structure, it is considered developmentally easier than the other two tasks, both of which assessed sensitivity to phonemic structure. In the initial consonant matching task, children heard two words and needed to judge whether they started with the same sound or not. The final consonant choice taskwas considered to be the hardest because it measured the skill expected to be acquired latest. In this task, children heard and repeated a target word and then heard three more words. Children had to select which of those words ended in the same sound as the target. This task was the most difficult because the ability to perform such tasks with final segments develops later than the ability to do them with initial segments (Stanovich, Cunningham, &Cramer, 1984), and because children had to hold four words in a memory buffer. Items for each task are shown in Appendixes A through C.

Specially written software controlled presentation of all stimuli, and the experimenter entered responses directly into the computer. Practice was provided prior to testing on each task. The percentage of correct answers in each task served as the dependent measures. In addition, incorrect answers were recorded and reviewed later for any evidence that children might be implementing a response strategy other than the one required to perform the task correctly. An example of such an alternative response strategywould be if a child responded on the basis of semantic relations between items.

VOT. Children's abilities to label stimuli along aVOT continuum were examined as a way to gauge their general abilities to form phonemic categories when signal structure is available to them. Consonant voicing contrasts are generally more resistant than many other kinds of consonant contrasts to hearing loss (e.g., Boothroyd, 1984), and children with CIs have been found to make these distinctionsmore readily than theymake other consonant contrasts (Giezen, Escudero, &Baker, 2010). The stimuli used here had been used in earlier studies and were found to evoke sharp labeling functions from children, even those with phonological processing problems (Nittrouer, 1999, 2011) or hearing loss (Nittrouer&Burton, 2005). These stimuli are synthetic replicas of da and ta, consisting of 270-ms vocalic portions. The first formant (F1) has a 40-ms transition at the beginning, going from a starting frequency of 200 Hz to a steady-state frequency of 650 Hz. The second and third formants (F2 and F3) change over the first 70 ms. The second formant starts at 1800 Hz and falls to a steady-state frequency of 1130 Hz. The third formant starts at 3000 Hz and falls to a steadystate frequency of 2500 Hz. The fourth and fifth formants (F4 and F5) are constant throughout the stimuli at 3250 Hz and 3700 Hz, respectively. The fundamental frequency (f0) is 120 Hz for the first 70 ms and then falls linearly through the rest of the stimulus to an ending frequency of 100 Hz. A nine-step continuum was created from these vocalic portions by cutting back the onset of voicing in 5-ms steps from 0 to 40 ms. Before voicing started, no source excited F1, but aspiration noise excited the higher formants. Two 10-ms portions of natural release bursts were used, both fromthe samemale speaker: One came from a production of da and one from ta. Appending these bursts to the start of the stimuli had the effect of creating a nine-step continuumwith effective VOTs of 10 ms to 50 ms.

Practice was provided with natural tokens of da and ta and then with the endpoint stimuli from the synthetic continuum. These endpoints consisted of the token with the briefest VOT paired with the da burst and the token with the longest VOT paired with the ta burst. Children needed to respond correctly to nine out of 10

presentations of the endpoints in order to proceed to testing.

Language comprehension. Children's abilities to comprehend spoken language were assessed using the Auditory Comprehension subtest of the Preschool Language Scales, Fourth Edition (Zimmerman, Steiner, &Pond, 2002). This task requires the child to demonstrate an understanding of spoken language by performing specific commands given by the examiner. It is particularly sensitive to children's abilities to comprehend syntactic structures. Standard scores were used as dependent measures.

Vocabulary. Expressive vocabulary was assessed with the Expressive One-Word Picture Vocabulary Test (Brownell, 2000). This task requires the child to provide the words that label a series of pictured items shown one at a time on separate pages. Standard scores were used as dependent measures.

Short-termmemory. For the short-termmemory task, words were presented over the speaker at a level of 68 dB SPL. Ten lists consisting of the same six words were presented, with the order of words varied across each list randomly by the program. The six words were ball, coat, dog, ham, pack, and rake. These words and this task have been used with children before (e.g., Nittrouer &Miller, 1999) and are known to be appropriate for children. Words in each list were presented with an onset-toonset rate of 1 s. After all words were presented, pictures of each item in random order, but not matching that of the audio presentation order, appeared at the top of the computer touch screen. The child's task was to touch each picture in the order heard. As the child touched a picture, it moved down and into place to the right of the picture of the just previously touched word. After all words were touched, the pictures were at the bottom of the screen, in order from leftto right according to how the child recalled hearing them. The computer program recorded the child's responses and compared them to the order in which words were actually presented.

Before testing, training was done using the letters F, H, Q, R, S, and Y, with the same procedures described above for testing. After training on how to do the task with those letter stimuli, the test words were introduced by presenting them over the speaker one at a time and showing them one at a time. All six pictures were then displayed, and the child had to select the picturematching each word presented in isolation to proceed to testing. After testing with the 10 lists, this procedure was repeated. Data were eliminated from the analysis if the child could not respond with perfect accuracy to the six words presented in isolation. The percentage of items out of 60 (10 lists of six words each) for which order was accurately recalled was used as the dependent measure.

Speed of perceptual processing. For a measure of processing speed, we used the Object Naming subtest of the Comprehensive Test of Phonological Processing (Wagner, Torgesen, &Rashotte, 1999). This task consisted of two pages of pictures arranged in four rows of nine pictures each. The child's task was to name the pictures, in order, as quickly as possible. The time required to name all 36 items was obtained from the videotape of the test session, and the sum across the two trials was used as the dependent measure.

Results

Data were screened to check for homogeneity of variance across groups and for linearity. Arcsine transformations of percentage correct word and phoneme recognition scores were used in inferential tests. An alpha level of .05 was applied, but precise p values are given when $p < .10$. When $p > .10$, results are described as not significant.

Speech Recognition

External and internal validity. Figure 1 shows mean percentage correct recognition for phonemes (top panel) and words (bottom panel) at each SNR and in quiet for each group, with standard errors of the means as error bars. In addition to these group results for the Mackersie et al. (2001) words presented in noise and in quiet, other group results are shown for comparison. For word recognition in noise, results for the same stimuli presented at the same SNRs to 14 typically developing 7-year-olds with NH from Nittrouer et al.'s (2011) study are shown next to mean scores for children with NH from this current study at each SNR. A two-way repeated-measures analysis of variance (ANOVA) on scores for children with NHin the twostudies, with study as the

between-subjects factor and SNRas the within-subject factor, revealed only a main effect of SNR, $F(2, 62) = 63.26$, $p < .001$. Neither the main effect of study nor the SNR ×Study interaction were significant, meaning $p > .10$. This outcome provides reassurance that participants with NHwere likely representative of children with NH.

Mean percentage correct recognition scores for phonemes and words presented in quiet are also shown for the CID W-22 word lists. These scores are from the children in the current experiment. For all groups of children, phoneme and word recognition scores appear to be similar for the Mackersie et al. (2001) words and the CID W-22 words, and a series of paired-sample t tests carried out on phoneme and word scores for each group separately failed to reveal any statistically significant differences for any group. Thus, the words used in the current test of speech perception in noise are neither harder nor easier than what children are routinely asked to recognize in such tests.

Group differences.We examined potential group differences for recognition of the Mackersie et al. (2001) words in quiet and in noise. For recognition in quiet, we performed one-way ANOVAs with post hoc contrasts. For both phonemes and words, the overall effect of listener group was significant: phonemes, $F(2, 51) = 30.33$, $p < .001$, and words, $F(2, 51) = 31.10$, $p < .001$. In both cases, contrasts between children with NH and children in both of the other two groups were significant ($p < .001$), both with and without Bonferroni adjustments, but contrasts between children with HAs and CIs were not. Thus, one can conclude that children with NH had better recognition in quiet than children with eitherHAs or CIs. In quiet, recognition was similar for children with hearing loss, regardless of whether they wore HAs and CIs.

The results of two-way repeated-measures ANOVAs performed on scores obtained for words presented in noise are shown in Table 2. Effects of SNR and group membership were both significant, for both phoneme and word scores. The Group ×SNR interaction was close to significant for phonemes ($p = .058$) and was significant for words ($p = .028$). For both phoneme and word scores, post hoc contrasts showed differences between children with NH and the two hearing loss groups ($p < .001$), both with and without Bonferroni adjustments. The contrast of scores between children with HAs and CIs was not significant for phoneme scores but was significant for word scores ($p = .040$), without a Bonferroni adjustment; with the adjustment, the contrastwas not significant.

There is one potential flaw in viewing performance strictly according to how well children recognized phonemes and words in noise: Differences were observed across groups for recognition in quiet. Consequently, scores for recognition in noise were influenced not only by the presence of that noise but by general speech recognition abilities as well. To control for the effects of how well children could recognizewords in quiet, wecomputed percentages of phonemes and words recognized correctly in noise for only those phonemes and words recognized correctly in quiet. For phonemes, this approach meant that recognition in noise was matched to recognition in quiet, based on specific words and locations of phonemes within thosewords.Figure 2 shows groupmeans for these scores, and Table 3 shows results of ANOVAs performed on these conditional phoneme and word scores. Overall, values and patterns of scores in Figure 2 closely resemble those of Figure 1. Statistical outcomes were similar, but the Group ×SNR interactions were not significant for these conditional scores. Again, post hoc contrasts showed differences in scores for children with NH and those of the two hearing loss groups ($p < .001$), for both phonemes and words, and again, no significant difference was found between children with HAs and those with CIs for phoneme scores, but for word scores, the contrast was significant ($p = .047$) without a correction for multiple contrasts; with a Bonferroni adjustment, the effect was no longer significant.

Lexical effects. Mean j factors for each group at each SNR are shown in Table 4. These factors were computed only on data fromchildren who had recognition scores between 5% and 95% correct for both phonemes and words. All children with NH had scores within this range at all three SNRs, but some children with hearing loss did not achieve 5% correct recognition at one or more SNRs. These reported j factors are similar to those

reported by Nittrouer and Boothroyd (1990) for children between 4 and 6 years of age: +3 dB SNR = 2.51 and 0 dB SNR = 2.45. Children were not tested at -3 dBSNRinthat study.

A two-way repeated-measures ANOVA run on the current data showed a significant effect of SNR, $F(2, 58) = 3.15$, $p = .05$, but neither the group effect nor the Group ×SNR interaction was significant. Simple effects analyses conducted on these values revealed a significant difference only between j factors for -3 dB versus +3 dB SNR ($p = .049$), although the comparison of -3 dB versus 0 dB was close to significant ($p = .058$). The comparison of j factors for 0 dB versus +3 dB SNR was not significant; thus, one can conclude that similar lexical effects were found for children in all groups. A slight trend was found toward reduced lexical effects at the poorest SNR.

Summary. Speech recognition diminished as SNR becamepoorer, and children with hearing loss did not perform as well as children with NH, regardless of whether they wore HAs or CIs. These differences could not be attributed to differences in lexical effects across groups. Significant differences were not observed between children with HAs and CIs for phoneme recognition in noise; however, for word recognition, contrasts reached statistical significance without Bonferroni corrections. Because the group of children withHAs was small, it is possible that a true difference between these groups may exist and was missed in these analyses. A difference in speech perception in noise for children with HAs and CIs could have been predicted because CIs do not preserve all the kinds of signal structure available through HAs. Because of the possibility of a group difference between children with HAs and those with CIs, results from children with HAs were not included in subsequent analyses; instead, analyses focused on potential differences between children with NH and those with CIs.

Other Measures

VOT. Labeling functions for the synthetic VOTstimuli are shown in Figure 3. Functions are very similar in location and slope for children with NH and those with CIs, and t tests done on phoneme boundaries and slopes all failed to reveal significant differences between children withNHand those with CIs. Thus, one can conclude that these children with CIs exhibited typical abilities for categorizing speech stimuli that are distinguishable based on the temporal cue of VOT.

General language. The top two rows of Table 5 show mean standard scores, standard deviations, outcomes of t tests, and effect sizes in the form of Cohen's ds for both auditory comprehension and expressive vocabulary measures. For both measures, children with NH performed better than children with CIs. These differences were significant, with large effect sizes.

Cognitive skills. The middle two rows of Table 5 show mean scores and other statistics for measures of cognitive skills. Children with NH performed better on both tasks than children with CIs. These differences were significant, but with effects of only moderate size.

Phonological awareness. The bottom three rows of Table 5 show mean scores and other statistics for the three measures of phonological awareness. Children with NH performed better than children with CIs on all three, but effects were greater for the two measures of phonemic awareness than the one measure of syllabic awareness. That likely reflects the fact that CIs preserve the amplitude structure affiliated with syllabic structure in the speech signal but are poor at conveying many of the acoustic cues associatedwith phonemes. In particular, spectral structure arising from the vocal tract filter is lacking.

A review of incorrect responses failed to reveal any evidence that any strategy other than the one designated by the task was used by any child for responding.

Regression Analyses

Separate linear regressions with one predictor variable in each analysis were performed with each of two dependent measures of speech recognition in noise. The twomeasures of speech recognition used in these analyses were the conditional (upon correct recognition in quiet) phoneme and word recognition scores. These scores were selected for use on the basis of principled grounds (they seem most valid), but in fact outcomes were no different when the nonconditional percentage-correct scores were used. The mean across the three

SNRs for each measure (phoneme and word recognition) was computed for each child. The predictor variables used were each of the seven measures shown in Table 5. These linear regressions were performed with scores for children with NH and those with CIs combined, as well as for each group separately. Standardized beta coefficients are shown in Table 6.

When we looked at scores for all children, we found that the predictor variables that explained significant proportions of variance in phoneme and word recognition were the language measures and the measures of phonemic awareness. The highest standardized beta coefficient obtainedwas for word recognition and the final consonant choice task (b = .782). Short-term memory also explained a significant proportion of variance for word recognition (b = .405), but the magnitude of that effect was smaller than for any general language or phonemic awareness measure. When we examined beta coefficients for each group separately, we noted that the only one that explained a significant proportion of variance for either group was the one for the initial consonant matching task and word recognition for children with NH (b = .594).

The pattern of finding significant beta coefficients when children in both groups are considered together, but finding no significant coefficients when they are considered separately, means that the two groups differ in performance for both variables (predictor and dependent), but there was not a continuous effect within the groups. Figure 4 illustrates this pattern for word recognition and final consonant choice, the analysis that resulted in the largest beta coefficient when all children were included. The pattern found here is one of two distinct groups defined by scores on each of the measures but no indication of a relationship between scores for either group. In fact, several children with NH performed similarly to children with CIs on the final consonant choice task but were more accurate at recognizing words in noise.

Factors Affecting Performance of Children With CIs

We again used the conditional phoneme and word recognition scores as dependent variables to examine potential effects of factors related to hearing loss and cochlear implantation in the children with CIs. First, we obtained standardized beta coefficients using age of identification, age at first implantation, and age at second implantation (for the 18 children who had two implants) as predictor variables. Of these, only age at first implantation revealed significant effects for phoneme recognition (b = .424, t = 2.341, p = .027), but not for word recognition, (b = .362, t = 1.945, p = .063). Thus, being younger at the time of the first implant was associated with better outcomes for speech recognition in noise: Roughly 18% of the variance in phoneme recognition scores was explained by age at first implant.

Next, we examined the effects of having one or two implants and of having had or not had some period of bimodal experience. Only one child was still wearing an HA and a CI at the time of testing. That child was not included in the analyses of one or two implants because she did not fit neatly into either group.Mean conditional phoneme and word recognition scores are shown in Table 7, and t tests were performed on these scores. The effect of having one or two implants was not significant (p >.10). The effect of having had some period of bimodal experience was not significant either; however, a trend toward better word recognition (t = 2.038, p = .052) was found for the group with some period of bimodal experience.

Finally, we examined scores for phoneme and word recognition in quiet for children with CIs. Because their performance was not close to 100% accurate in quiet, as was the case for children with NH, the abilities of children with CIs to recognize speech in noise were highly constrained by their abilities to recognize speech in quiet. Thus, it seemed important to determine what explained those quiet recognition abilities. Stepwise linear regressions were performed, with the percentages of phonemes and words recognized correctly in quiet serving as dependent variables. Predictor variables included the seven measures that have been considered thus far (shown in Table 5), as well as age of first implantation, because that was found to explain a significant proportion of variance for phoneme recognition in noise.

The results of these analyses are shown in Table 8. For both phoneme and word recognition in quiet, expressive vocabulary scores explained a large proportion of variance, such that the better a child's vocabulary

was, the better the child's recognition in quiet was. Scores on the initial consonant matching task were also found to explain significant proportions of variance in phoneme and word recognition scores. However, the interesting aspect of this result is that the direction of relationship was opposite to what would be expected: Higher scores on the initial consonant task were associated with lower scores on phoneme and word recognition in quiet.

Discussion

We undertook this study to examine factors that were considered likely candidates to help explain speech recognition in noise by children who use CIs.We fully anticipated before the study was conducted that children with CIs would perform more poorly than children with NH on measures of speech recognition in noise, and that was indeed found to be the case. However, only small Group ×SNR interactions were obtained, and only when scores not contingent on performance in quiet were used in statistical analyses. Those patterns of result suggest that noise effects on recognition were either similar or only slightly greater for children with CIs than for children with NH. This finding could be interpreted as indicating that-at least for children-the limitations on the kind of signal delivered by CIs take the greatest toll on speech recognition in quiet. Adding noise to the signal appears to have comparable effects for all children, regardless of hearing status.

That situation differs from the one presumed to exist for adults. It is commonly believed that noise has more deleterious consequences for implant users than for listeners withNH(e.g., Carroll, Tiaden,&Zeng, 2011), but perusal of the literature fails to provide strong evidence of this position. Few studies have quantified phoneme or word recognition scores in various levels of noise for adults with NH and those with CIs (cf. Zeng &Galvin, 1999). One report that gave scores derived from real words showed close to a 40-percentage-point drop in phoneme recognition scores between 25 dB SNR (which is effectively listening in quiet) and 0 dB SNR for implant users and listeners with NH alike (Hochberg, Boothroyd,Weiss, &Hellman, 1992). Those recognition scores match what is typically found for listeners with NH (e.g., Boothroyd &Nittrouer, 1988) and for listeners with CIs (e.g., Friesen, Shannon, Baskent, &Wang, 2001) at those noise levels. Consequently, it could be that the processing limitations imposed by CIs have their primary effects on recognition in quiet even for adults, and noise effects are consistent in magnitude for listeners with NH and those who use CIs. Be that as it may for adults, the current study suggests that it is likely the case for children.

Of course, these results spark the question of why childrenwithCIs are somuch poorer at recognizing speech than children with NH, even in quiet. Some of the explanationmust surely be that implants provide only a sparse signal representation, lacking many of the acoustic properties, especially spectral ones, traditionally thought to underlie phonetic perception. At the same time, children with CIs demonstrate a variety of language deficits, including those of vocabulary, phonological awareness, and comprehension of language structures. Although the source of those difficulties may very well be traced to the impoverished signals provided through implants, the language and phonological deficits would nonetheless be expected to feed back and have negative effects of their own on speech recognition. As Ahissar (2007) suggested, highly refined language knowledge allows listeners to make predictions about the structure that is likely to be in the signal; conversely, the absence of such knowledge inhibits recognition. This phenomenon presumably would be just as applicable to perception in quiet as in noise, especially if the signal is degraded due to processing limitations.

Nonetheless, children with CIs performed significantly more poorly than children with NH when it came to recognizing speech in noise. This difference between groups was strongly related to group differences in language and phonological awareness measures, but no evidencewas found to suggest that recognition scores in noise were explained by the language and/or phonological awareness measures for children with CIs: No withingroups effects were found. Only one measure (initial consonant matching) was found to explain a significant proportion of variance for recognition in noise, but only for the children with NH.

Given the trends observed in this study, one can conclude that the difficulties in recognizing speech in noise experienced by children with CIs differ from those of children with dyslexia. Children in the latter group

recognized speech perfectly well in quiet and exhibited problems only for recognition in noise. Thus, there is a clear and disproportionately large effect of noise on recognition abilities for children with dyslexia, compared to that experienced by children with NH and without dyslexia. Children with CIs showed deficits for speech recognition in quiet and an effect of noise similar in magnitude to what was observed for children withNH. The implication of these findings is that improved processing strategies for CIs, if and when they are developed, should be expected to have positive effects on recognition in both quiet and noise for children with CIs. In fact, if processing strategies that preserve phonemically relevant spectral structure in the signal and/or temporal fine structure were to be developed, children with CIs could reasonably be expected to acquire better language and phonological skills as well. That prediction follows fromthe fact that results fromthe VOT continua revealed that these children are perfectly capable of forming well-defined phonological categories, as long as they have access to the signal properties on which those categories are based. Until such time as improved processing strategies can be implemented in CIs, teachers and clinicians will need to continue providing extra support to these children to help them acquire the language and phonological skills they need to succeed in academic settings. Care should be given to maximize signal-to-noise levels for these children, as well.

Auditory Brainstem Response to Complex Sounds Predicts Self-Reported Speech-in-Noise Performance

Author: Anderson, Samira; Parbery-Clark, Alexandra; White-Schwoch, Travis; Kraus, Nina.

Publication info: Journal of Speech, Language and Hearing Research (Online) 56.1 (Feb 2013): 31-43.
ProQuest document link

Abstract: To compare the ability of the auditory brainstem response to complex sounds (cABR) to predict subjective ratings of speech understanding in noise on the Speech, Spatial, and Qualities of Hearing Scale (SSQ; Gatehouse &Noble, 2004) relative to the predictive ability of the Quick Speech-in-Noise test (QuickSIN; Killion, Niquette, Gudmundsen, Revit, &Banerjee, 2004) and pure-tone hearing thresholds. Participants included 111middle- to older-age adults (range = 45-78) with audiometric configurations ranging from normal hearing levels to moderate sensorineural hearing loss. In addition to using audiometric testing, the authors also used such evaluation measures as the QuickSIN, the SSQ, and the cABR. Multiple linear regression analysis indicated that the inclusion of brainstem variables in a model with QuickSIN, hearing thresholds, and age accounted for 30% of the variance in the Speech subtest of the SSQ, compared with significantly less variance (19%) when brainstem variables were not included. The authors' results demonstrate the cABR's efficacy for predicting self-reported speech-in-noise perception difficulties. The fact that the cABR predicts more variance in self-reported speechin- noise (SIN) perception than either the QuickSIN or hearing thresholds indicates that the cABR provides additional insight into an individual's ability to hear in background noise. In addition, the findings underscore the link between the cABR and hearing in noise.

Full text: Headnote

Purpose: To compare the ability of the auditory brainstem response to complex sounds (cABR) to predict subjective ratings of speech understanding in noise on the Speech, Spatial, and Qualities of Hearing Scale (SSQ; Gatehouse &Noble, 2004) relative to the predictive ability of the Quick Speech-in-Noise test (QuickSIN; Killion, Niquette, Gudmundsen, Revit, &Banerjee, 2004) and pure-tone hearing thresholds.
Method: Participants included 111middle- to older-age adults (range = 45-78) with audiometric configurations ranging from normal hearing levels to moderate sensorineural hearing loss. In addition to using audiometric testing, the authors also used such evaluation measures as the QuickSIN, the SSQ, and the cABR.
Results: Multiple linear regression analysis indicated that the inclusion of brainstem variables in a model with QuickSIN, hearing thresholds, and age accounted for 30% of the variance in the Speech subtest of the SSQ, compared with significantly less variance (19%) when brainstem variables were not included.
Conclusion: The authors' results demonstrate the cABR's efficacy for predicting self-reported speech-in-noise perception difficulties. The fact that the cABR predicts more variance in self-reported speechin- noise (SIN) perception than either the QuickSIN or hearing thresholds indicates that the cABR provides additional insight into an individual's ability to hear in background noise. In addition, the findings underscore the link between the cABR and hearing in noise.

Key Words: central auditory processing, brainstem, speech-in-noise perception, clinical audiology, speech perception, electrophysiology, aging

Older adults often report difficulty hearing in background noise. Providing appropriate assessment and management for these individuals can be challenging for the audiologist and other clinicians. Historically, the traditional audiologic assessment included pure-tone threshold and word recognition measures; more challenging assessments, such as repeating sentences in competing background noise, were reserved for the assessment of central auditory processing. Researchers gave little thought to addressing the older adult's most challenging concern-hearing speech in noise (SIN). The use of clinical measures of SINperception, such as the Quick Speech-in-Noise test (QuickSIN; Killion, Niquette, Gudmundsen, Revit, &Banerjee, 2004), the Bamford-Kowal-Bench Speech-in-Noise test (BKBSIN; Bench, Kowal, &Bamford, 1979), the Hearing in Noise Test (HINT; Nilsson, Soli, &Sullivan, 1994), and theWords-in-Noise test (WIN;Wilson, Abrams, &Pillion, 2003), has been more prevalent in the last decade. These measures classify performance into degrees of hearing

handicap in noise, providing clinicians the information needed to make specific recommendations for hearing enhancement in noise (e.g., directional microphones, FM systems). Although these tests are useful, particularly when counseling patients, it remains challenging for clinicians to predict actual performance in difficult, real-world listening situations. Any assessment requiring a voluntary response is affected by cognitive factors, which can be compromised in the elderly (Dennis &Cabeza, 2007; Salthouse, 1985)-the group that most often seeks out assistance for hearing difficulties. What is needed, then, is an objective measure that is unaffected by cognitive status and can be used to predict real-world SIN performance.

An objective measure requires no response from the patient. Such measures, including auditory brainstem responses, otoacoustic emissions, and acoustic reflex thresholds, are routinely used for hearing screening and diagnosis in babies and other difficult-to-test patients (Hall, 2007). An objective measure for predicting SIN perception in the older adult population would require evaluation of more complex processing than that offered by simple stimulus detection and would be sensitive to agerelated changes in central auditory system function. Researchers have documented the effects of aging on temporal resolution in the auditory system (Anderson, Parbery- Clark, White-Schwoch, &Kraus, 2012), which can generally be attributed to overall slowing of neural processing. This slowing may arise from a number of factors including, but not limited to, delayed neural recovery time (Walton, Barsz, &Wilson, 2008), decreased inhibition (Caspary, Ling, Turner, &Hughes, 2008), and increased temporal jitter (Pichora-Fuller, Schneider, MacDonald, Pass, &Brown, 2007). Evidence of neural slowing has been documented in the auditory cortex (Iragui, Kutas, Mitchiner, &Hillyard, 1993; Matilainen et al., 2010; Tremblay, Billings, &Rohila, 2004) and brainstem (Anderson, Parbery-Clark, Yi,&Kraus, 2011; Finlayson, 2002; Vander Werff& Burns, 2011). Neural slowing can affect precise encoding of temporal speech features, accounting in part for the older adult's difficulty with hearing in background noise (Tremblay, Piskosz, &Souza, 2002; Walton, 2010).

The auditory brainstem response to complex sounds (cABR) provides an objective means for evaluating the brainstem's ability to accurately encode timing and frequency information and also reflects neural slowing in older adults (Parbery-Clark, Anderson, Hittner, &Kraus, 2012; VanderWerff& Burns, 2011). The cABR's high reliability in individuals lends itself to clinical uses such as assessment and documentation of treatment outcomes (Hornickel, Knowles, &Kraus, 2012; Russo, Hornickel, Nicol, Zecker,&Kraus, 2010; Song, Nicol,&Kraus, 2011a, 2011b). The use of complex stimuli provides more sensitivity than do clicks or tone bursts to subtle differences in impaired populations, relative to normal controls (Song, Banai, Russo, &Kraus, 2006), thus highlighting the potential for the cABR to provide an effective means of assessing central auditory system function. In a previous study, we documented that accurate neural timing is an important factor in SIN performance in older adults (Anderson et al., 2011). In the present study, weexamined the utility of the cABR for predicting self-reported SIN perception in older adults, using a clinically available software platform.

To achieve our objective of finding an efficacious measure of real-world performance, we compared the sensitivity of monaural, binaural, and binaural-in-noise presentation protocols for assessing differences in SIN perception. The monaural protocol has proved useful to clinicians assessing language-based learning impairments in children (Banai et al., 2009), but we included the binaural protocol in case the monaural presentation failed to elicit a robust, replicable response in older adults. The binaural-in-noise presentation was used to simulate speech processing in degraded conditions. We did not include a monaural-in-noise protocol because pilot testing revealed that the individuals tested did not have a sufficiently replicable response for peak identification. Our aim was to determine which of these protocols was most predictive of self-reported SIN perception.

We also developed a stimulus-compensation protocol to reduce the effects of peripheral hearing loss on the cABR in individuals with hearing loss. This protocol created an amplified waveform based on individual hearing loss in each participant.We compared responses to these three presentation conditions using amplified and unamplified stimuli and anticipated that the use of amplified stimuli would minimize expected effects of audibility

loss (e.g., loss of detectable response peaks) in individuals with a hearing loss.

We used the Speech, Spatial, andQualities of Hearing Scale (SSQ; Gatehouse& Noble, 2004) because we wanted a measure that reflects self-reported performance rather than behavioral performance obtained in the clinic or laboratory. Specifically, by virtue of it being a self-report measure, the SSQ provides clinicians with important information about self-perception of the ability to perceive speech in noise, a common clinical complaint in older adults. The SSQ was developed in response to recognized limitations of the traditional audiological battery for predicting listening ability in challenging environments, such as rooms with multiple talkers and other noise sources. The SSQ covers a range of hearing contexts, asking individuals to rank perceived hearing difficulty ranging from easier one-on-one conversations in a quiet setting to conversing in a large, noisy restaurant.Gatehouse and Noble administered the SSQ to 153 patients with hearing loss prior to hearing aid fitting and concluded that the SSQ elicits new dimensions of hearing (e.g., attention switching, spatial hearing), thus providing a measure of complex and dynamic aspects of hearing in noise not captured by traditional assessment tools. Since its development, the SSQ has been used to document the benefit of using one versus two hearing aids (Most, Adi-Bensaid, Shpak, Sharkiya, &Luntz, 2012; Noble &Gatehouse, 2006), the advantages of directional microphones for speech intelligibility in noise (Wilson, McArdle, &Smith, 2007), and the benefit of cochlear implant algorithms (Vermeire, Kleine Punte,&Van de Heyning, 2010), as well as to obtain an individual self-assessment of speech understanding in noise abilities (Agus, Akeroyd, Noble, &Bhullar, 2009; Helfer&Vargo, 2009). The SSQis a reliable instrument: Researchers administering tests 6 months apart (Singh&Pichora-Fuller, 2010) obtained test.retest correlations from both one-on-one interviews (r = .83) and mailed questionnaires (r = .65).

We predicted that the cABR, a highly reliable and objective measure of spectral and temporal resolution, would be a better predictor of real-world SINperformance than would clinical measures requiring patient responses. We expected that the effects of aging.including delayed neural recovery, decreased inhibition, and increased temporal jitter.would result in delayed onset and offset timing as well as decreased overall morphology and sharpness of the response to the stimulus onset.

Method

Participants

We recruited 111 participants (64 women, 47 men; ages 45.78; Mage = 61.1) from the Chicago area. We obtained audiometric thresholds at octave intervals (interoctave at 3000 and 6000 Hz) from 125.12,000 Hz. The participants included individuals with hearing levels ranging from normal hearing to moderate hearing loss, with the exclusion of any participant who had hearing thresholds greater than 40 dB HL (below 4000 Hz) or greater than 60 dB (from 4000 to 8000 Hz). Pure-tone averages (500.4000 Hz) ranged from 2.5 dB HL to 44.5 dB HL (M= 17.29, SD=8.7; seeFigure 1). Inaddition, no participant had air-bone gaps greater than 10dBat 2 ormore frequencies in either ear, nor had neurological disorders, asymmetric pure-tone thresholds (defined as >15 dB difference at 2 or more frequencies between ears), delayed Wave V latencies for the click-evoked auditory brainstem response (defined as a latency >6.8 ms at 80 dB SPL presented at a rate of 31.4 Hz), interauralWaveVlatency differences greater than 0.2 ms, or nonreplicating onsets or offsets in the cABR. Finally, exclusionary criteria included IQ scores <85 on the vocabulary and matrix design subtests of the Wechsler Abbreviated Scales of Intelligence (WASI; Zhu&Garcia, 1999) and scores <22 (from participants who were age.60) on the Montreal Cognitive Assessment (M°CA; Nasreddine et al., 2005), a screening for cognitive impairment. Participantswere compensated for their time and procedures were approved through the Northwestern University Institutional Review Board.

SIN

Self-Reported SIN Perception

Participants answered questions on the SSQ about hearing performance in various environments using a 10-point Likert scale, ranging from one-on-one listening in a quiet environment to listening to multiple talkers in a

background of other talkers. In addition tomeasuring the ability to understand speech, the questionnaire also measures an individual's self-perception of localization abilities and judgment of sound quality. Because we are primarily interested in speech understanding, we restricted our analysis to the Speech subscale. We mailed the questionnaires to our participants and asked them to fill them out prior to coming to their appointments so that their answers would not be influenced by our testing. The Speech subscale has higher reliability (r = .83) than do the three combined subscales (r = .65) in mailed formats (Singh &Pichora-Fuller, 2010).

Clinical Measure of SIN Perception

We assessed SIN performance with the QuickSIN because of its widespread clinical use and its superior ability to separate performance between groups of participants with normal hearing and groups of participants with hearing impairment compared with other tests containing sentences, such as theBKB-SIN orHINT (Wilson et al., 2007). Four sets of six sentences were presented binaurally at 70 dB HL in a background of four-talker babble noise (three females and one male) through insert earphones (ER-2; Etymotic Research). The first set of sentences was presented at +25 dBsignal-to-noise ratio (SNR), with the SNR decreasing by 5 dB for each subsequent sentence down to 0 dB SNR. Five key words in each sentence were marked as correct or incorrect. The total number of key words repeated correctly in each set of six sentences was subtracted from 25 to obtain the SNR loss in dB, defined as the difference between the individual's SIN threshold and the average SIN threshold (Killion et al., 2004). The SNR loss scores were averaged over the 4 lists to obtain the final SNR loss. A lower SNR loss score indicated better SIN performance.

Electrophysiology

Stimulus. The stimulus was a 40-ms [da] syllable synthesized in KLATT (Klatt, 1980). The stimulus began with a noise burst and was followed by a consonant-to-vowel transition.The fundamental frequency (F0) of the stimulus rose linearly from 103 Hz to 125 Hz. The formant trajectories were as follows: The first formant rose from 220 Hz to 720 Hz, the second and third formants decreased from 1700 Hz to 1240 Hz and from 2580 Hz to 2500 Hz, respectively, and the fourth (3600 Hz) and fifth (4500 Hz) formants remained constant for the duration of the stimulus. The stimulus did not include the steady-state vowel of the syllable, but it was perceived as a consonant-vowel syllable. This stimulus has been used in previous studies examining rate (Krizman, Skoe, &Kraus, 2010), sex differences (Krizman, Skoe, &Kraus, 2012), reading disorders (Banai et al., 2009), and maturation (Johnson, Nicol, Zecker, &Kraus, 2008). Figure 2 displays the stimulus and the grand average response.

An amplified stimulus was used for individuals who had hearing loss greater than 20 dB at any frequency from 125 Hz to 4000 Hz or greater than 25 dB at 6000 Hz or 8000 Hz. Using the National Acoustics Laboratory-Revised algorithm (NAL-R; Byrne &Dillon, 1986), we selectively amplified stimulus frequencies based on individual hearing thresholds in MATLAB (MathWorks).

For individuals with normal hearing, we presented the unamplified [da] stimulus at a rate of 10.9Hz through electromagnetically shielded insert earphones (ER-3A; NatusMedical) at 80.3 dB SPL in the following three conditions: Monaurally (right ear) in quiet, binaurally in quiet, and binaurally in pink noise (+10 dB SNR). For participants with hearing loss, we presented both the amplified and the unamplified [da] stimuli for each of the three conditions (monaurally in quiet, binaurally in quiet, and binaurally in pink noise), making a total of six conditions. We chose the right ear for monaural presentation because right-ear stimulation produces more robust frequency encoding and earlier latencies than does stimulation to the leftear (Hornickel, Skoe,&Kraus, 2009).We presented the [da] stimuli in alternating polarities tominimize stimulus artifact and the cochlear microphonic (Gorga, Abbas, &Worthington, 1985; Russo, Nicol, Musacchia, &Kraus, 2004), an approach that emphasizes the envelope following response (Aiken&Picton, 2008; Campbell, Kerlin, Bishop, &Miller, 2012; Skoe &Kraus, 2010).

Recording.We recorded responses using the Biologic Navigator Pro System (Natus Medical). Prior to each recording, we calibrated the click and [da] stimuli to 80 dB SPL using a Brüel &Kjæ r 2238 Mediator sound level

meter coupled to an insert earphone adapter. We sampled the SPL for each stimulus over 60 s to obtain the average SPL. Responses were recorded via a vertical electrode montage of four Ag-AgCl electrodes (central vertex [Cz] active, forehead ground, and linked earlobes reference) for the binaural recordings and three electrodes (same as described above, with only the right earlobe as reference) for the monaural recordings.We used a criterion of ±23 mV for online artifact rejection. Two blocks of 3,000 artifact-free sweeps were collected in each condition for each participant and averaged using an 85.3-ms window, including a 15.8-ms prestimulus period. The responses were sampled at 12 kHz and were online bandpass-filtered from 100 Hz to 2000 Hz (12 dB/octave).

Data Analysis

We conducted data analysis using established MATLAB routines (Johnson et al., 2008; Krizman et al., 2010). A second observer manually identified and confirmed the onset peak and trough (labeled V and A) and the offset peak (labeled O; see Figure 2). Peaks that were not detectable were marked as missing data points and were excluded from the analysis. To obtain a measure of sharpness of the neural response, we calculated the slope between the onset peak (V) and trough (A). We also obtained a measure of the overall response morphology and neural fidelity to the stimulus by cross-correlating the stimulus and response waveforms, yielding a stimulus-toresponse correlation value. These measures (onset latency and slope, offset latency, and response morphology) were obtained for all six conditions and were labeled as follows:

Monaural

Onset latency: Vlat

Onset slope: VAslope

Offset latency: Olat

Response morphology: STRr

Binaural

Onset latency: Bi_Vlat

Offset slope: Bi_VAslope

Offset latency: Bi_Olat

Response morphology: Bi_STRr

See Table 1 for means and standard deviations of all cABR variables for the monaural, binaural, and binauralin-noise conditions.

Statistical Analysis

To determine the effectiveness of the amplification algorithm, we performed paired t tests between responses to amplified and unamplified stimuli for onset latency (Vlat), offset latency (Olat), VAslope, and morphology STRr.We performed linear regressions, with the average SSQ score (14 items on the speech subscale) entered as the dependent variable and QuickSIN scores, pure-tone average (PTA; average of thresholds from 500-4000 Hz), Age, Vlat, Olat, VAslope, and STRr entered in that order. Using the "Enter" method of multiple linear regression, we specified the order of variable entry to prevent brainstem variables from accounting for the variance that might have otherwise been ascribed to QuickSIN, PTA, and Age. We compared the outputs of the linear regressions for monaural versus binaural presentation conditions to determine the most efficacious protocol.

In all models, we checked residuals for normality to ensure that the linear regression analysis was appropriate for the data set (Kolmogorov-Smirnov Test; M = 0, SD = 0.97, p = .355). We ran collinearity diagnostics with satisfactory variance inflation factor (highest = 2.02) and tolerance (lowest = 0.494) scores, indicating the absence of strong correlations between two or more predictors.

Results

Amplification Algorithm

Monaural presentation. We applied the amplification algorithm in the 50 of 111 cases in which hearing loss

exceeded our criteria for normal thresholds. Stimulus amplification in the monaural presentation resulted in greater onset and offset peak detectability (amplified: 47 of 50 detectable onsets and 44 of 50 detectable offsets vs. unamplified: 38 of 50 detectable onsets and 35 of 50 detectable offsets; Related-Samples McNemar Test: VAslope, p = .031; Olat, p = .004). Comparisons of responses to the unamplified versus amplified stimuli in individuals with hearing loss revealed that VAslope was sharper in the amplified versus unamplified stimuli, t(37) = 2.887, p = .0006: Mamplified = -0.29, Munamplified = -0.25. Although Olat was slightly earlier for the amplified stimuli, the differences were not significant, t(34) = 0.384, p = .703:Mamplified = 48.83ms,Munamplified = 48.91ms. The STRr values did not differ between conditions, although the r value was slightly higher in the amplified condition, t(49) = 0.837, p = .437: Mamplified = 0.113, Munamplified = 0.106. The final number of participants with hearing loss with detectable onsets and offsets was 44. The final total of participants (those with normal hearing and those who were hearing impaired) with detectable onsets and onsets was 104. All individuals with normal hearing had detectable onsets and offsets. Figure 3 compares the average waveforms of participants with hearing loss in response to amplified versus unamplified stimuli.

Binaural presentation. The response to the binaural presentation was robust, with detectable onset peaks in all responses to amplified or unamplified stimuli and little difference in detectability of the offset peaks (amplified: 48 of 50 detectable offsets vs. unamplified: 44 of 50 detectable offsets; Related-Samples McNemar Test: Olat, p = .219). The greatest effects were seen for the onset, with Bi_Vlat earlier and Bi_VAslope sharper in responses to amplified versus unamplified stimuli-Bi_Vlat, t(49) = 3.662, p = .001;Mamplified = 6.62 ms, Munamplified = 6.74 ms; Bi_VAslope, t(49) = 5.250, p <.001,Mamplified = -0.45,Munamplified = -0.37. The Bi_Olat and Bi_STRr values did not differ significantly between conditions: Bi_Olat, t(43) = 1.213, p = .234, Mamplified = 49.17 ms, Munamplified = 49.35 ms; Bi_STRr: t(49) = 0.529, p=600,Mamplified=0.093,Munamplified=0.097. All individuals with normal hearing had detectable onsets and offsets.

Binaural-in-noise presentation. The response to the binaural-in-noise presentation was degraded compared with the responses in binaural quiet and monaural presentations. We found little difference between responses to amplified or unamplified stimuli with equivalent detectability of the onset peaks (36 of 50 detectable onsets to both amplified and unamplified stimuli) and offset peaks (amplified: 36 of 50 detectable offsets vs. unamplified: 39 of 50 detectable offsets; Related-Samples McNemar Test: Bin_Olat, p = 1.00). There were no significant differences between amplified and unamplified measures (Bin_Vlat: p >.1; Bin_VAslope, Bin_Olat, and Bin_STRr: p >.5). We also observed a loss of replicability in the responses of individuals with normal hearing (N = 60; 47 of 60 and 51 of 60 detectable onsets and offsets, respectively).

Multiple Linear Regression

Monaural presentation. Results of multiple linear regression analysis indicated that our selected brainstem variables predicted a greater amount of variance in selfassessed SINperception on theSSQin middle- to older-age adults than did PTA, QuickSIN, and Age. We chose to use the "Enter" method of linear regression, which specifies the order of variables entered into the model. By entering the cABR variables last, we ensured that the cABR variables did not use up the variance that might have otherwise been attributed to PTA, QuickSIN, or Age. Our model (PTA, QuickSIN, Age, Vlat, Olat, VAslope, and STRr, entered in this order) is a good fit for the data, F(6, 103) = 5.982, p <.001, with an R2 value of .306. Only the brainstem variables of Olat and STRr significantly contributed to the variance. Table 2 provides standardized (b) and unstandardized (B) coefficients and levels of significance for the independent variables. In order to disambiguate the contributions of brainstem variables from other measures, we reran the regression hierarchically with PTA, QuickSIN, and Age on the first step and brainstem variables on the second step. The variables on the first step contributed significantly to the variance in SSQ, F(2, 103) = 5.721, p = .001, with an R2 value of .148. The addition of brainstem variables in Step 2 produced a significant change to the variance, R2 change = .158, F(3, 103) = 5.413, p = .001. Table 3 provides standardized coefficients (b), changes in R2, and levels of significance for the variables in Models 1 and 2.

Binaural presentation. Results using the binaural presentation indicated again that selected brainstem variables predicted a greater amount of variance in self-assessed SIN perception on the SSQ than did PTA, QuickSIN, and Age. Our model ("Enter" method: PTA, QuickSIN, Age, Bi_Vlat, Bi_Olat, Bi_VAslope, and Bi_STRr, entered in this order) is a satisfactory fit for the data, $F(6, 103) = 2.608$, $p = .017$, with an R2 value of .170. Only the Bi_STRr significantly contributed to the variance of the model. Table 4 provides standardized (b) and unstandardized (B) coefficients and levels of significance for the independent variables. We reran the regression hierarchically with PTA, QuickSIN, and Age on the first step and brainstem variables on the second step. Again, the variables on the first step contributed significantly to the variance in SSQ, $F(2, 103) = 5.721$, $p = .001$, with an R2 value of .148. However, we found that the addition of brainstem variables in Step 2 did not produce a significant change to the variance, R2 change = .073, $F(3, 103) = 1.964$, $p = .107$. Table 5 provides standardized coefficients (b), changes in R2, and levels of significance for the variables in Models 1 and 2.

Binaural-in-noise presentation. The lack of detectable peaks in individuals with either normal hearing or hearing loss resulted in a total number of 56 of 111 participants who had both detectable onsets and onsets, because some of the participants who had detectable onsets did not have detectable offsets and vice versa. Results of the linear regression indicated that the model including PTA, QuickSIN, Age, Bin_Vlat, Bin_Olat, Bin_VAslope, and Bin_STRr variables was not satisfactory for predicting SSQ, $F(6, 55) = 1.778$, $p = .117$, $R2 = .224$. The results of the binaural-in-noise presentation should be interpreted with caution, however as we did not have the recommended number of participants for performing a linear regression analysis (98; see Green, 1991).

Correlations. Tables 6 and 7 display intercorrelations among the SSQ and the independent variables-monaural cABRvariables in Table 6 and binaural cABRvariables in Table 7. The following variables were related to SSQ: PTA, QuickSIN, Age, monaural onset latency (Olat), and monaural and binaural morphology (STRr and Bi_ STRr). No significant correlations were noted between the SSQ and the binaural-in-noise cABR variables. Scatter plots demonstrating relationships among SSQ and Olat (monaural presentation), QuickSIN, and PTA are presented in Figure 4.

Summary. Brainstem variables (particularly the offset latency and stimulus-to-response correlation) significantly contribute to the variance in self-perception of SIN ability; in fact, they contribute greater variance than either hearing thresholds or QuickSIN scores. The monaural presentation protocol predicted greater variance than did the binaural protocol (Hotelling's t/Stegler's Z: $t103 = 2.05$, $Z = 2.00$, $p < .05$). In individualswith hearing loss, the use of amplified stimuli produced more detectable peaks, sharper onset slopes, and greater overall morphology (stimulus-to-response correlations) than did the use of unamplified stimuli.

Discussion

Our results demonstrate the important role of subcortical function in SIN performance as perceived by the listener. In our model, offset latency and overall morphology of the response waveform made significant contributions to the predictions of self-assessed SIN ability. Our study also revealed that using an amplified stimulus for the cABR produced more replicable waveforms in individuals with hearing loss, thereby reducing the number of participantswho needed to be excluded fromthe analysis. Themonaural protocolwasmost efficacious for predicting SIN perception, likely because ceiling effects in the binauralin- quiet presentation produced robust responses in almost all participants, limiting its ability to differentiate between good and poor SIN perceivers. Onthe other hand, floor-like effects were apparent in the binaural-in-noise presentation in which the noise degraded the neural responses in many participants to such a degree that useful information from the response was limited.

What are the mechanisms underlying the offset latency's importance for successful communication in background noise? Detection of stimulus offsets and onsets contributes to the activation of duration-tuned neurons in the inferior colliculus and at higher levels of the auditory system(Brand, Urban,&Grothe, 2000; Faure, Fremouw, Casseday, &Covey, 2003). Researchers have posited that duration selectivity results from temporal interaction of excitatory and inhibitory inputs that are offset in time (for review, see Sayegh, Aubie,&Faure,

2011). Activation of inhibitory transmitters is essential for duration tuning; for example, when pharmacological inhibitory antagonists are applied, duration tuning is abolished (Casseday, Ehrlich,& Covey, 2000). Caspary et al. (2008) documented the reduction of inhibitory transmitters in the midbrains of older mammals. Taken together, these results suggest that imprecise duration tuning is one of the consequences of aging; in fact, deficits in duration discrimination for tones and gaps in noise have been observed in older versus younger adults (Fitzgibbons &Gordon-Salant, 1994). In addition, duration-tuned neurons are tuned in frequency andamplitude, so that responses of these neurons are highly specific. Therefore, duration-tuned neurons may act as spectrotemporal filters (Sayegh et al., 2011), providing the precise encoding necessary for understanding speech in noise.

The other brainstem factors contributing to variance in SIN perception-reduced onset slope and poorer stimulus-to-response correlation (representing decreased morphology)-can result from temporal jitter or loss of neural synchrony that accompanies aging. The SIN performance of young adults with normal hearing when they listen to temporally jittered speech decreases to the levels expected of older adults (Pichora-Fuller et al., 2007), providing a potential explanation for the older adults' listening-in-noise difficulties.We did not, however, find the expected relationships between age and onset latency (Olat), onset slope (VAslope), and morphology (STRr). The lack of relationship between these variables and age might be explained by the restricted age range in our study, which did not include anyone younger than 45 years. Because onset latencies can be delayed in adults as young as 47 years (Parbery-Clark et al., 2012), the relationship between age and latency might have been obscured by an age-related delay in all of our participants.

Even though the QuickSIN's contribution to the SSQ variance was less than that of the cABR, the QuickSIN and other clinical tests of SIN perception remain an important part of the audiological protocol. In the first author's experience, patients often express satisfaction that their actual difficulty has finally been evaluated after being tested with the QuickSIN.We are not recommending that these tests be dropped from the protocol; rather,we suggest that clinicians beaware of the limitations of a strictly behavioral protocol. Cognitive factors, such as memory or attention, will affect tests results, such as those of the QuickSIN (Parbery-Clark, Skoe, Lam, &Kraus, 2009; Shinn-Cunningham &Best, 2008), and memory and/or attention may be compromised in some older adults (Pichora-Fuller, 2003). Therefore, the clinician should consider the QuickSIN and other SIN test results in the context of the patient's overall function and his or her stated difficulties.

If one accepts that an objective measure of SIN perception is warranted in the assessment of older adults, how can the cABR be incorporated into clinical practice? The protocol for obtaining the measures described in this article requires approximately 20 min (including time for electrode application). While we acknowledge that a typical audiologist cannot routinely extend the assessment time by 20 min, the cABR nevertheless can be considered for inclusion when an individual's reports of hearing difficulty are not reflected in the traditional battery of speech and pure-tone tests. In Figure 5 we provide two examples of cABRs from participants who have good and poor SSQ scores, respectively. While the individual with a better SSQ score has poorer hearing thresholds and QuickSIN score, he has earlier onset and offset latencies, a sharper slope, and better cABR morphology. We envision the use of such measures as informing the clinician of the need to assess suprathreshold auditory function; in the future, a clinicianmight rely on normative values to assess auditory function in an individual patient. For example, the cABR may benefit patientswho are having inordinate difficulties adjusting to their hearing aids, thus helping clinicians determine whether problems with central auditory processing are interfering with patients' ability to benefit from amplification and whether auditory training or assistive listening devices are indicated (for review, see Anderson& Kraus, in press). Because the cABR is highly reliable and consistent over time (Song et al., 2011b), its uses are interpretable on an individual level, suggesting a use for monitoring changes. The cABR has been used to document training benefits in children (Russo, Nicol, Zecker, Hayes, &Kraus, 2005) and young adults (Song, Skoe, Banai, &Kraus, 2012), but more work is needed to determine the cABR's efficacy for predicting and assessing training benefit in older

adults.

We chose to use the SSQ rather than a more direct measure of SINperception, suchas theQuickSIN, because we wanted to address individual self-perception of ability, which is what generally motivates someone to seek help for hearing difficulties. In addition, the SSQ is an approximation of overall, day-to-day SIN performance, as opposed to a one-time test in a clinic. The linear regression model used in this study predicted 30% of the variance in the SSQ, leaving much of the variance attributed to unknown factors. Personality characteristics and occupations likely affect individual answers on the SSQ. The person who works in a noisy area with high communication demands will answer questions differently than would the older, retired individual who spends much of his or her time at home watching television. If we had selected a standardized clinical or laboratory SIN perception measure as our predicted variable, we expect that our model might have predicted more variance because the dependent variable would be somewhat freer of the influence of personality and lifestyle biases. It should be noted that our data set is not typical for patients of an audiologic clinic, in thatmost of themcameto our laboratory to participate in research, not because they were seeking treatment or advice for hearing problems. Nevertheless, many of our participants were motivated to participate in the study because they had noticed some trouble when listening in noise and wanted to participate in a research study before seeking clinical consultation. In the future, we plan to extend this analysis to a clinical population of individuals seeking treatment for hearing loss.

Other factors, such as cortical processing, cognitive function, aging, and general life experiences, would also add to the predicted variance of our model. The auditory cortex can make use of degraded or limited signals and translate them into meaningful input, as is noted in individuals with auditory neuropathy (Kraus et al., 2000) or those who wear cochlear implants (Psarros et al., 2009). Therefore, cortical processing likely contributes significantly to SIN perception. Although age did not significantly contribute to the variance in the SSQ in our data set, it has been established that age-related declines in cognitive function affect clinical and laboratory measures of SIN perception (Gordon-Salant &Fitzgibbons, 1997; Humes, 2007; Pichora-Fuller &Souza, 2003). The ability to compensate for loss of acoustic or linguistic redundancy in unfavorable environments is compromised by age-related decreases in prefrontal lobe function, thus affecting memory, attention, and inhibition of unwanted background noise (Wong, Ettlinger, Sheppard, Gunasekera,&Dhar, 2010). These changes affect performance on clinical measures of SIN perception; for example, workingmemory is related to QuickSIN scores in both young (Parbery-Clark et al., 2009) and older (Parbery- Clark, Strait, Anderson, Hittner, &Kraus, 2011) adults with normal hearing.

Even though SIN perception difficulties are frequently found in older adults, age did not significantly contribute to our model. Deficits in SIN perception are present as early as middle age (ages 45-54; Helfer &Vargo, 2009); therefore, in our data set, self-perception of speech in noise in all of our participants may have been affected by aging to some extent. Finally, life experiences, such as years ofmusical training, offset age-related declines in SIN perception (Parbery-Clark et al., 2011). Therefore, a comprehensivemodel must necessarily include cortical, cognitive, and life experiences in addition to the subcortical and peripheral measures used in this study. Our future work will evaluate interactions among peripheral, central (brainstem and cortical), cognitive, and lifeexperience variables using structural equation modeling.

Conclusion

The cABR provides an objective means for assessing the central processes contributing to SINperception. Our results demonstrate evidence in the cABR of a possible link between neural slowing, as evidenced by delayed offset, reduced morphology, and diminished SIN perception. In the future, this objective test may play a role in the audiological protocol, particularly in patients whose reported hearing difficulties, whether aided or unaided, are greater than would be predicted from traditional audiological measures; therefore, the clinical use of the cABR merits further study. Our analysis also contributes to the understanding of the biological mechanisms underlying SIN perception.

Acknowledgments

This work was supported by an NUCATS Institute CTI Pilot Grant Proposal, National Institutes of Health Grant T32 DC009399-01A10, and by the Knowles Hearing Center. We thank the participants who graciously participated in our testing. We also thank Sarah Drehobl, Jane Hornickel, Trent Nicol, and Karen Chan for their critical review and comments on the article and Sarah Anderson for her assistance with the statistical analysis. We acknowledge the work of Erika Skoe and Sumitrajit Dhar in developing the MATLAB routine and stimulus compensation protocol.

Factors Affecting the Processing of Intensity in School-Aged Children

Author: Buss, Emily; Hall, Joseph W, III; Grose, John H.

Publication info: Journal of Speech, Language and Hearing Research (Online) 56.1 (Feb 2013): 71-80.
ProQuest document link

Abstract: Thresholds of school-aged children are elevated relative to those of adults for intensity discrimination and amplitude modulation (AM) detection. It is unclear how these findings are related or what role stimulus gating and dynamic envelope cues play in these results. Two experiments assessed the development of sensitivity to intensity increments in different stimulus contexts. Thresholds for detecting an increment in level were estimated for normal-hearing children (5- to 10-year-olds) and adults. Experiment 1 compared intensity discrimination for gated and continuous presentation of a 1-kHz tone,with a 65-dB-SPL standard level. Experiment 2 compared increment detection and 16-Hz AM detection introduced into a continuous 1-kHz tone, with either 35- or 75-dB-SPL standard levels. Children had higher thresholds than adults overall. All listeners were more sensitive to increments in the continuous than the gated stimulus and performed better at the 75- than at the 35-dB-SPL standard level. Both effects were comparable for children and adults. There was some

evidence that children's AM detection was more adultlike than increment detection. These results imply that memory for loudness across gated intervals is not responsible for children's poor performance but that multiple dynamic envelope cues may benefit children more than adults.

Full text: Headnote

Purpose: Thresholds of school-aged children are elevated relative to those of adults for intensity discrimination and amplitude modulation (AM) detection. It is unclear how these findings are related or what role stimulus gating and dynamic envelope cues play in these results. Two experiments assessed the development of sensitivity to intensity increments in different stimulus contexts.
Method: Thresholds for detecting an increment in level were estimated for normal-hearing children (5- to 10-year-olds) and adults. Experiment 1 compared intensity discrimination for gated and continuous presentation of a 1-kHz tone,with a 65-dB-SPL standard level. Experiment 2 compared increment detection and 16-Hz AM detection introduced into a continuous 1-kHz tone, with either 35- or 75-dB-SPL standard levels.
Results: Children had higher thresholds than adults overall. All listeners were more sensitive to increments in the continuous than the gated stimulus and performed better at the 75- than at the 35-dB-SPL standard level. Both effects were comparable for children and adults. There was some evidence that children's AM detection was more adultlike than increment detection.
Conclusion: These results imply that memory for loudness across gated intervals is not responsible for children's poor performance but that multiple dynamic envelope cues may benefit children more than adults.
Key Words: children, psychoacoustics, hearing, development

Studies of auditory intensity discrimination in children have introduced a wide range of possible developmental trends. For example, Berg and Boswell (2000) reported adultlike performance by 3 years of age, whereas others have reported a protracted period of development up to or beyond 10-12 years of age (e.g.,Maxon &Hochberg, 1982). One procedural factor that could play an important role in the variability across studies is the use of gated versus continuous stimuli (Berg &Boswell, 2000;Werner &Marean, 1996). For a gated stimulus, the listener must retain a memory of the loudness associated with each interval and compare percepts across intervals separated in time. In the case of a continuous stimulus, on the other hand, the task can be performed based on detecting a within-interval change in loudness.Detecting an intensity increment in an ongoing sound does not require the listener to compare the loudness associated with stimuli in separate intervals, potentially reducing the memory requirements of the task. This study sought to clarify the role of memory in the development of intensity discrimination in school-aged children.

For intensity discrimination tasks with two or more gated intervals, performance in adults is thought to rely on two types of memory: sensory and context coding (Durlach &Braida, 1969). Sensory memory is a vivid, modalityspecific memory which lastsÈ10-20 s after stimulus exposure and decays in a logarithmic fashion (Cowan, 1988; Laming &Scheiwiller, 1985). Context coding, on the other hand, is associated with a more stable memory trace, in which some sensory detail is lost; it is based on a comparison of the target stimulus with previously presented stimuli. Berliner and Durlach (1973) measured intensity discrimination in adults for pairs of tones as a function of the intertone delay, with the level of the standard tone either fixed or roved in an unpredictable way on a trialby- trial basis. They found that the delay between pairs of tones in a trial had a larger effect when the standard level was roved than when it was fixed. This result is consistent with the idea that the decay of sensory memory has a large effect when level rove requires the listener to compare stimuli within a trial. In the absence of rove, however, listeners seem to rely in part on context coding, which reduces their susceptibility to memory decay.

Performance on a wide range of memory tasks improves over childhoodand into early adolescence (Gathercole, 1998), including tasks relying on sensory memory. For example, Keller and Cowan (1994) showed a difference

between 6- to 7-year-olds and adults in a task relying on sensory memory for tone pitch. That study involved two stages of testing. In the first stage, pairs of tones separated by 2 s were presented, and their frequency separation was adjusted to estimate the frequency difference (Df) associated with 84% correct. In the second stage, the Df for each listener was fixed, and the duration of the intertone interval was adjusted to estimate points on the psychometric function associated with 84% and 71% correct. The 84% threshold was near 2 s for all listeners, as expected based on the first stage of testing.The71%threshold, however,was significantly shorter for the 6- to 7-year-olds than the adults. This result was interpreted as reflecting a more rapid decay of sensory memory for pitch in young children than adults. In a subsequent study, Gomes et al. (1999) showed an analogous effect by using mismatch negativity, supporting the idea that maturation in the persistence of sensory memory for pitch is independent of attention or strategy. Although there are fundamental differences in sensory memory for pitch and loudness (e.g., more rapid decay in memory for loudness; Clement, Demany, &Semal, 1999), it is possible that sensorymemory for loudness follows a similar developmental time course to that observed for pitch.

In addition to maturation of sensory memory, development in the ability to carry out context coding could limit the performance of young children in intensitybased psychoacoustic tasks. Context coding is an active process, requiring attention, reliance on accumulated knowledge, and the use of specific listening strategies (Durlach &Braida, 1969). These factors have been implicated in the development of short-term memory, generally (Chi, 1976; Cowan, Saults, &Elliott, 2002), and they could play a significant role in performance of gated intensity discrimination. Further, immature sensory memory could reduce the attentional resources available for cognitive processing (Gomes et al., 1999), including resources associated with context coding.

Expressed in 10 log(DI/I), intensity discrimination in adult listeners is on the order of 4.5 dB better for continuous than gated stimuli (Green, Nachmias, Kearney, &Jeffress, 1979; Viemeister &Bacon, 1988). Although this effect is not completely understood, one possibility is that it is related to the introduction of dynamic cues that reduce reliance on memory for loudness. The effect of stimulus gating on intensity discrimination in children is not known, but it is possible that the maturation of auditory memory for loudness could affect children's performance differently for gated and continuous stimuli. Some support for this hypothesis is garnered by reports that 3-year-olds are nearly adultlike at detecting increments in a continuous 55-dB-SPL, two-octave band of noise (Berg &Boswell, 2000), whereas intensity discrimination for a gated pure tone continues to develop well into childhood (Fior &Bolzonello, 1987; Jensen&Neff, 1993; Maxon&Hochberg, 1982).

Detection of amplitude modulation (AM) that is sufficiently low in rate to be temporally resolved by the auditory system is similar to intensity increment detection, in that both tasks are based on changes in stimulus level over time. As the rate of modulation increases, sensitivity toAMfor a gated noise carrier declines (Viemeister, 1979), a result that is interpreted in terms of temporal resolution. Hall and Grose (1994) reported that although 4- to 10-year-old children are less sensitive to AM of a noise carrier than adults, thresholds worsen as a function of increasing AM rate similarly in the two groups. In other words, the time constant associated with AM detection is similar in young school-aged children and adults. In conjunction with developmental effects for intensity discrimination, this observation is consistent with the hypothesis that both intensity discrimination and AM detection are limited by sensitivity to changes in intensity, with no additional developmental effects in temporal processing of AM.

Wojtczak and Viemeister (1999) demonstrated a strong relationship between increment detection and AMdetection in adults. That study measured increment detection and detection of low-rateAMwith a continuous pure tone at several stimulus levels. Increment-detection thresholds, in units of 10 log(DI/I), were linearly related to AM-detection threshold, in units of 20 log(m), wheremis a value 0-1 that represents modulation depth. This finding suggests that AM may be detected based on the discriminability of stimulus intensities at different points in the stimulus envelope and not so much based on the dynamic transitions between these intensities. That is, envelope fluctuation itself may not be important in the detection of AM, apart from considerations related to

temporal resolution. In contrast to this view, several groups have proposed that dynamic envelope changes are of critical importance to both AM detection and the detection of a level increment (Gallun &Hafter, 2006; Oxenham, 1997). In Gallun and Hafter (2006), adults detected an intensity increment imposed in the temporal center of a relatively long-duration tonal pedestal. Sensitivity was reduced by the introduction of AMmaskers that were either at the target frequency or more than two octaves above the target frequency. These results were shown by Gallun and Hafter (2006) to be consistent with the use of dynamic transition cues, modeled using a modulation filterbank. In that modeling approach, detection was based on the outputs of bandpass filters acting on the stimulus envelope. Regardless of the exactmechanismresponsible, the results of Wojtczak and Viemeister (1999) and Gallun and Hafter (2006) support the view that AM detection and increment detection are closely related and likely rely on similar processes.

The present set of experiments sought to clarify the factors responsible for relatively poor intensity discrimination in school-aged children compared with adults. The first experiment assessed the role of stimulus gating in the development of intensity discrimination abilities by comparing performance for gated stimuli and for continuous presentation of the standard tone. If memory for loudness is a major contributor to the developmental effect observed for gated stimuli, then presenting the pedestal continuously should be more beneficial for child listeners than adult listeners. The second experiment tested the hypothesis that intensity discrimination and AM detection are limited by the same factors in children and adults. If this is incorrect and children benefit more from dynamic cues than adults-as they might if memory for loudness were a limiting factor-then this would be reflected in relatively better AM detection than intensity discrimination for children. An ancillary goal of this experimentwas to evaluate the effect of level of the standard tone in the developmental effect observed for intensitybased tasks. Intensity discrimination for a pure tone improves as a function of signal level in adults, a result often attributed to spread of excitation and greater numbers of auditory channels providing cues to changes in intensity at higher presentation levels (e.g., Florentine &Buus, 1981). Some data indicate a maturation in the level effect for intensity discrimination (Maxon &Hochberg, 1982), with relatively greater benefit of increasing stimulus level in younger children. However, it is unknownwhether presentation level affects increment detection and AM detection in an analogous way for children and adults.

Experiment 1

Method

Listeners. Child listeners were 5.2 to 9.0 years of age (M= 7.1 years), including 10 boys and six girls. Adult listeners were 19.8 to 51.7 years of age (M = 29.9 years), including five men and six women. All had normal hearing, defined as thresholds of 15 dB HL or better at octave frequencies 250-4000 Hz (American National Standards Institute [ANSI], 2010).

Stimuli. Stimuli were generated using a real-time processor (RP2, Tucker-Davis Technologies [TDT]), with dynamic parameters and experimental procedures controlled by MATLAB. Sounds were played out at a rate of 12.2 kHz(RP2,TDT), routed through a headphone buffer (HB7, TDT) and presented diotically with circumaural headphones (Sennheiser, HD650).

The stimulus was a 1-kHz pure tone, played at a level of 65 dB SPL in the standard (no-signal) intervals, and the listener's task was to indicate the interval associated with a level greater than 65 dB SPL. The increment was 500 ms in duration, including 25-ms raised-cosine ramps, and it was defined in units of 10 log(DI/I). In the continuous condition, the standard tone played throughout a threshold estimation track, and the increment was gated on in the signal interval. In the gated condition, either the standard or the standard plus increment was gated on for 500 ms.

Procedures. Trialswere presented as a three-alternative forced choice. Although a three-alternative task could tax the listener'smemorymore than a one- or two-alternative task, this procedure is often used in studies with children because it does not require a sophisticated understanding of the perceptual features of the target signal. Rather than describing the qualities of the signal, the instructions are just to select the interval that

sounds different from the other two, a task that is easily understood by almost all typically developing school-aged children. A 2-down 1-up stepping rule was used to estimate threshold, defined as the 71% correct point on the psychometric function (Levitt, 1971). Increment intensity was initially adjusted in 4-dB steps, reduced to 2 dB after the second track reversal, and tracks continued until eight reversals had been obtained. A threshold estimate was the average increment at the last six track reversals. Three such estimates were obtained and assessed for variability. If the initial three estimates spanned a range of 3 dB or more, then a fourth was collected. All thresholds in a condition were completed in a single block, and conditions were completed in random order. All estimates were averaged to compute the final threshold estimate for each listener in each condition. Listeners viewed an animated sequence marking the listening intervals, entered their responses on a touchscreen, and received only positive feedback. All methods were approved by the Institutional Review Board at the University of North Carolina at Chapel Hill.

Results

Figure 1 shows the distributions of intensity discrimination thresholds for each group (as indicated on the abscissa) and each condition (as indicated above each panel). Median values are plotted with horizontal lines, boxes span the 25th-75th percentiles, vertical lines indicate the 10th-90th percentiles, and circles showthe minimum and maximumthresholds. Visual inspection of this figure indicates that thresholds were higher in children than adults and higher for the gated than the continuous stimulus but that the effect of gating was uniform across subject groups. This was confirmed with a repeated-measures analysis of variance (ANOVA), incorporating two levels of group (child, adult) and two levels of condition (continuous, gated). There was a significant main effect of group, $F(1, 25) = 18.20$, $p < .001$, and of condition, $F(1, 25) = 241.65$, $p < .001$, but no interaction,$F(1, 25) = 0.62$, $p = .440$.

Both groups were affected equally by gating when thresholds were represented in units of 10 log(DI / I). Intensity discrimination thresholds can be represented a number of different ways, however (Grantham &Yost, 1982; Green, 1988). The question of howbest to characterize psychophysical intensity discrimination has received significant attention in the literature, with different studies supporting the use of 10 log(DI/I), 20 log(Dp/p), and DL (e.g., Buus&Florentine, 1991; Moore, Peters,&Glasberg, 1999; Shepherd &Hautus, 2007).1 Statistical analyses indicated that the interaction between group and condition was not statistically significant when thresholds were expressed in terms of 10 log(DI/I) or 20 log(Dp/p). The interaction was significant, however,when units of DLwere used, $F(1, 25) = 10.90$, $p = .003$, with a larger effect of group for gated than for continuous stimuli. There are reasons to prefer units of 10 log(DI/I) over units of DL in the present data set. Box's test indicated that covariance matrices were not significantly different across data sets in units of 10 log(DI/I),$M = 1.39$, $p = .739$, but theywere different when assessed in units of DL,$M = 10.34$, $p = .025$. On the basis of this observation, units of 10 log(DI/I) were used to characterize intensity discrimination in the remainder of this article.

Figure 2 shows intensity discrimination thresholds for individual child listeners, plotted as a function of age. Mean adult data are shown at the far right of the graph, with error bars spanning ±1 SD. Symbol style reflects the stimulus condition, as defined in the legend, and vertical lines connect data points of individual listeners. In addition to the significant difference in thresholds across groups, there was also modest evidence of a developmental trend within the child group. Using a one-tailed significance criterion, the correlation with child age was significant for thresholds in the gated condition ($r = -.50$, $p = .023$) and for thresholds in the continuous condition ($r = -.45$, $p = .041$). The finding of a robust correlation between thresholds in these two conditions ($r = .77$, $p < .001$) suggests that individual differences may be a more important determinant of sensitivity than listener age. This possibility receives additional support from the finding of a significant partial correlation between thresholds in the gated and continuous conditions after controlling for child age ($r = .70$, $p = .002$, one-tailed). There was no correlation between the gated-continuous difference and child age ($r = -.09$, $p = .36$, one-tailed), indicating that there was no development in the ability to benefit from continuous stimulus presentation

within the child group.

Discussion

Intensity discrimination thresholds for a 500-ms 1-kHz tone are better for adults than school-aged children.Thresholds as a function of child age tended to improve over the range tested here (5-9 years), but this effect was modest. Robust correlations in the child data across conditions indicated consistent individual differences that are not accounted for by age. This finding suggests that although sensitivity improves over the age range tested here, there are individual differences in the time course of this development. This would be consistent with our previous data on pure-tone intensity discrimination in this age range (Buss, Hall, &Grose, 2006) and with the observation that particularly large individual differences are often observed at ages associated with rapid development (Werner &Gray, 1998).

Presenting the stimuli in gated intervals rather than in the context of a continuous stimulus elevates thresholds, but this effect is comparable for adults and children when results are represented in units of 10 log(DI/I). Previous work on intensity discrimination in adult listeners has demonstrated better performance for continuous than gated stimuli, with differences of 4.6 dB (Viemeister &Bacon, 1988) and 4.2 dB (Green et al., 1979) under conditions comparable to those of this study. These effects are similar to the average gated-continuous differences obtained with adults (4.9 dB) and children (5.4 dB) in this experiment.

There are several possible explanations for the gated- continuous difference in adult listeners (reviewed by Turner, Zwislocki, &Filion, 1989). One is that presenting the stimulus continuously leads to loudness adaptation, such that there is better ability to encode a subsequent increase in intensity. There is no reason to believe that loudness adaptation differs in school-aged children and adults (Baruch, Botte, &Scharf, 1993). Therefore, adaptation is unlikely to introduce age effects in the tasks of this experiment. Another explanation for the gated-continuous difference is the extra memory requirement associated with a gated stimulus (Durlach&Braida, 1969). Results of this study do not support the hypothesis that memory for loudness, necessary for across-interval comparisons, limits the performance of children more than that of adults. This leaves open the possibility that the neural representation of intensity in the central auditory system is more variable in children than in adults, a hypothesis considered by Buss et al. (2006).

Experiment 2

The goal of Experiment 2 was to assess the parallel between the developmental effects observed for intensity discrimination andAMdetection. In adult listeners,Wojtczak andViemeister (1999) demonstrated a linear relationship between increment detection and the detection of lowrate AM, with performance improving in both tasks as the presentation level is increased. This result suggests that the perceptual cues supporting performance of these two tasks may be highly related. It was hypothesized that the same relationship would hold for child listeners. This prediction is based on the finding in Experiment 1 that children benefit to a comparable degree as adults from the introduction of dynamic cues for intensity discrimination with the use of continuous, rather than gated, stimuli.

Method

Listeners. Child listeners were 5.4 to 9.5 years of age (M= 7.1 years), including eight boys and eight girls. Adult listeners were 17.9 to 43.1 years of age (M = 25.0 years), including five men and six women. All had normal hearing, defined as thresholds of 15 dB HL or better at octave frequencies 250-4000 Hz (ANSI, 2010). One of the child listeners had previously participated in Experiment 1.

Stimuli. Stimulus generation and presentation followed the procedures described for Experiment 1 (above), with the exception that stimuli were presented monaurally to the leftear. In the increment-detection conditions, the standard stimulus was a continuous 1-kHz pure tone played at a level of 35 or 75 dB SPL, and the listener's task was to indicate the interval associated with an intensity increment, defined in units of 10 log(DI/I). Each increment was 500 ms in duration, including onset and offset ramps. Ramps were 15.6-ms raised cosines, resembling the onset of the first period of modulation in the AM-detection task.

For amplitude modulation detection, modulation was achieved by multiplying a 1-kHz tone with a raised 16-Hz sinusoid, and the result was scaled to either 35 or 75 dB SPL. Modulation began and ended at envelope values associatedwith the standard intensity, with no further smoothing or ramping. In all cases, modulation began with a positive slope (i.e., approximately sine phase), such that the first envelope maximum occurred approximately 15.6 ms after modulation onset (onequarter of a period of 16-Hz AM). Target modulation lasted for approximately 500 ms and was embedded in a continuous tone. This listener's task was to indicate the interval associated with the amplitude-modulated stimulus. Modulation depth was defined in units of 20 log(m).

Procedures. Procedures closely followed those of Experiment 1. Thresholds were obtained in blocks by condition. At least three estimates were obtained in each condition, and a fourth was taken when the first three spanned a range of 3 dB or more. Conditions were completed in random order.

Results

Thresholds are plotted in Figure 3, with individual child listeners' results plotted as a function of age. The mean adult thresholds are plotted at the far right of each panel, with error bars spanning ±1 SD. Symbols reflect the level of the standard, as indicated in the legend, and data for each child are connected with a vertical line. The two panels show results for increment detection (top) and AM detection (bottom).

Increment detection is considered first. For both levels, mean thresholds for child listeners were poorer than those for adults. This difference was, on average, 3.0 dB for the 35-dB level and 2.8 dB for the 75-dB level. This is comparable to the 3.5-dB difference across groups observed in Experiment 1 for the continuous stimulus presented at 65 dB SPL. Age group differences were assessed by using a repeated-measures ANOVA, with two levels for each of two variables: level (low, high) and group (child, adult). This analysis confirmed a main effect of group, $F(1, 27) = 29.06$, $p = .001$. There was also a main effect of level, $F(1, 27) = 111.33$, $p < .001$, but there was no interaction between group and level, $F(1, 27) = 0.04$, $p = .849$. This result indicates that the detection advantage associated with the higher level standard was not significantly different in child and adult listeners, with an across-group average difference of 4.2 dB-SPL between the 35- and 75-dB-SPL thresholds. The data were examined for effects of age within the child group by performing an analysis of covariance (ANCOVA), with level as a between-listener variable and child age as a within-listener variable. The effect of age and the Level X Age interaction failed to reach significance (p . .138).

The bottom panel of Figure 3 shows results of the AMdetection task. Thresholds for child listeners were poorer than adults' thresholds at both standard levels, with mean differences of 3.9 dB and 2.6 dB for the 35- and 75-dB-SPL levels, respectively. Age-group differences were assessed by using a repeated-measures ANOVA, with two levels for each of two variables: level (low, high) and group (child, adult). There was a main effect of group, $F(1, 27) = 6.48$, $p = .017$, and amain effect of level,$F(1, 27) = 148.98$, $p < .001$, but no interaction between group and level, $F(1, 27) = 0.61$, $p = .443$. As in increment detection, children performed more poorly than adults, but they benefited from increasing the level of the standard stimulus to the same degree. The average difference between thresholds for the 35- and 75-dB-SPL stimulus levels was 10.7 dB. The data were examined for effects of age within the child group by performing an ANCOVA. The effect of age and the Level X Age interaction failed to reach significance in this analysis (p . .394).

Figure 4 shows individual listener's incrementdetection thresholds plotted as a function of their AMdetection thresholds. Symbols indicate the level of the standard stimulus, as defined in the legend. Data for the two groups are plotted in separate panels. Lines were fitted to the data in each group by minimizing the sum of the squared error. The solid lines in both panels are the best fit to adult data, and the dotted line is the best fit to child data. The slopes fitted to these data are similar across groups, with values of M = 0.37 for adult data and M = 0.32 and for child data. This is somewhat lower than the value of 0.44 reported by Wojtczak and Viemeister (1999) for adults tested under comparable stimulus conditions. The y-intercept differs across groups. For adult data, the intercept is .0.33 dB, and for child data, it is 0.45 dB. These age effects are similar to those observedwhen lines are fitted to group mean data.

We assessed the significance of differences in line fits to adult and child data by fitting child data using the parameters that characterize adult data and then examine the residuals. Therewas no significant association between residuals and thresholds in theAM-detection task, $F(1, 30) = 1.47$, $p = .234$, indicating that the slope of the data was well fitted by the adult slope estimate. The mean of the residuals was significantly different from zero, $t(31) = 5.80$, $p < .001$, however, reflecting the fact that the intercept fitted to adult data was not an optimal fit to the child data. These results can be interpreted as showing that the developmental effect is relatively greater for increment detection than for 16-Hz AM detection in the context of continuously presented stimuli.

Discussion

Increment-detection thresholds measured in this experiment improved with level of the standard. For adults, mean thresholds were -6.2 and -10.4 dB at 35 and 75 dB SPL, respectively. For children, these values were -3.3 and -7.6 dB, respectively. These level effects can be compared with those reported by Rabinowitz, Lim, Braida, and Durlach (1976), who compiled data of 15 studies that measure intensity discrimination as a function of stimulus level for a 1-kHz tone. On the basis of that review, the average expected change in thresholds between 35 and 75 dB SPL is on the order of 2.5 dB. This is less than the approximately 5-dB change found by Wojtczak and Viemeister (1999) and the 4.6-dB change obtained in this study. Threshold improvement with increasing level has been described as the near miss to Weber's lawbecause sensitivity to intensity increments is not constant relative to the level of the standard. It is widely accepted that the near miss is due to greater spread of excitation at higher stimulus levels and, hence, a wider range of frequencies providing cues to changes in intensity (e.g., Florentine &Buus, 1981). These results suggest that whereas school-aged children performmore poorly overall, they benefit fromthese additional cues to the sameextent as adult listeners.

Previous data on the effect of stimulus level for intensity discrimination have shown that younger listeners tend to perform particularly poorly for low-level stimuli, such that the age effect is largest at the lowest presentation levels. Berg and Boswell (2000) measured increment detection for two-octave bands of noise in 1- to 3-year-olds and adults, and they found a greater age effect at lowthan at high presentation levels. Maxon and Hochberg (1982) found an analogous result for gated intensity discrimination of a 500-Hz tone. In a comparison of results across a group of 4- to 12-year-olds, the age effect was largest at the lowest stimulus level, equated in dB SL. However, this age effect was dominated by the pronounced effect of level for the youngest group of listeners (4-year-olds); level effects were nearly identical for 6- to 12-year-olds. Data from this and previous studies are consistent with the conclusion that level effects reach maturity between 4 and 6 years of age.

Like increment detection, AM-detection thresholds improved with increasing level in both groups, with an average difference of 10.7 dB between thresholds at the 35- and 75-dB-SPL presentation levels. This result is consistent with previous literature on adults (Kohlrausch, 1993; Wojtczak &Viemeister, 1999). As for increment detection, AM detection was worse for child listeners than for adult listeners, with a mean group difference of 3.3 dB. These results can be compared with those of Hall and Grose (1994), who reported a significant age effect for AM detection. In that study, the stimulus was a continuous 75-dB-SPL Gaussian noise, bandpass filtered between 200 and 1200 Hz, and modulation was achieved through multiplication with a raised sinusoid. AM-detection thresholds improved as a function of age: the child-adult difference was approximately 3.6 dB for 6- to 7-year-olds, the mean age of listeners in the present experiment. That age effect for a noise carrier is consistent with these results for a pure-tone carrier.

The relationship between AM detection and intensity discrimination for a continuous tone in the child data follows the same general trend as described previously in adult data-better sensitivity to AM is associated with better sensitivity to intensity increments (Wojtczak &Viemeister, 1999). There is evidence that AM detection may be less prone to developmental age effects, however, reflected in the offset in the intercept of the line relating these two variables. One reason for this could be related to the number of opportunities to hear a dynamic change in stimulus intensity; the AM-detection task provides multiple opportunities to detect dynamic changes in intensity, whereas the increment-detection task is associated with dynamic changes only at increment onset

and offset. This explanation suggests that envelope fluctuation itself may be an important factor in children's AM detection, as contrasted with comparisons of stimulus intensities at different points in the stimulus envelope. The ability to benefit from multiple dynamic envelope transitions could be related to the benefit of "multiple looks," which is described in studies of temporal integration (Viemeister &Wakefield, 1991). There is some indication that children experience more temporal integration than adultswhen detecting a 1625-Hz tone (He, Buss, &Hall, 2010), and it is possible that integration of multiple looks in AM detection follows a similar trend.

General Discussion and Conclusion

At the outset of this study, it was hypothesized that children's intensity discrimination thresholds could be limited by memory to a greater extent for gated than for continuous stimuli. These limits could include immaturities in sensory memory, the ability to carry out context coding, or some combination of these factors. As previously observed in adults, intensity discrimination was better when the standard played continuously than when it was gated on and offin each listening interval. This benefit was seen to a comparable degree in the data of both adults and school-aged children. Because the continuous presentation introduces a within-interval cue, this result suggests that development of memory for loudness across intervals is not responsible for children's poor performance with gated stimuli. One possibility is that both sensorymemory and context coding for intensity are mature in school-aged children. Another possibility is that such differences do exist but that other factors dominate the results of the present experiments. For example, whereas continuous presentation alleviates demands on the listener's memory for loudness, the listener must select from among three possible signal intervals. Near threshold, the ability to identify the target interval is improved by comparing cue strength across intervals. Development could affect the accuracy of this comparison. In either case, our results imply that the large variability in developmental data for intensity discrimination (Experiment 1 of this article; Buss, Hall, &Grose, 2009) cannot be attributed to the use of gated versus continuous stimuli.

One generalization that might be drawn from the results of the first experiment is that dynamic, withininterval cues for intensity discrimination have a similar effect on children and adults. This conclusion is not fully consistent with results of the second experiment, however. For a continuous stimulus, detection of 16-Hz AM was relatively better in children than adults when compared with increment detection. That is, the more dynamic envelope changes characterizing the AM stimulus were easier for the children to detect than the relatively more stationary intensity increment. Therefore, a comparable gated-continuous difference across age groups (Experiment 1) is consistent with the adultlike ability to benefit from dynamic envelope cues, but the relatively good performance onAMdetection in children (Experiment 2) seems to indicate maturation of that ability.

One way to resolve this apparent conflict is to propose a different process for exploiting onset cues present for increment detection and modulation cues present for AM detection. There is a linear relationship in the data obtained for these measures within listener groups (Experiment 2, Figure 4;Wojtczak &Viemeister, 1999), but there could nonetheless be important differences in the cues underlying these two tasks. Modeling work using the modulation filterbank speaks against this possibility, supporting the idea that increment detection and AM detection are based on the same underlying cues. However, this modeling has typically used relatively brief signals (e.g., <100 ms; Gallun &Hafter, 2006), and it is unclear whether these results would hold for longer duration stimuli (e.g., the 500 ms used in the present experiments). Better performance in AM detection might occur if children benefit to a greater degree than adults from multiple looks for dynamic envelope features. Increment detection in a continuous stimulus provides a pair of dynamic cues (an onset and offset), whereasAMdetection for a 16-Hz rate provides eight such pairs of cues in a 500-ms listening interval. It has been proposed that integration of cues across modulation periods for continuous stimuli may not be optimal in adults because of temporal stimulus uncertainty regarding the onset of modulation (Sheft& Yost, 1990); one possibility is that children are more prone to overintegration than adults, leading to a larger benefit for stimuli with ongoing AM. Greater integration of dynamic envelope cues in children is broadly consistent with the finding of greater temporal integration for detection of tones in children under some conditions (He et al.,

2010).However, additional data onthe temporal integration of AM would be required to confirm this interpretation.

Patents; Agency Reviews Patent Application Approval Request for "Feedback Control in a Listening Device"

Publication info: Telecommunications Weekly (Jan 16, 2013): 801.
ProQuest document link

Abstract: Supplementing the background information on this patent application, VerticalNews reporters also obtained the inventors' summary information for this patent: "When an actuation element on a listening device (e.g. a hearing aid) located at or behind the ear of a user is activated by the user's hand, it is expected that the hand will be removed as soon as the user has performed the intended action, e.g. changed to a desired program or modified another setting, e.g. volume.

Full text: 2013 JAN 16 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- A patent application by the inventors PEDERSEN, Michael Syskind (Smorum, DK), filed on June 26, 2012, was cleared for further review on January 3, 2013, according to news reporting originating from Washington, D.C., by VerticalNews correspondents.

Patent application serial number 533293 has not been assigned to an institution or company.

The following quote was obtained by the news editors from the background information supplied by the inventors: "The following account of the prior art relates to one of the areas of application of the present application, hearing aids.

"Two different ways exist for changing programs/volume in a hearing aid. This is illustrated in FIG. 1. One way is to use a button at the hearing aid (FIG. 1a). The other way is to wirelessly change the program/volume through an external device such as a remote control (FIG. 1b). The difference is that the local acoustics around the hearing aid changes while the hand is near the ear (pressing an activation element on the hearing aid, FIG. 1a), but the local acoustics is unlikely to change in the other case where the hand is far from the hearing aid (on the remote control, FIG. 1b). When the local acoustics changes, the feedback path will change. This may result in howling.

"EP 2 148 525 A1 describes a hearing instrument comprising a codebook of plausible feedback channel impulse responses (or any equivalent representation) and to make them available for selection and use by a signal processing unit in the appropriate listening situation, e.g. by storing them in a memory of the hearing instrument."

Supplementing the background information on this patent application, VerticalNews reporters also obtained the inventors' summary information for this patent: "When an actuation element on a listening device (e.g. a hearing aid) located at or behind the ear of a user is activated by the user's hand, it is expected that the hand will be

removed as soon as the user has performed the intended action, e.g. changed to a desired program or modified another setting, e.g. volume. In this situation, the feedback cancellation filter update algorithm is preferably adapted to not react on the acoustic changes caused by the manual operation of the activation element, because the acoustics is expected to change back to normal after a short while (where 'normal' typically will be the situation a (possibly short) while before the activation by the user of the actuation element, i.e. while the user's hand is approaching the hearing aid). When the program change (or other modification of a setting of the hearing aid) is done wirelessly, no local acoustic changes are expected, and the hearing aid feedback cancellation filter estimation should be adapted to its normal update routine. The present invention is related to the physical change of the local acoustic environment caused by a user's operation of an activation element on the listening device, rather than to the functional effect of the operation of the activation element in the listening device (e.g. a program change, a volume change, etc.).

"An object of the present application is to provide an improved control mechanism for an adaptive filter.

"Objects of the application are achieved by the invention described in the accompanying claims and as described in the following.

"A Listening Device:

"In an aspect of the present application, an object of the application is achieved by a listening device adapted for being located in or at an ear of a user and comprising an input transducer for converting an input sound to an electric input signal; and an output transducer for converting a processed electric signal to an output sound; a forward signal path being defined there between and comprising a signal processing unit for processing the electric input signal or a signal derived therefrom and providing a processed output signal; a manually operable user interface located at or on the listening device allowing a user to control a function of the listening device; a feedback estimation system for estimating a feedback path from the output transducer to the input transducer, the feedback estimation system comprising an adaptive filter, the adaptive filter comprising a variable filter part, and an algorithm part comprising an adaptive algorithm, the variable filter part being adapted for providing a transfer function to a filter input signal and providing a filtered output signal, the transfer function being controlled by filter coefficients determined in the algorithm part and transferred to the variable filter part, the feedback estimation system further comprising an update control unit adapted for controlling the adaptive algorithm including the transfer of filter coefficients to the variable filter part, wherein the update control unit is adapted to monitor the manually operable user interface and to provide that an activation of the manually operable user interface is used for influencing the control of the adaptive algorithm.

"This has the advantage of providing a scheme for handling the risk of howl during manual operation of a listening device adapted for being located at or in an ear of a user.

"The term 'used for influencing the control of the adaptive algorithm' is in the present context taken to include the delay or omission or change of an action related to the adaptive algorithm that would otherwise have been performed in the listening device (had the user not activated the user interface). The 'control of the adaptive algorithm' may e.g. relate to the timing of the calculation or re-calculation of filter coefficients (and/or to change of the adaptation rate of the adaptive algorithm) and/or to the transfer of filter coefficients from the algorithm part to the variable filter part.

"In an embodiment, the listening device comprises an analysis path (in parallel to the forward signal path) comprising functional components for analyzing the input signal (e.g. determining a level, a modulation, a type of signal, an acoustic feedback estimate, etc.). In an embodiment, some or all signal processing of the analysis path and/or the signal path is conducted in the frequency domain. In an embodiment, some or all signal processing of the analysis path and/or the signal path is conducted in the time domain.

"The listening device comprises an adaptive acoustic (and/or mechanical) feedback suppression system. Feedback suppression may be achieved by subtracting an estimate of the feedback signal within the listening device. It has been proposed to use a fixed coefficient linear time invariant filter for the feedback path estimate

[Dyrlund, 1991]. This method proves to be effective if the feedback path is steady state and, therefore, does not alter over time. However, the feedback path of a listening device, e.g. a hearing aid, does vary over time and some kind of tracking ability is often preferred. Adaptive feedback cancellation has the ability to track feedback path changes over time. It is also based on a linear time invariant filter to estimate the feedback path but its filter weights are updated over time [Engebretson, 1993]. The filter update may be calculated using stochastic gradient algorithms, including some form of the popular Least Mean Square (LMS) or the Normalized LMS (NLMS) algorithms. They both have the property to minimize the error signal in the mean square sense with the NLMS additionally normalizing the filter update with respect to the squared Euclidean norm of some reference signal. Various aspects of adaptive filters are e.g. described in [Haykin].

"In an embodiment, the manually operable user interface comprises a touch sensitive activation element. A touch sensitive element can e.g. comprise any switch element for selecting one of two or more options, e.g. a push button, a touch (sensitive) screen, a rotating wheel, a mechanical switch, a proximity sensor, etc.

"In an embodiment, the listening device is adapted to provide that the feedback estimate is used to minimize or cancel feedback from the output transducer to the input transducer. In an embodiment, such adaptation is implemented by a combination unit for combining (e.g. a summation unit) the feedback path estimate with (e.g. subtracting from) an input signal, e.g. from a microphone or microphone system, of the listening device.

"In an embodiment, the update control unit is adapted to control the timing of the calculation of filter coefficients and/or the transfer of filter coefficients to the variable filter part. In an embodiment, the update control unit comprises a timing unit that controls when new filter coefficients are to be calculated. In an embodiment, the update control unit comprises a timing unit that controls when newly calculated (or stored) filter coefficients are transferred to the variable filter part of the adaptive filter. When the manually operable user interface has been activated, the timing unit is adapted to influence the timing of the calculation of the filter coefficients and/or their transfer to the variable filter (based on the event of occurrence of the activation, and e.g. for a predefined time thereafter).

"In an embodiment, the update control unit is adapted to inhibit or delay the calculation of filter coefficients and/or the transfer of filter coefficients to the variable filter part with a predefined time (after activation of the manually operable user interface). In an embodiment, the delay is adapted to be sufficiently large to allow the acoustic situation (including the feedback path from the output to the input transducer of the listening device) after user's activation of the manually operable user interface to be normalized, e.g. based on an estimated average value. In an embodiment, the delay is larger than 1 s, such as in the range from 1 s to 5 s, e.g. around 2 s. In an embodiment, the delay is larger than 5 s.

"In an embodiment, the update control unit is adapted to modify the adaptation rate of the adaptive algorithm. In an embodiment, the adaptation rate is decreased when an activation of the manually operable user interface is detected in the listening device. In an embodiment, the adaptation rate is governed by a step size of the algorithm. In an embodiment, the step size of the algorithm is decreased when an activation of the manually operable user interface is detected. In an embodiment, the step size is set to zero when an activation of the manually operable user interface is detected and held at zero for a predefined (delay) time, where after it is returned to its original value or to a default value or to a value determined by the chosen program, if the activation of the manually operable user interface resulted in a program change. In an embodiment, the step size is frequency dependent, e.g. in that feedback estimation is performed fully or partially in the frequency domain. In an embodiment, the calculation of updated filter coefficients is performed in a number of frequency bands, whereas the filtering is performed in the time domain (cf. e.g. FIG. 3c).

"In an embodiment, the listening device, e.g. the update control unit, comprises a memory wherein one or more default feedback path estimates is/are stored, and wherein the update control unit is adapted to select a default feedback path estimate from the memory and to transfer corresponding filter coefficients to the variable filter part when the manually operable user interface has been activated. In an embodiment, the default feedback

path estimate comprises a channel impulse response, a complex-valued transfer function, or a set filter coefficients. In an embodiment, the one or more default feedback path estimates is/are determined and stored in the listening device in advance of its normal operation, e.g. in a fitting procedure. Alternatively or additionally, the one or more default feedback path estimates is/are determined during normal operation of the listening device. Different default feedback path estimates may be stored for different programs of the listening device corresponding to different listening situations (e.g. music, telephone, speech in noise, 'cocktail party', etc.). Preferably, changes to the feedback path estimate over time are monitored. During a stable time period, where little or no large changes to the feedback path estimate occurs, a value (e.g. an average value) of the feedback path estimate is stored in a memory of the listening device as a default feedback path estimate. In an embodiment, the 'stable' feedback path stored in memory is determined off-line, e.g. during a fitting session of the listening device. In an embodiment, a number of the last determined feedback path estimates (F.sub.x(n), n being time) (e.g. corresponding filter coefficients) are stored in a memory. In an embodiment, a difference between the current feedback estimate (F.sub.x(n)) and the immediately preceding feedback estimate (F.sub.x(n-1)) is determined, e.g. as |F.sub.x(n)-(F.sub.x(n-1)|.sup.2. In an embodiment, an average value (e.g. a running average) of the previous feedback path estimates is stored in the memory. In an embodiment, the older estimates are weighted less than the newer estimates, e.g. according to the recursive formula F.sub.st,p(n)=.alpha.F.sub.x(n-1)+(1-.alpha.)F.sub.x(n), where F.sub.st,p is the stored previous feedback estimate, n is a time index and .alpha. is a constant between 0 and 1. The smaller the value of .alpha., the more weight on the latest values of the feedback estimate, and the larger the value of .alpha., the more weight on the historic values of the feedback estimate. In an embodiment, .alpha. is smaller than 0.5, such as smaller than 0.3, such as smaller than 0.2, such as in the range from 0.05 to 0.2. In an embodiment, a difference between the current feedback estimate (F.sub.x(n)) and the stored feedback estimate (F.sub.st(n-1)) is determined, e.g. as |F.sub.x(n)-(F.sub.st(n-1)|.sup.2. In an embodiment, the current feedback estimate is an average over a number of the latest feedback estimates. In an embodiment, a difference between the current feedback estimate (F.sub.st,c) and the preceding feedback estimate (F.sub.st,p) is determined, e.g. as |F.sub.st,c-F.sub.st,p|.sup.2. In an embodiment, one of the stored feedback path estimates is defined as a default feedback path estimate. This may be the case, if the difference between the current feedback estimate and the previous feedback estimate (e.g. the stored previous feedback estimate or the immediately preceding feedback estimate) is larger than a predetermined value (e.g. more than 50% larger or more than 100% larger) AND if the user interface is activated within a predetermined time of the last determined feedback path estimates (e.g. .ltoreq.0.1 s after, or .ltoreq.1 s after, or .ltoreq.5 s after). In an embodiment, after a user interface activation event, a choice between a number Nd of available stored default feedback path estimates is performed by choosing the feedback path estimate that provides the lowest prediction error, e.g. MIN .epsilon.[|y-Fd.sub.x*u|.sup.2], or, when normalized, MIN .epsilon.[|y-Fd.sub.x*u|.sup.2/|y|.sup.2], where .epsilon. is the expected value operator, y is the current input signal (e.g. ER in FIG. 2, 3), Fd.sub.x is a default feedback estimate x, and u is the current output signal (e.g. REF in FIG. 2, 3), and where x is varied over the Nd available feedback paths.

"Any operating parameter or function of the listening device may in principle be influenced by the manually operable user interface. In an embodiment, a function of the listening device that may be controlled via the manually operable user interface is a program shift or a volume change.

"In an embodiment, the listening device is a portable device, e.g. a device comprising a local energy source, e.g. a battery, e.g. a rechargeable battery.

"In an embodiment, the listening device comprises a hearing aid, a headset, an active ear protection device or a combination thereof.

"In an embodiment, the listening device is adapted to provide a frequency dependent gain to compensate for a hearing loss of a user. In an embodiment, the signal processing unit is adapted for running algorithms for

enhancing an input signal and providing a processed output signal. Various aspects of digital hearing aids are described in [Schaub; 2008].

"In an embodiment, the output transducer comprises a receiver (speaker) for providing an acoustic signal to the user.

"The listening device comprises an input transducer for converting an input sound to an electric input signal. In an embodiment, the listening device comprises a directional microphone system adapted to provide a resulting directional microphone characteristic of the system, e.g. for separating two or more acoustic sources in the local environment of the user wearing the listening device and/or for attenuating one acoustic source relative to another acoustic source. In an embodiment, the directional system is adapted to detect (such as adaptively detect) from which direction a particular part of the microphone signal originates. This can be achieved in various different ways as described in the prior art.

"In an embodiment, the listening device comprises an antenna and transceiver circuitry for wirelessly receiving a direct electric input signal from another device, e.g. a communication device or another listening device. In an embodiment, the listening device comprises a (possibly standardized) electric interface (e.g. in the form of a connector) for receiving a wired direct electric input signal from another device, e.g. a communication device or another listening device.

"In an embodiment, the communication between the listening device and the other device is in the base band (audio frequency range, e.g. between 0 and 20 kHz). Preferably, communication between the listening device and the other device is based on some sort of modulation at frequencies above 100 kHz. Preferably, frequencies used to establish communication between the listening device and the other device is below 50 GHz, e.g. located in a range from 50 MHz to 50 GHz.

"In an embodiment, the listening device further comprises other relevant functionality for the application in question, e.g. compression, noise reduction, etc.

"Use:

"In an aspect, use of a listening device as described above, in the 'detailed description of embodiments' and in the claims, is moreover provided. In an embodiment, use is provided in a system comprising audio distribution, e.g. a system comprising a microphone and a loudspeaker in sufficiently close proximity of each other to cause feedback from the loudspeaker to the microphone during operation by a user. In an embodiment, use is provided in a system comprising one or more hearing instruments, headsets, ear phones, active ear protection systems, etc., e.g. in handsfree telephone systems, teleconferencing systems, public address systems, karaoke systems, classroom amplification systems, etc.

"A method:

"In an aspect, a method of operating a listening device, the listening device comprising an input transducer for converting an input sound to an electric input signal; and an output transducer for converting a processed electric signal to an output sound; a forward signal path being defined there between and comprising a signal processing unit for processing the electric input signal or a signal derived therefrom and providing a processed output signal; a manually operable user interface located at or on the listening device allowing a user to control a function of the listening device is furthermore provided by the present application.

"The method comprises estimating a feedback path from the output transducer to the input transducer using an adaptive algorithm for determining filter coefficients for a variable filter; transferring filter coefficients to the variable filter thereby providing an estimated feedback path transfer function; monitoring the activation of the manually operable user interface; controlling the adaptive algorithm, including the transfer of filter coefficients to the variable filter, depending on the activation of the manually operable user interface.

"It is intended that the structural features of the device described above, in the 'detailed description of embodiments' and in the claims can be combined with the method, when appropriately substituted by a corresponding process and vice versa. Embodiments of the method have the same advantages as the

corresponding devices.
"A Computer Readable Medium:
"In an aspect, a tangible computer-readable medium storing a computer program comprising program code means for causing a data processing system to perform the steps of the method described above, in the 'detailed description of embodiments' and in the claims, when said computer program is executed on the data processing system is furthermore provided by the present application. In addition to being stored on a tangible medium such as diskettes, CD-ROM-, DVD-, or hard disk media, or any other machine readable medium, the computer program can also be transmitted via a transmission medium such as a wired or wireless link or a network, e.g. the Internet, and loaded into a data processing system for being executed at a location different from that of the tangible medium. In an embodiment, the data processing system comprises the signal processing unit of the listening device described above, in the 'detailed description of embodiments' and in the claims.
"A Data Processing System:
"In an aspect, a data processing system comprising a processor (e.g. the signal processing unit of the listening device described above, in the 'detailed description of embodiments' and in the claims) and program code means for causing the processor to perform the steps of the method described above, in the 'detailed description of embodiments' and in the claims is furthermore provided by the present application.
"A Listening system:
"In a further aspect, a listening system comprising a (first) listening device as described above, in the 'detailed description of embodiments', and in the claims, AND an auxiliary device is moreover provided. In an embodiment, the system comprises two or more auxiliary devices. In an embodiment, the listening system is portable.
"In an embodiment, the system is adapted to establish a communication link between the listening device and the auxiliary device to provide that information (e.g. control and status signals, possibly audio signals) can be exchanged between them or forwarded from one to the other.
"In an embodiment, the auxiliary device is an audio gateway device adapted for receiving a multitude of audio signals (e.g. from an entertainment device, e.g. a TV or a music player, a telephone apparatus, e.g. a mobile telephone, or a computer, e.g. a PC, a telecoil, a wireless microphone, etc.) and adapted for allowing a user to select and/or combine an appropriate one of the received audio signals (or combination of signals) for transmission to the listening device.
"In an embodiment, the auxiliary device comprises a remote control function with a user interface adapted for allowing a user to modify settings of the first listening device.
"In an embodiment, the auxiliary device is another (second) listening device. In an embodiment, the second listening device is a listening device as described above, in the 'detailed description of embodiments', and in the claims. In an embodiment, the listening system comprises two listening devices adapted to implement a binaural listening system, e.g. a binaural hearing aid system. In an embodiment, the listening system, comprises a binaural listening system, e.g. a hearing aid system, AND a further auxiliary device, e.g. an audio gateway device and/or a remote control device.
"Further objects of the application are achieved by the embodiments defined in the dependent claims and in the detailed description of the invention.
"As used herein, the singular forms 'a,' 'an,' and 'the' are intended to include the plural forms as well (i.e. to have the meaning 'at least one'), unless expressly stated otherwise. It will be further understood that the terms 'includes,' 'comprises,' 'including,' and/or 'comprising,' when used in this specification, specify the presence of stated features, integers, steps, operations, elements, and/or components, but do not preclude the presence or addition of one or more other features, integers, steps, operations, elements, components, and/or groups thereof. It will also be understood that when an element is referred to as being 'connected' or 'coupled' to

another element, it can be directly connected or coupled to the other element or intervening elements may be present, unless expressly stated otherwise. Furthermore, 'connected' or 'coupled' as used herein may include wirelessly connected or coupled. As used herein, the term 'and/or' includes any and all combinations of one or more of the associated listed items. The steps of any method disclosed herein do not have to be performed in the exact order disclosed, unless expressly stated otherwise."

iHear Medical, Inc.; Patent Issued for Hearing Device with Semipermanent Canal Receiver Module

Publication info: Telecommunications Weekly (Jan 9, 2013): 1118.
ProQuest document link

Abstract: News editors obtained the following quote from the background information supplied by the inventors: "Brief Description of Ear Canal Anatomy and Physiology "The ear canal 10 (FIG. 1) is generally narrow and tortuous and is approximately 26 millimeters (mm) long from the canal aperture 11 to the tympanic membrane 15 (eardrum).

Full text: 2013 JAN 9 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- From Alexandria, Virginia, VerticalNews journalists report that a patent by the inventor Shennib, Adnan (Oakland, CA), filed on August 12, 2010, was cleared and issued on December 25, 2012.
The patent's assignee for patent number 8340335 is iHear Medical, Inc. (Oakland, CA).
News editors obtained the following quote from the background information supplied by the inventors: "Brief Description of Ear Canal Anatomy and Physiology
"The ear canal 10 (FIG. 1) is generally narrow and tortuous and is approximately 26 millimeters (mm) long from the canal aperture 11 to the tympanic membrane 15 (eardrum). The lateral-part 12 is referred to as the cartilaginous region due to the underlying cartilaginous tissue 19. The cartilaginous region 12 of the ear canal 10 deforms in shape and moves in response to the mandibular (jaw) motions, which occur during talking, yawning, eating and also when sleeping over the ear. Hair and earwax (cerumen) are primarily present in this cartilaginous region 12. The medial part, proximal to the tympanic membrane, is rigid and referred to as the bony region 13 due to the underlying bone tissue 7. The skin in the bony region is very thin (relative to the skin in the cartilaginous region) and is far more sensitive to touch or pressure. A characteristic bend roughly occurring at the bony-cartilaginous junction 8 separates the cartilaginous region 12 and the bony region 13. The dimensions and contours of the ear canal vary significantly among individuals.
"A cross-sectional view of the typical ear canal (not shown) reveals generally oval shape with a long diameter in the vertical axis and a short diameter in the horizontal axis. Canal dimensions vary significantly along the ear canal and among individuals. FIG. 2 shows an alternate view of the ear canal 10 (top-down) indicting the narrowness of the contoured ear canal. This view shows the challenge of placing a contiguous hearing device

entirely in the ear canal, particularly for placement in the bony region 13. Even with smaller receivers fitting in the bony region 13, frequent insertions leads to skin irritation, pain and lacerations. For this reason among others, canal placements have been largely limited to the cartilaginous region. Placement of a device entirely in the bony region is not possible with state of the art components due to component size limitations and to difficulty in accessing a hearing device placed deeply and entirely in the bony region alone. Nevertheless, placement of a speaker in the bony region is desired to achieve acoustic advantages including reduction of occlusion effect, less distortion, less receiver vibrations, improved high frequency reception, and other non-acoustic benefits such as reduced receiver exposure to earwax, water and moisture.

"Physiological debris is primarily produced in the cartilaginous region 12 of the ear canal, and includes cerumen (earwax), sweat, and oils produced by the various glands underneath the skin in the cartilaginous region. Debris is naturally extruded from the ear canal by the process of lateral epithelial cell migration which starts from the tympanic membrane laterally towards the lateral (outer) par of the ear canal. There is no cerumen production or hair in the bony part of the ear canal thus less exposure to debris for parts placed in the bony region. The ear canal ends medially (inner direction) at the tympanic membrane 15 is which is connected to the ossicular bone chain and more specifically to the malleus handle 17. Externally and lateral to the ear canal are the concha 5 and the auricle 6 which are important for collecting sound and frequency shaping it into the ear canal.

"Several types of hearing losses affect millions of individuals. Hearing loss naturally occurs as we age beginning at higher frequencies (above 4000 Hz) and increasingly spreads to lower frequencies with age.

"The Limitations of Conventional Canal Hearing Devices

"The limitation of current canal hearing devices is well described in US patent applications U.S. Pat. No. 6,473,513 and U.S. Pat. No. 6,137,889 incorporated herein by reference. These limitations include the well know occlusion effect (speaking into a barrel effect), dexterity limitation for placing a device deep in the ear canal, device size for fitting a miniature device with all standard components including a microphone, circuitry, battery and a receiver (speaker) into ear canals, particularly small and contoured ones. A major limitation is the propensity of a completely-in-the-canal (CIC) device to feedback when set at high volume settings due to the proximity of internal components and the mechanical coupling within the integrated device package. Integrated CIC and in-the-canal (ITC) devices in general, such as in U.S. Pat. No. 5,701,348 are typically not offered to those with severe impairment due to feedback concerns for the high gain requirements.

"The Limitation of Current Extended Wear Hearing Devices

"Extended wear devices recently conceived and developed are disclosed in U.S. Pat. No. 7,424,124, U.S. Pat. No. 7,310,426, U.S. Pat. No. 7,298,857, U.S. Pat. No. 7,215,789, U.S. Pat. No. 6,940,988 and U.S. Pat. No. 6,473,513. They attempt to circumvent the limitation of conventional canal hearing devices, mainly by placing a device deep in the ear canal in close proximity to the tympanic membrane thus reducing the level of amplification needed to deliver sound to the tympanic membrane. A major limitation of prior art extended wear device is the high contraindication leading o the exclusion of approximately 50% of potential wearers according to industry reports. The high contraindication rate is mostly due to size and shape limitation of the ear. These devices also suffer from limited longevity, rarely reaching 4 months, due to the contamination and damage to the continuously worn device from earwax and moisture accumulation in the ear canal. The long term sealing of the extended wear devices prevents moisture from periodically drying out as would normally occur in the unoccluded ear canal. The cost of prior art extended wear devices is high and prohibitive to most consumers.

"In contrast, daily wear canal devices have the advantage of being removed daily to periodically maintain the device such as drying it out, replace the battery when needed and allow the ear canal to rest and dry out. On the other hand, an extended wear canal device has the distinct advantage of deeper canal placement thus 'invisible' with reduced stigma. However, as mentioned before, it is not possible to insert an integrated device package in many ears, particularly in small and contoured ear canals. Providing articulation with respect to the receiver portion (for example U.S. Pat. No. 7,424,124) helps in dealing with the insertion but also presents

known problems such as jackknifing and lack of visualization during the insertion process. For example, one inserting the device cannot know how deep the receiver portion is in the bony region, since receiver viewing is entirely blocked by the lateral portion of the hearing device.

"It is well known that moisture and contamination are mainly present in the cartilaginous part of the ear unlike the boy region, which is relatively 'clean'. However, the cartilaginous region is far less sensitive to frequent touch and pressure, unlike the bony region which is easily prone to damage and irritation, particularly from frequent device insertions. These paradoxical constrains have prevented the hearing aid industry from providing an 'invisible' hearing device that is easy to insert, comfortable to wear, long-lasting, cost effective for the user, and easy to maintain.

"It is a principal objective of the present invention to provide a more optimal combination of features including; (1) delivering sound deeper in the bony region within exceptional proximity to the eardrum, (2) provide extended wear in the bony region without resorting to daily insertions and removals therein, (3) provide easy access for device maintenance, and (4) provide moisture relief for the device and the canal.

"Another objective is to provide a more space efficient design of a canal device that fits a greater range of ears including small and contoured ones, thus reducing the contraindication rate experienced by current designs.

"A further objective of the invention is to provide an acoustically non-occluding hearing device by selectively occluding the bony region while providing occlusion-relieve venting and moisture drying in the ear canal.

"The terms 'short-term' and 'daily wear' are used interchangeably, and so are the terms 'semi-permanent' and 'extended-wear'. 'Short-term' and 'extended-wear' are relative terms and intended here to contrast one another. Extended-wear refers herein to continuous wear exceeding 1 month, and preferably exceeding 4 months as enabled by the present invention. Short term generally refers to daily wear as known in conventional hearing devices and further defined herein as any wear of less than 1 month. The words 'speaker' and 'receiver' are used interchangeably throughout the application."

As a supplement to the background information on this patent, VerticalNews correspondents also obtained the inventor's summary information for this patent: "The present invention provides a modular canal hearing device positioned entirely in the ear canal having a receiver module (also referred to as speaker module) that is separate and is inserted in the bony region semi-permanently. A separate main module is subsequently placed laterally in the cartilaginous part of the ear canal and is removable separately from the ear canal for maintenance while the receiver module remains therein for relatively an extended period. The receiver module comprises a receiver (speaker) and a retainer for retaining the speaker module and providing acoustic sealing to prevent feedback. The receiver module also comprises a wireless coupler for wirelessly receiving power and/or audio signals from the main module. The receiver module is passive and activated by wireless near-field coupling when the main module is inserted in the ear canal in proximity thereto.

"The placement of the receiver module in the bony region is semi-permanent thus minimizes insertion frictions in the bony region, known to be extremely sensitive to touch and pressure. The receiver module being extremely small and separate from the rest of the device allows for improved fit, manipulation, visualization and navigation into and out of the ear canal. The receiver module is not encumbered by the presence of large components associated with an integrated hearing device. Similarly, the main module is smaller by excluding a receiver assembly, thus easier to insert and manipulate into and out of the ear canal.

"The receiver module is placed in proximity to the tympanic membrane resulting in superior sound and energy efficiency. The main module comprises a microphone, a battery, a sound processor/amplifier (electronic circuit), and in the preferred embodiment an inductive coupling coil for transmitting audio signals wirelessly to the receiver module. The receiver module remains immobile during its semi-permanent wear in the ear canal. The immobility of the receiver module allows for rapid acclimation of the sensitive bony region to the receiver module as a foreign object. In contrast, the main module is positioned in the cartilaginous region, which is robust and far less sensitive to frequent touch and motion of the device including from mandibular movements. When the main

module is removed, the receiver module remains in the ear canal with its acclimated skin undisturbed.
"The main module and the receiver module are electromechanically isolated, either by an air gap or by the incidental contact of the coupling elements. At least one coupling element, if connecting, must be flexibly connected to provide vibration isolation to control feedback. Vibration-caused feedback is well known in hearing aid design and particularly for CICs, thus they are limited in their application to less severe hearing impairments. The present invention eliminates such vibration coupling and also prevents the transfer of motion from the main module to the receiver module (for example due to jaw movements, sleeping on the ear, yawning, etc.), thus eliminating skin rubbing and irritation in the bony region where the receiver module resides.
"The main module is placed preferably entirely in the ear canal with the lateral end at or past its aperture, beyond the concha region. In other embodiments, the main module may extend to the concha region for improved access for persons of limited dexterity. The receiver module being in the bony region is less prone to contamination from physiologic debris (i.e, cerumen) present in the cartilaginous area thus can be worn for extended wear exceeding 4 months. By eliminating frequent insertions, cumulative scooping of earwax is minimized. Earwax contamination of receiver sound port is a common problem that plagues canal hearing devices, leading to exceptionally high repair and return rates.
"Deep placement of the invented device allows for invisible and hassle-free wear, features highly sought after by hearing impaired individuals. Placement of the microphone inside the ear canal or within the concha area provides natural sound pick-up by taking advantage of natural ear acoustics. The combined effect of receiver placement near the eardrum and microphone placement in the ear leads to significantly improved sound quality including less distortion, less apparent noise, less wind noise, improved frequency response, and improved speech perception by preserving localization of sound, particularly in noisy conditions.
"The receiver module is preferably inserted by a hearing professional such as an ENT physician, an audiologist or a hearing specialist to provide proper inspection and cleaning of the ear canal and for the safe placement of the receiver module deep in the bony region within exceptional proximity of the eardrum. The receiver module is preferably placed within 4-10 mm from the eardrum. The main module is designed for self-insertion and self-removal, since it is more accessible and with less concern for damage to the ear canal. The modules comprise compressible retainers, which are preferably generic and assorted in size and shape to fit a variety of ear canals without resorting to custom manufacturing as with conventional canal devices. In the preferred embodiments, the main device is remotely controlled for activation and or adjustment as well known in the field of hearing aid design.
"The main module can be removed relatively frequently as needed to maintain the device or the ear canal. For example to replace the battery, replace a disposable cover, replace a sound filter, clean the device, recharge the battery if rechargeable, drying the device, or to simply rest and aerate the ear canal. The receiver module may be designed for self-insertion but preferably after sizing and trial fit by a hearing professional to ensure proper size, fit, and medical considerations of the ear, particularly in the bony region.
"In the preferred embodiment, the receiver module remains in the bony region continuously for extended wear exceeding four months while the main module is removed daily or as needed for device and ear canal maintenance.
"In one aspect, the present invention provides a modular hearing device for inconspicuous wear in the ear canal, comprising: a speaker module for placement medially in the ear canal in the bony region and in proximity to the eardrum, said speaker module comprises a speaker assembly for delivering amplified sound to the tympanic membrane, a skin contacting retainer concentrically positioned over said speaker assembly for retaining said receiver assembly entirely in said ear canal, and a receive coil for wireless reception of electromagnetic signal representing audio signals; and a main module laterally positioned primarily in the cartilaginous region of the ear canal, comprising a microphone, a power source and a transmit coil for wireless transmission of said electromagnetic signal representing audio signal to said receive coil within said speaker

module, said main module is separately removable from the ear canal while said speaker module remains therein when said main module is removed; and wherein said speaker module is activatable by the presence of said main module when placed inside the ear canal in proximity thereto.
"In some embodiments, the retainer provides acoustic attenuation of at least 20 decibels between said speaker assembly output and microphone input within the audiometric frequency range between 500 and 4000 Hz. In some embodiments, the power source is a primary battery or a rechargeable battery. In some embodiments, the said receive coil and/or transmit coil comprise a flexible connection for providing vibration and motion isolation between said speaker module and said main module when said receive and transmit coils are in contact. In some embodiments, the receive coil and/or transmit coil comprise means for vibration dampening at the coupling interface therebetween."

Abstract: Doc number: 91
Abstract
Background: Noise induced injury of the cochlea causes shifts in activation thresholds and changes of frequency response in the inferior colliculus (IC). Noise overexposure also induces pathological changes in the cochlea, and is highly correlated to hearing loss. However, the underlying mechanism has not been fully elucidated. In this study, we hypothesized that overexposure to noise induces substantial electrophysiological changes in the IC of guinea pigs.
Results: During the noise exposure experiment, the animals were undergoing a bilateral exposure to noise. Additionally, various techniques were employed including confocal microscopy for the detection of cochlea hair cells and single neuron recording for spontaneous firing activity measurement. There were alterations among three types of frequency response area (FRA) from sound pressure levels, including V-, M-, and N-types. Our results indicate that overexposure to noise generates different patterns in the FRAs. Following a short recovery (one day after the noise treatment), the percentage of V-type FRAs considerably decreased, whereas the percentage of M-types increased. This was often caused by a notch in the frequency response that occurred at 4 kHz (noise frequency). Following a long recovery from noise exposure (11-21 days), the percentage of V-types resumed to a normal level, but the portion of M-types remained high. Interestingly, the spontaneous firing in the IC was enhanced in both short and long recovery groups.
Conclusion: Our data suggest that noise overexposure changes the pattern of the FRAs and stimulates

spontaneous firing in the IC in a unique way, which may likely relate to the mechanism of tinnitus.

Background

Tinnitus is a condition normally associated with hearing loss, and involves the perception of sound without the corresponding stimulus [1-3]. The reorganization of the frequency topographic map (FTM) has shown to be a direct outcome from hearing loss [4-7]. This could be associated with an increase of spontaneous firing in the brain auditory center [8-9]. It is accepted that such reorganization and spontaneous firing [1-10] are likely involved in the mechanism of tinnitus.

Previous studies have determined that the auditory system contains a topographic representation of tone frequency. The inner hair cells of the cochlea are tonotopically organized, resulting in each inner hair cell having tonotopic connections, through its associated ganglion cells, to cells in the cochlear nucleus [11]. Interestingly, topographic plasticity in the adult central auditory system has been well documented using a wide variety of techniques that result in partial ablation within the periphery of the auditory system. These techniques include mechanical disruption of the organ of Corti [5-6] and spiral ganglion [7-12], administration of cochleotoxic drugs [4-14], and exposure to high intensity sounds [15-16].

The documented changes in the inferior colliculus (IC) included: expanded lesion-edge frequency representations, shifts in characteristic frequencies that cause the expanded lesion edge frequency representations within affected frequency-response areas (FRA) [7-12], reduced levels of sideband inhibition at the particular frequency causing hearing loss [12-17], and reduced inhibition response from multi-units [4]. The changes within the IC occurred immediately after lesions developed and continued for several weeks to several months. For example, hearing loss greater than 10 dB, induced by noise exposure, caused instantaneous changes in the primary auditory cortex [15].

At a single-unit level, tonotopic re-organization of the IC is related to a shift in the characteristic frequency (CF). The shift included a distinct staircase pattern [18] along the dorsoventral axis. Following noise exposure, the original stepwise frequency-depth function changed significantly. In some distortions, only two or three "steps" appeared. The V-type, which is most common in the IC [7-19], translated to double peaks or multi-peaks in the FRA. Non V-type FRAs included two or three frequency peaks [16]. The CF thresholds significantly increased with the time following noise exposure, partially accounting for the occurrence of tinnitus [15]. Furthermore, previous reports have shown that auditory neural hyperactivity appears in the auditory cortex, IC, and cochlear nucleus, occurring simultaneously with tinnitus [1-20]. Yet, the mechanisms of tinnitus, which are associated with hearing loss, have not been clearly identified in these models.

To understand these complex mechanisms associated with tinnitus, narrow-band noise was utilized to induce cochlear damage in guinea pigs. We have measured the FRAs, spontaneous firing of single units in the IC, and

cochlear damage in a single cell level, following noise overexposure of one day (short recovery) and 11-21 days (long recovery), respectively. Our data provide a new perspective in understanding the mechanism of noise induced tinnitus.

Methods

All procedures were approved by the Department of Otolaryngology at The First Affiliated Hospital of Chinese PLA General Hospital and followed all required guidelines. Care and use of the animals in this study was also approved by the Institutional Animal Care and Use Committee of the Chinese PLA General Hospital. Nineteen healthy guinea pigs of both sexes with normal auricular reflex, weighing between 227 g and 525 g were used. The animals were randomly divided into three groups. Short recovery group (7 animals) was evaluated 24 hours after noise exposure and long recovery group was evaluated 11-21 days after exposure (6 animals). In the control group, six healthy animals were used. This timeframe (11-21 days) was consistent with previous studies, which showed that compound action potential (CAP) thresholds were fractionally recovered two weeks after noise-exposure [3-22].

ABR thresholds

The auditory brainstem response (ABR) was also measured. Specifically, guinea pigs were anesthetized with xylazine (0.1 mg/kg) and ketamine (30 mg/kg). Subdermal electrodes were inserted at the vertex and pinna. A speaker was positioned directly above the mid-line of the animal's head at a height of 12 cm. Tone-pips (0.5-ms on rise/fall time, at 30/sec) at 2, 4, 8, and 16 kHz were used as sound stimuli. The response signal was amplified, filtered, and averaged using the Intelligent Hearing System software (ISEN Tech and Trading, Ltd. Beijing, China) [23].

Conditions for noise exposure

During this procedure, the animals were not anesthetized and thus were fully awake, undergoing a bilateral exposure to noise, which was produced from a signal machine (Model 33220A, Agilent Technologies, Inc., UK), intensified by a power amplifier (Model 2706, Brüel &Kjær Sound &Vibration Measurement A/S, Denmark), and transmitted to the surrounding speakers (Model D1002, Beijing First Radio Equipment Factory, Beijing, China). The acoustic overexposure stimulus was a 1/3 octave narrow band noise (i.e. white noise filtered by 1/3 octave band filter) at 4 kHz and 120 dB, measured by a sound level meter (Model 2209, Brüel and Kjær Sound and Vibration Measurement A/S, Denmark), and lasted 4 hours within a sound insulated room. The speakers were placed 4 cm in front of the head of an unrestrained guinea pig within small cells in a subdivided cage (1 animal/cell). Noise calibration, targeting SPL, was performed immediately before each exposure session. It should be noted that sound pressure levels varied by <1 dB across the cages.

Surgery procedure

Before the surgery, a dosage of 0.7 ml/100 g urethane was injected intraperitoneally for anesthetic purposes. The level of anesthesia was monitored in accordance with breathing state and blink reflex during the experiment. If the blink reflex occurred, one third of the concentration of the first dose of urethane was added to maintain a state of unconsciousness. The animals were given a preoperative subcutaneous injection of a dosage of 0.05 ml/100 g atropine to reduce respiratory secretion and to prevent respiratory tract obstruction during the experiment. Oxygen was administered through a customized mask while conducting the experiment. The animal body temperature was maintained by an electric blanket (Model 050100C0001B, FHC Inc. Bowdoin, ME, USA). After the guinea pigs were anesthetized, they were placed in the stereotaxic apparatus. The scalp, temporal muscle, and connective tissue were removed and the skull was exposed. A 10 cm long flat head screw was fixed on the top of the skull using glue and reinforced by dental cement (Model: 200805, Dental Division in Shanghai Medical Equipment, Ltd., Shanghai, China). An area which is 2 mm behind lambda, and 2.5 mm to the right side of the midline, was marked as a circle center with a radius of 2.5 mm. The skull included in the radius of the circle was removed by a micro-drill and the dura mater was removed.

Generation of stimuli

Digital signals generated with 200 kHz sampling rate were used as the sound stimuli. After analog conversion (RX6; Tucker-Davis Technologies, USA) [24-25], the stimuli were applied to the anesthetized animals through the speakers (Electrostatic speaker 1, TDT Co., USA) which were placed next to each ear 20 cm from lambda in a free field. The rise/fall time of pure tone was 5 ms [17]. The stimulation sequences included two steps: 1) A sweep sequence was used for the determination of CF and minimum threshold of the IC neurons, followed by random sweep sequences including 561 pure tones (50 ms duration) at an interval of 250 ms between each tone pip; in this set-up, the frequency ranged from 1 kHz to 60 kHz with 5.9 octaves, and sound intensities were randomly ranged from 10 to 60 dB SPL with 11 linear steps on the intensity curves. 2) Repetitive stimulation sequences were used for determination of neuronal discharge patterns at CF 40 dB above threshold; this was repeated 100 times with a stimulation interval of 600 ms and duration of 200 ms.

Single neuron recording

Extracellular electrophysiological recordings were performed in an anechoic chamber where the anesthetized guinea pigs were fixed in place with both ears in a natural unblocked state, which allowed all data obtained in the IC to be binaural. The speakers were placed next to each ear 20 cm from lambda. Single tungsten electrodes (Model 575300, A-M Systems, Sequim, WA, USA), with tip diameters of 50 microns, were controlled by micro-thrusters. Each electrode track through the IC was continued until a reduction in field potential amplitude was observed. The electrode was then immediately withdrawn and repositioned and a new track was started. The raw signal was sampled at 25 kHz, amplified (X 5000; A-M systems, Sequim, WA, USA), and filtered (0.3 ~ 3 kHz; Tucker-Davis Technologies, TDT Co., Alachua, FL, USA). The FRA, CF and threshold at CF of a single IC neuron were determined audio-visually after a sweep sequence was used. Spontaneous activities of the IC neuron were identified during this recording process, following the criteria: firing rate ≥5 spikes/s, duration ≥10 s. Data were analyzed with OpenSorter software 2.5.0 (Tucker-Davis Technologies, TDT Co., Alachua, FL, USA). The typical IC neurons with spontaneous activities were detected according to the FRAs and the post stimulus time histogram (PSTH) as described previously [10-19].

Nuclear DNA staining of cochlear hair cell

DNA fluorescent dye Hoechst 33342 (Sigma, St. Louis, USA) was used for the nuclear staining of the Organ of Corti [26]. Hoechst was prepared as 0.04% (wt/vol) stock solution using distilled water and stored in the dark at 4°C. For staining, the stock solution was diluted to 1:200 by phosphate buffered saline (PBS, Beijing Puboxin BioTech Ltd., Beijing, China). After signal recording in IC cells, the animal was sacrificed. The temporal bone was removed along with the opening of the oval window and round window of the ear. A solution of 4% paraformaldehyde was repeatedly infused into the cochlea through both windows. Then the cochlea was quickly dissected from the surrounding bones, and the basilar membrane was isolated, being placed in Hoechst staining solution for 10 minutes in the dark at room temperature. The specimen was washed in the PBS and mounted using 50% glycerol (Beijing Puboxin BioTech Ltd., Beijing, China) on a slide. The fluorescence excitation wavelength for Hoechst 33342 was 337 nm, and the corresponding emission wavelength was 430 nm. Imaging was performed using an Olympus confocal microscope (FluoView FV1000, Olympus China Ltd., Beijing, China), which can be used to count the number of hair cells in the randomly selected areas.

The total number of nuclei in either inner or outer hair cells was counted from three 1-mm sections in length located within the cochlea duct. For the control group, we used 12 cochleae from six guinea pigs. Similarly, for the long recovery group, 12 cochleae from six animals were also examined. The three sites were chosen at 14.5-15.5, 10.5-11.5, and 4.0-5.0 mm from the basal end of the basilar membrane, respectively. The nucleus condition was determined through visual inspection under microscopy.

Statistical analysis

All results were presented as mean ±standard error (mean ±SE). Comparisons of constituent proportions among the three groups (FRA) were made using PASW Statistics 18.0 software and SPSS 13.0 software (SPSS Inc. IBM Co. Armonk, New York, USA). Comparisons between groups were performed through

Student's t-Test, and $P < 0.05$ was considered significant.

Results

ABR thresholds in noise exposure group

Prior to noise exposure, the average auditory brainstem response (ABR) threshold was screened using 2, 4, 8, and 16 kHz. One day after noise overexposure, the ABR thresholds were raised at all the above frequencies compared to pre-exposure levels ($P < 0.01$ from 13 animals). The specific data are listed in Figure [figure omitted; refer to PDF] .

Figure 1

ABR Thresholds of auditory brainstem response before and after noise exposure (NE).

ABR Thresholds of auditory brainstem response before and after noise exposure (NE). Statistical data representative of ABR (auditory brainstem response) thresholds before and one day after noise exposure ($n = 13$ from 13 animals) in guinea pigs. Four frequencies were tested: 2 kHz, 4 kHz, 8 kHz, and 16 kHz. *Significant difference from pre-NE group at the same frequency ($P < 0.01$).

[figure omitted; refer to PDF]

Nuclear changes of inner and outer hair cells of the cochlea following noise exposure

During the long recovery after noise overexposure, we found significant portions of fragmentation or disappearance of the nuclei within both outer and inner hair cells of the cochlea, as compared to control; for inner hair cells, irregular shape and disorganized alignment of the nuclei were observed (Figure [figure omitted; refer to PDF] A-D). Furthermore, it appears that there are more considerable nuclear disruptions in the 1st and 2nd turn of the cochlea compared to the 3rd turn, suggesting more high frequency damages (in 1st and 2nd turns) than low frequency damage (3rd turn). It has been noted that Figure [figure omitted; refer to PDF] A is a typical picture represented for 1st, 2nd, or 3rd turn in control cochlea (no NE), because in our confocal settings, there was no marked difference among the images taken from these cochlear sections. Thus, Figure [figure omitted; refer to PDF] A was used as a general image taken from the 1st to 3rd turns.

Figure 2

Representative confocal microscopy (x 40) of fluorescence stained nuclei within inner and outer hair cells in the cochlea of guinea pigs, 11 days after noise exposure (120 dB, 4 hours).

Representative confocal microscopy (x 40) of fluorescence stained nuclei within inner and outer hair cells in the cochlea of guinea pigs, 11 days after noise exposure (120 dB, 4 hours). A : Normal levels are observed in the nuclei of inner and outer hair cells of the control subject. The nuclei were arranged normally and no disruption or fragmentations were found. **B** : The image location is in the third turn of the cochlea after noise exposure, where signs of fragmentation equally occurred throughout both inner and outer hair cells. **C** : In the second turn of the cochlea, after noise exposure, more disruption and fragmentation appears to occur in the inner and outer hair cell nuclei compared to the third turn of the cochlea. **D** : The first turn in the cochlea, after noise exposure, exhibited severe disruption and fragmentation compared to the second and third turns in the inner and outer hair cell nuclei.

[figure omitted; refer to PDF]

As shown in Figure [figure omitted; refer to PDF] , the number of cochlea nuclei in the after-noise exposure (NE) group was significantly reduced compared to pre-NE group (213.1 ±3.5 *vs.* 242.5 ±2.1 for inner hair cells; 615.9 ±12.5 *vs.* 720.9 ±12.5 for outer hair cells; $n = 12$, $P < 0.05$).

[figure omitted; refer to PDF]

Composition change of FRA

The description of the FRA follows the methods of Hernandez et al. [19]. The FRA types of recorded neurons from all guinea pigs we used were similar to those previously reported [19]. The majority of FRAs have a single peak, the V-type, as defined by Hernandez et al. [19]. In order to compare the V-type to other types, the double peak or multi-peak type was defined as M-type, and the elongated narrow rectangular band was defined as N-type (Figure [figure omitted; refer to PDF]). As shown in Figure [figure omitted; refer to PDF] , during a short recovery period after noise overexposure, the percentage of V-type was significantly lower than the normal group (61.1 ±2.4% *vs.* 86.6 ±4.7%, n = 6-7, P <0.01). During the long recovery period, the percentage of V-type shifted back towards normal (76.6 ±7.8% *vs.* 86.6 ±4.7%, n = 6, n.s.). The percentage of M-type is significantly increased during both short (19.3 ±5.4%, n = 7, P <0.05) and long recovery groups (16.7 ±6.7%, n = 6, P <0.05) compared to the normal group (6.0 ±3.1%, n = 6). However, the percentage of N-type remained constant in both short and long recovery periods (Figure [figure omitted; refer to PDF]).

Figure 4

[figure omitted; refer to PDF]

Figure 5

The percentage of FRA types including V-, N- and M-types in normal, short recovery, and long recovery groups.

The percentage of FRA types including V-, N- and M-types in normal, short recovery, and long recovery groups. # P <0.05 compared to normal groups in V-type (n = 6 from 6 animals for normal and n = 7 from 7 animals for short recovery). * P <0.05 compared to normal groups in M-type (n = 6 from 6 animals for normal, n = 7 from 7 animals for short recovery, and n = 6 from 6 animals for long recovery).

[figure omitted; refer to PDF]

Changes of characteristic frequency (CF) over depth

As shown in Figure [figure omitted; refer to PDF] A, the neuronal CF increased with the increasing depth of the tungsten electrode insertion along the dorsoventral axis of the IC in normal groups (114 neurons from 6 animals). Interestingly, we have observed that for the short recovery group, there is a noticeable gap at 4 kHz (161 neurons from 7 animals, Figure [figure omitted; refer to PDF] B, P <0.01, neurons with 4 kHz gap in short recovery group *vs.* neurons with 4 kHz gap in normal group, post hoc contrast). However, this gap was partially reduced in the long recovery group (74 neurons from 6 animals, P <0.01, neurons with 4 kHz gap in long recovery group *vs.* neurons with 4 kHz gap in normal group; P <0.05 neurons with 4 kHz gap in long recovery group *vs.* in neurons with 4KHz gap in short recovery group, post hoc contrast) (Figure [figure omitted; refer to PDF] C).

Figure 6

Function curves providing a correlation between CF (characteristic frequency) and protrusion depth within the IC.

Function curves providing a correlation between CF (characteristic frequency) and protrusion depth within the IC. A : A normal distribution can be observed within the control CF map. CF and depth have a positive trend, resulting in higher frequencies the deeper the protrusions within the IC. **B** : Short recovery group shows more of a randomized pattern with dispersed responses above and below 4 kHz creating a gap specifically at that frequency. **C** : Long recovery group exhibited the same type of gap at 4 kHz, but at a reduced level showing signs of recovery.

[figure omitted; refer to PDF]

Changes of IC neurons with spontaneous firing

Representative FRA with typical spontaneous firing activity (A), corresponding spontaneous firing curve (B), and the percentage of neurons with spontaneous firing activity in different groups (C) are illustrated in Figure [figure omitted; refer to PDF] . Spontaneous activities in the neuron were identified following the criteria: firing rate ≥5 spikes/s, duration longer than 10 s. Thus, any firing rate lower than 5 spikes/s was regarded as the absence of spontaneous activities. Specifically, in Figure [figure omitted; refer to PDF] C, the percentage of IC neurons with spontaneous firing activity in the short recovery group was significantly increased compared to normal group (31.6 ±3.6% *vs.* 15.3 ±3.0%, n = 6-7, P <0.05). The percentage of IC neurons showing spontaneous activity in the long recovery group was also higher than normal group (40.5 ±13.8% *vs.* 15.3 ±3.0%, n = 6, P <0.05). There was no statistical difference between the short and long recovery groups.

Figure 7

Spontaneous firing activities in IC neurons.

Spontaneous firing activities in IC neurons. A : Representative FRA showing typical spontaneous firing. **B** : A typical spontaneous firing curve over time in an IC neuron. **C** : The percentage of neurons with spontaneous firing activity in normal (114 neurons from 6 animals), short recovery (161 neurons from 7 animals) and long recovery groups (74 neuron from 6 animals). *Significant difference from normal group (P <0.05).

[figure omitted; refer to PDF]

Discussion

In this study, noise exposure caused two pathological consequences: one is FRA constituent proportions which were noticeably changed; the other is the IC cells which showed higher spontaneous firing activities. We also observed that average ABR thresholds at 4 kHz, 8 kHz, and 16 kHz were ~10 dB higher in the acute noise exposure group. In addition, images of nucleus staining in the hair cells clearly showed extensive disruption and fragmentations in both inner and outer hair cells in the 1st and 2nd turns after NE. However, we are not clear whether the cells were undergoing inflammation or apoptosis. Thus, we only speculate that the cells could possibly be in these stages, which requires further studies.

Consistent with previous studies, narrow-band frequency noise, or pure tone could cause a diffused elevation of CAP thresholds in adjacent frequencies which are normally higher than the exposure frequency. This may be due to the basalward shift of damage to inner and outer hair cells located on the basilar membrane [2-28]. According to Seki's study, hearing loss of more than 10 dB can cause changes of auditory central CF maps in cats [12-17]. Moreover, in our study, the underlying causes of the histogram changes (Figure [figure omitted; refer to PDF]) may be complex. FRA constituent proportions' changes may be induced by elevation of ABR thresholds. After noise exposure, the neuronal output of the cochlea decreased proportionally along with the increased numbers of damaged inner hair cells [17]. Mechanistically, inner hair cells can accurately convert nano level ciliary beats, caused by sound waves, to electrical energy [29]. Outer hair cells can process the space-time coding through a conversion from mechanical energy to the electrical energy generated by the inner hair cells [29]. Therefore, damage to outer hair cells caused changes of space-time coding for output sound, resulting in a decreased cochlear signal output. Thus, the inhibition/excitation balance of IC neurons became disrupted and new sound space-time coding was reconstructed.

We have found that FRA constituent proportions noticeably changed after noise exposure, which is consistent with previous studies [12-17]. Specifically, the aforementioned change was most notable in the short recovery group regarding V- and M-type. The long recovery following noise exposure allowed for the continuous restructuring of FRA types back to normal levels, resulting in reduced differences among proportions of FRA types between normal and long recovery groups. This suggests that IC neurons show signs of self-repair during a prolonged time period. These changes in tuning curves are possibly correlated to the fundamental cause of tinnitus or hyperacusis (oversensitivity) [30], which will be the focus of further research.

In the function curves of CF and depth in our experiments, there is a marked gap at 4 kHz measured in the short recovery group as shown in the CF *vs.* depth map. The reduced gap observed in the long recovery group

implied the presence of self-repair processes 11-21 days following noise exposure. Although, when compared to chronic tinnitus, the period of 11-21 day is relatively short, it provides a sufficient timeframe to measure the pathological changes in hearing during this period. Note that the noise overexposure frequency was set at 4 kHz, which correlated with this gap. A former study showed that the maximal inhibitory frequency is normally lower than the major frequency at which tinnitus occurs [31]. Our research suggests that the noise of 4 kHz caused a significant shift at 4, 8 and 16 kHz in ABR thresholds.

Increased spontaneous firing rates and the reorganization of the tonotopic map closely follow sensory deafferentation. This also provides an objective signal for tinnitus when associated with hearing loss [32]. It has been reported that after tone-induced (6 kHz) hearing loss in cats, increased synchrony was largely restricted to regions of the auditory cortex where reorganization of the tonotopic map occurred (6 - 10 kHz) compared to non-reorganized regions [8].

In this study, we observed that the FTM reorganization was more noticeable in the short recovery group than the long recovery group. Both groups also had higher spontaneous firing activities than normal. The reorganization of the FTM is obvious in either recovery period when the increased spontaneous firing activity occurs, suggesting that the firing is a relatively dependent event with FTM reorganization. Interestingly, spontaneous rates are increased in animals with tinnitus [33]. Other research has shown that neural tinnitus can continue for life-long periods after recovery from noise-induced damage, whereas CAP thresholds recover only partially weeks after noise-exposure [3-29]. Therefore, we speculate that these enhancements in spontaneous firing within the IC neurons relate to tinnitus models previously described [34]. The mechanism of increased spontaneous firing after noise exposure has not yet been fully understood. However, it is likely related to hyperactivity of the auditory nuclei in the brain stem, or a reduction in the normal suppressive activity of the central auditory cortex on peripheral auditory nerve activity as indicated in previous research [35]. It is possible that the disruption of inhibition/excitation balance in IC may arise from noise induced damage to both inner- and outer-hair cells, resulting in increased spontaneous activities in the IC neurons.

Conclusion

Our research has determined the response of FRAs following noise overexposure. IC neurons during both short and long recovery periods show increased spontaneous firing activity after noise overexposure, when compared to the normal group. In addition, we found that the spontaneous firing and FTM reorganization are two correlated events. Noise induced damage in both inner- and outer- hair cells should be related to these two phenomena. Our results may be useful to develop potential treatments for related hearing diseases.

Competing interests

No conflicts of interest, financial or otherwise, are declared by the authors.

Authors' contributions

FW, LZ, YS, WG performed the experiments, LZ, FW analyzed experimental data, FW, BH and LL designed the project, LL and DH sponsored and supervised the experiments, LZ, FW and EMR wrote the paper, LZ and EMR made figures, LZ supervised the paper submission, editing, and revision. All authors read and approved the final manuscript.

Oticon A/s; "Diminishing Tinnitus Loudness by Hearing Instrument Treatment" in Patent Application Approval Process

Publication info: Telecommunications Weekly (Dec 26, 2012): 842.
ProQuest document link

Abstract: "According to a first aspect of the present invention, the above identified technical object is achieved by a listening device for a hearing impaired person being subjected to a tinnitus at a tinnitus frequency range that comprises the following components: an input transducer configured to provide an electric input signal comprising audio, a detector coupled to the input transducer and configured to determine whether the electric input signal is a broadband signal or not and to provide a detection signal in response and a controllable filter for filtering the electric input signal that is coupled to the detector and the input transducer and configured to output a filtered electric input signal such that a component of the electric input signal in the tinnitus frequency range is attenuated, if the detection signal indicates that the electric input signal is a broadband signal, and to output an unfiltered electric input signal such that a component of the electric input signal in the tinnitus frequency range is not attenuated, if the detection signal indicates that the electric input signal is not a broadband signal.

Full text: 2012 DEC 26 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- A patent application by the inventors PONTOPPIDAN, Niels Henrik (Smorum, DK), filed on June 5, 2012, was cleared for further review on December 13, 2012, according to news reporting originating from Washington, D.C., by VerticalNews correspondents.

Patent serial number 489264 is assigned to Oticon A/s.

The following quote was obtained by the news editors from the background information supplied by the inventors: "A hearing impaired person using a hearing instrument for compensating his/her hearing impairment can additionally be bothered by a tinnitus. A conventional approach for treating tinnitus is to emit a sound through the hearing instrument that either compensates the tinnitus noise by means of a destructive interference or that disturbs the source of the tinnitus, such as hair cells or subsequent auditory functionality, in generating the tinnitus. Such a conventional approach is, for instance, described in U.S. Pat. No. 6,047,074. This publication suggests treating tinnitus with a programmable hearing aid that includes a signal processing chain responsible for producing a useful signal by acting on an input signal in a manner to correct a hearing impairment of a wearer of the hearing aid.

"In the publication 'Listening to tailor-made notched music reduces tinnitus loudness and tinnitus-related auditory cortex activity', Proceedings of the National Academy of Sciences of the United States of America (PNAS), 107 (3): 1207-1210, 2010, authors H. Okamoto et al. describe a causal treatment approach of treating a tinnitus by targeting the tinnitus percept more directly. According to the described new approach, a chronic tinnitus patient is exposed to self-chosen music, which was notched to contain no energy in the frequency range surrounding the patient's tinnitus frequency. For instance, a frequency band of one octave width centered at the individual tinnitus frequency was removed from a music energy spectrum via a digital notch filter."

In addition to the background information obtained for this patent application, VerticalNews journalists also obtained the inventors' summary information for this patent: "It is an object of the present invention to provide a listening device offering an improved tinnitus treatment possibility. It is furthermore an object of the present invention to provide a corresponding operating method of operating a listening device and a corresponding computer program.

"According to a first aspect of the present invention, the above identified technical object is achieved by a listening device for a hearing impaired person being subjected to a tinnitus at a tinnitus frequency range that comprises the following components: an input transducer configured to provide an electric input signal comprising audio, a detector coupled to the input transducer and configured to determine whether the electric input signal is a broadband signal or not and to provide a detection signal in response and a controllable filter for filtering the electric input signal that is coupled to the detector and the input transducer and configured to output a filtered electric input signal such that a component of the electric input signal in the tinnitus frequency range is attenuated, if the detection signal indicates that the electric input signal is a broadband signal, and to output an unfiltered electric input signal such that a component of the electric input signal in the tinnitus frequency range is not attenuated, if the detection signal indicates that the electric input signal is not a broadband signal.

"The present invention includes the recognition that, on the one side, the introductorily mentioned conventional approach of treating a tinnitus by emitting a sound is, in the outcome, merely a symptom management. A conventional approach of treating a tinnitus results at best at a temporary partial elimination of the tinnitus noise, namely for the time when the signal is emitted; however, the emission of a signal does not heal the tinnitus itself. If the known hearing aid stops emitting the sound, the tinnitus will keep on bothering the hearing impaired person. On the other side, the causal treatment approach described by Okamoto et al. requires the hearing impaired person to listen to the prerecorded music over and over again in order to sustainably reduce tinnitus loudness.

"In contrast, the listening device of the first aspect of the present invention automatically achieves a sustainable

reduction of tinnitus loudness by detecting that the electric input signal is a broadband signal and by dampening a frequency component of the electric input signal in the tinnitus frequency range. If the listening device detects that the electric input signal is not a broadband signal, the filter will not filter the electric input signal but let it pass substantially unmodified, in particular unfiltered. Thereby, the listening device automatically promotes a reversing of maladaptive auditory cortex reorganization in the ear/ears of the hearing impaired person.
"The listening device can be any hearing instrument, hearing aid, headset, earphone and in-the-ear (ITE) listening component, a completely-in-canal (CIC) listening component, a behind-the-ear (BTE) listening component, or a receiver-in-the-ear (RITE) listening component. The listening device can furthermore be an analog, a digital or an analog-digital hybrid listening device.
"The term 'tinnitus frequency range' of a user is in the present context to mean a frequency range around a central tinnitus frequency f.sub.t which is perceived by a user as comprising the disturbing frequencies associated with tinnitus. The tinnitus frequency range (including the central tinnitus frequency can e.g. be determined for a given user by playing a number of narrow-band sounds (e.g. pure tones or harmonic series with missing fundamentals that span small frequency range) centered at different frequencies over the human audible frequency range (e.g. between 20 Hz and 20 kHz) and have the user identify the frequency (or frequencies) that is perceived as closest to the disturbing tinnitus sounds. In an iterative procedure, the distances in frequency between the sounds played for the user can be diminished to successively more precisely identify one or more tinnitus frequency ranges (and thus corresponding central tinnitus frequency/ies). In an embodiment, more than one distinctly different (non-overlapping) tinnitus frequency ranges of a user is defined.
"In an embodiment, the component of the electric input signal in the tinnitus frequency range that is attenuated defines a 'tinnitus filtering range' (e.g. between respective minimum and maximum tinnitus filtering frequencies, e.g. corresponding to 3 dB cut-off frequencies of a band-pass filter).
"The term 'a broadband signal' is in the present context taken to mean a signal having a bandwidth that is larger than the component of the electric input signal in the tinnitus frequency range that is attenuated. A broadband signal is e.g. defined as a signal that has a bandwidth larger than one third octave, e.g. larger than one octave, relative to a centre frequency f.sub.t of the tinnitus frequency range. In an embodiment, the bandwidth of the broadband signal is larger than 500 Hz, such as larger than 1 kHz, such as larger than 2 kHz. The filtering characteristic of the controllable filter is adapted to the tinnitus frequency range of the hearing impaired person that wears the listening device. This can mean that the controllable filter dampens a frequency component in the electric input signal that has a frequency identical to the frequency/frequencies of the individual tinnitus noise. However, if it is determined that a treatment of the tinnitus can be improved if other or additional components in the electric input signal that have a frequency other than the frequency of the individual tinnitus noise are dampened, the controllable filter is adjusted such that these components of the electric input signal are dampened. Thus, the filtered electric input signal can be target filtered such that a frequency band of a certain range centered at the individual tinnitus frequency is dampened from the broadband electric input signal. In another approach, the filtered electric input signal can also be a filtered signal, whose frequency components that directly surround the individual tinnitus frequency remain substantially unchanged and that other frequency components at a certain distance to the individual tinnitus frequency are dampened. However, it is preferred that the controllable filter dampens such a component of the electric input signal, whose frequency is substantially identical to the individual tinnitus frequency/frequencies. Measurement results have shown that such target filtering offers a more effective treatment of tinnitus loudness.
"The controllable filter dampens the component of the electric input signal such that the amplitude of the component of the filtered electric input signal is reduced compared to the amplitude of the component of the electric input signal prior to be subjected to the filter. It is preferred that the controllable filter is configured to completely remove the component, if the detection signal indicates that the electric input signal is a broadband

signal. However the advantageous effects of the controllable filter in the listening device can also be achieved, if the component is substantially reduced. For instance, the controllable filter is a notch filter, such as a digital notch filter or an analogue notch filter. Alternatively, the dampening is performed by an analysis-synthesis filter bank whose respective bands are set to zero or to another dampening value.

"It shall be understood that in case that it is detected that the electric input signal is not a broadband signal and an unfiltered electric input signal is provided by the controllable filter correspondingly, such unfiltered electric input signal can be subjected to further filter means that the listening device can optionally comprise. The primary function of the controllable filter is to attenuate the relevant component of the electric input signal, if the electric input signal is a broadband signal. The controllable filter can be embedded in a filter bank of the listening device, if present, the filter bank configured to fulfill filter function that are conventional within the scope of listening devices, such as noise filtering etc. However, the controllable filter can alternatively be arranged separately in the listening device.

"The wording tinnitus is to be understood to follow its standard definition in the technical field of acoustic signal processing.

"In a preferred embodiment, the detector comprises a classifier for determining whether the electric input signal is a broadband signal or not. The classifier is configured to classify the electric input signal in one of a plurality of classes comprising at least: broadband music, broadband noise, such as car noise or other environmental noise, non-broadband own voice and non-broadband speech. In a preferred embodiment, the controllable filter outputs a filtered electric input signal, whose component in the tinnitus frequency range is attenuated, if the detector classifies the input signal as one or more of broadband music or broadband noise (such as car noise or other environmental noise). If, on the other hand, the electric input signal is classified as non-broadband own voice or as non-broadband speech, the controllable filter outputs a substantially unmodified electric input signal, that is to say: the controllable filter does not process the electric input signal but rather forwards it substantially unmodified to a component connected downstream of the controllable filter.

"In order to perform the classification, the classifier can comprise estimation means for estimating in which class the electric input signal is to be classified. Such estimation means can perform the estimation on a regular basis known from the prior art, cf. e.g. US 2003/0144939 A1 or US2006/0179018 A1.

"In a preferred embodiment, the detector is configured to provide the detection signal indicating that the input signal is a broadband signal only, if the electric input signal has not been classified as own voice or as speech. If own voice or speech is contained in the acoustic input signal, filtering the electric input signal with a controllable filter could harm the intelligibility of the signal eventually presented to the hearing impaired person wearing the listening device. Thus, if the signal is classified as voice of speech, the controllable filter does not filter the electric input signal. As the classifying can be based on estimation, the electric input signal could both be identified as being a broadband signal and as containing own voice and speech. In this case, no filtering shall take place. Level detection in hearing aids is e.g. described in WO 03/081947 A1 or U.S. Pat. No. 5,144,675. A speech detector is e.g. described in WO 91/03042 A1. Own voice detection is e.g. dealt with in US 2007/009122 A1 and in WO 2004/077090 A1.

"In a particular preferred embodiment, the listening device comprises an activator coupled to the controllable filter and to the detector, which is configured to activate and deactivate the controllable filter in dependence of the detection signal. For instance, if the detection signal yields that the input signal is a broadband signal, the activator activates the filter such that the electric input signal is converted into a filtered electric input signal. If, in the other case, the detection signal yields that the electric input signal is a non-broadband signal or, respectively, that the electric input signal contains own voice or speech, the activator deactivates the controllable filter, such that the controllable filter does not process the electric input signal but rather forwards it substantially unmodified to a component of the listening device connected downstream to the controllable filter.

"In another preferred embodiment, the listening device comprises a user interface configured to provide a user

submitted tinnitus treatment user signal to the activator, wherein the activator is configured to activate and deactivate the controllable filter in dependence of the detection signal and the tinnitus treatment user signal. This embodiment takes into account that the hearing impaired person wearing the listening device may want to decide whether or not the controllable filter shall output a filtered electric input signal or not, as the filtered electric input signal can lead to an output signal to be presented to the hearing impaired person that differs from an output signal which has been derived from an unfiltered electric input signal. Thus, the hearing impaired person can, for instance, decide that the controllable filter only operates at certain time periods during the day.
"In another preferred embodiment, the listening device additionally comprises a programmable timer configured to provide a timer signal to the activator, wherein the activator is configured to activate and deactivate the controllable filter in dependence of the detection signal and the timer signal. This embodiment can be combined with the embodiment described above that comprises a user interface. For a certain tinnitus therapy, it can be advantageous that the controllable filter is only activated at a certain times of the day and/or, respectively, for a maximum amount of time per day or, respectively, per hour or any other time unit. In an embodiment, the activator can receive the detection signal, the timer signal and a user signal and only activates the controllable filter, if all of the three aforementioned signals yield that the controllable filter should be activated, that is to say: The detection signal yields that the input signal is a broadband signal, the user signal indicates that the hearing impaired person wishes that the tinnitus therapy takes place and the timer signal allows for operation of the controllable filter. If one of the aforementioned three signals yields contrary, the controllable filter is not activated but deactivated and outputs an unfiltered electric input signal such that a component of the electric input signal in the tinnitus frequency range is not dampened.
"In case the tinnitus frequency range of the user is relatively broad (or comprises a number of different (non-overlapping) frequency ranges spaced over a relatively broad frequency range), e.g. comprises more than one octave of frequencies, the listening device may be adapted to split the tinnitus therapy into a number of separate treatments (separate in time), each concentrating on a specific frequency range, each frequency range being e.g. smaller than one octave. The listening device is then adapted to provide the number of separate treatments at different points in time, e.g. in a repetitive pattern, so that that only one of the number of frequency ranges is stimulated (treated) at a given time.
"It is preferred that the programmable timer is configured to determine the amount of operation time during which the controllable filter outputs the filtered electric input signal and to ensure that the operation time does not exceed a predetermined limit, wherein the predetermined limit is programmed to the timer. The predetermined limit can, for instance, analogously be formulated as '2 h per day' or '10 min per hour', 'total of 100 hours maximum' and so on. Such setting of a predetermined time limit may in an embodiment be set during fitting by a Health Care Professional (HCP) of the listening device to a particular user's needs. In another embodiment, the setting of a predetermined time limit may be controlled by the user of the listening device via a user interface, e.g. a button or a remote control.
"In an embodiment, the listening device is adapted to allow a user to activate a traditional tinnitus treatment (e.g. comprising playing audio pieces masking noises, delivering pleasant sounds, etc.). In the fitting process the Hearing Care Professional (HCP) may define the 'treatment' schedule providing tinnitus treatment according to the present invention to a predefined period per day, e.g. 2 hours per day. If, however, the user of the listening device (e.g. via a user interface) requests the traditional tinnitus treatments with a certain frequency and/or a certain duration during daily use, the listening device may be adapted to monitor such behavior and to increase or decrease the frequency or duration of the treatments (between certain maxima and minima, e.g. set by a HCP during fitting of the device to the user in question) based on said monitored behaviour.
"In another preferred embodiment, the listening device additionally comprises a memory coupled to the controllable filter and configured to store one or more individual frequency values representing the tinnitus frequency range, wherein the controllable filter is configured to adapt its filter characteristic according to the

stored frequency values. Thus, after production, the listening device does not have to be a priori exactly adapted to the designated user, but can be adapted to the individual tinnitus appearance during a fitting process. Such fitting process can result in a spectral characterization of the hearing impaired person's tinnitus and in determined frequencies that shall be removed by the controllable filter. Thus, by determining the one or more individual frequency values during the fitting process, the listening device for the hearing impaired person can be adjusted to the individual tinnitus appearance.

"The listening device of the first aspect of the present invention is not limited to only treat a tinnitus, but can also, in a preferred embodiment, compensate other hearing deficiencies of a hearing impaired person and generally improve intelligibility of the incoming acoustic signal.

"In another preferred embodiment, the listening device comprises a signal processor connected downstream of the controllable filter and configured to process either the filtered or the unfiltered electric input signal according to a processing algorithm and to output a processed electric signal. It is further preferred that the listening device comprises an output transducer connected downstream of the signal processor and configured to convert the processed electric signal to an analog output signal to be presented to the hearing impaired person. In an embodiment, the output transducer comprises a number of electrodes of a cochlear implant or a vibrator of a bone conducting hearing device. In an embodiment, the output transducer comprises a receiver (speaker) for providing the stimulus as an acoustic signal to the user.

"The input transducer is e.g. adapted to convert an acoustic input signal to an electric input signal comprising audio. The input transducer can comprise one or more microphones. The input transducer can alternatively or additionally comprise a wireless receiver for receiving an electromagnetic signal and extracting (e.g. demodulating the received signal to provide) an audio signal therefrom. The wirelessly received signal may be transmitted to the listening device from any appropriate device comprising a transmitter of an audio signal, e.g. a microphone, a telecoil, another listening device (e.g. a contralateral listening device of a binaural system), a communication device (e.g. a cellphone), an audio gateway for receiving a number of audio signals and transmitting a selected one (or a mixture of several selected signals) to the listening device (e.g. controlled by the user of the listening device), etc. The wireless transmission may be based on any communications technology of relevance to a portable listening device, e.g. near-field or far-field electromagnetic communication, light communication, etc.

"According to a second aspect of the present invention, the above identified technical object is achieved by a method of operating a listening device for a hearing impaired person being subjected to a tinnitus at a tinnitus frequency range, wherein the method comprises steps of receiving an electric input signal comprising audio, determining whether the electric input signal is a broadband signal or not and providing a detection signal in response and forwarding the electric input signal to a controllable filter and outputting a filtered electric input signal such that a component of the electric input signal in the tinnitus frequency range is attenuated, if the detection signal indicates that the electric input signal is a broadband signal, or outputting an unfiltered electric input signal such that a component of the electric input signal in the tinnitus frequency range is not attenuated, if the detection signal indicates that the electric input signal is not a broadband signal.

"The operating method of the second aspect of the present invention principally shares the advantages of the listening device of the first aspect of the present invention. In particular, the operating method has preferred embodiments that correspond to the additional optional features of the listening device of the first aspect of the invention described above. For instance, it is preferred that the method comprises the step of classifying the electric input signal into one of the classes: broadband sound, broadband music, broadband noise, non-broadband own speech, non-broadband voice and performing the filtering step, only if the electric input signal is a broadband signal and not a non broadband voice or speech signal. The method preferentially also comprises the step of receiving a user signal and performing the filtering step only, if the user signal yields that the hearing impaired person wishes the tinnitus treatment to be commenced. It is furthermore preferred that the method

comprises a step of monitoring the time period during which a filtered electric input signal is generated and to prevent further filtering of the electric input signal, if it is determined that a predefined maximum of time has been exceeded. The received electric signal comprising audio is e.g. received from a wireless receiver (or transceiver) or from an acousto-electric transducer such a as a microphone or a microphone system (e.g. comprising a number on microphones and e.g. providing as an output a directional signal).
"According to a third aspect of the present invention, the above identified object is achieved by a computer program for operating a listening device, the computer program comprising program code means for causing the listening device to carry out the steps of the method of the second aspect of the present invention, when the computer program is run on a computer controlling the listening device.
"The computer program of the third aspect of the invention may be stored/distributed on a suitable medium, such as an optical storage medium or a solid-state medium supplied together with or as part of other hardware, but may also be distributed in other forms, such as via the Internet or other wired or wireless telecommunication systems."

Appeals court to hear deaf student's complaint

Author: England-Nelson, Jordan

Publication info: Orange County Register [Santa Ana, Calif] 20 Dec 2012.
ProQuest document link

Abstract (Abstract): "At the end of the day, (the student is) emotionally very tired from all the intense concentration" and "come(s) home mentally exhausted from trying to listen," a court order reads. "She reports that she will laugh at school when she sees others laughing and worries about looking stupid if others realize she did not catch the joke."
"It's much more complex than the cost issue," says Jack Clarke, the attorney representing Tustin Unified. "I can't speak in specifics about any particular student, but we believe that by complying with federal law we have not discriminated against any student in the district."
The original hearing of the case, which took place in 2009, examined whether the district had denied the plaintiff a "free and appropriate public education" as required by the Individuals with Disabilities Education Act. Citing another case as precedent, the judge affirmed that schools are not required to provide "every special service necessary to maximize each handicapped child's potential."

Full text: A hearing-impaired Tustin high school student has asked that her complaint against the Tustin Unified School District be re-examined.

The girl says the district's refusal to provide speech-to-text transcription in real time constitutes discrimination. Two judges have already sided with Tustin Unified, holding that the school is not required by law to provide the service. Now the case has been brought before the 9th Circuit Court of Appeals.

Although the girl is deaf, a cochlear implant allows her to communicate by listening and speaking, rather than using sign language. The electronic device stimulates the auditory nerve to provide a sense of sound, but does not restore normal hearing, as it does not filter out background noise that hearing people do naturally. As it stands, the girl - whose name is not given in the suit because she was a minor at the time it was filed - finds it difficult to follow what is happening in class, particularly during student discussions.

"At the end of the day, (the student is) emotionally very tired from all the intense concentration" and "come(s) home mentally exhausted from trying to listen," a court order reads. "She reports that she will laugh at school when she sees others laughing and worries about looking stupid if others realize she did not catch the joke."

Despite her difficulty in classes, the student generally earns average to above-average grades in school, according to court records.

The high school has offered to provide an FM system, which involves a wireless microphone that beams a signal to an ear piece worn by the student. The girl dislikes the FM technology because the microphone picks up static and side conversations when the teacher moves around the classroom, and she didn't want to force students to pass around a microphone in class.

The service that the girl has requested in her appeal is called communication access real-time translation, or CART. The technology costs $100-$150 an hour and involves a person listening in on the class and transcribing what is said.

"It's much more complex than the cost issue," says Jack Clarke, the attorney representing Tustin Unified. "I can't speak in specifics about any particular student, but we believe that by complying with federal law we have not discriminated against any student in the district."

The original hearing of the case, which took place in 2009, examined whether the district had denied the plaintiff a "free and appropriate public education" as required by the Individuals with Disabilities Education Act. Citing another case as precedent, the judge affirmed that schools are not required to provide "every special service necessary to maximize each handicapped child's potential."

The act only provides basic and low-level protections, said David Gray, the Tustin student's lawyer. He said the previous judges did not take into sufficient consideration the Americans with Disabilities Act, which he says ensures greater equality of opportunity for disabled individuals than the Individuals with Disabilities Education Act.

"If you have someone in a wheel chair, you give him a ramp to get up the steps -- you don't make him crawl," Gray said by phone.

Gray's client first asked for captioning service as she was entering ninth-grade. She is now a senior, and would no longer directly benefit from a reversal of the judges' decision.

"The hope is to get some clear legal precedent so the next kid coming up from middle school will have a clear definitive answer for this," said Gray.

Publication info: Lodging Hospitality (Dec 10, 2012).

Full text: AMENITIES

Olive Branch Botanicals offers a line of bathroom amenities that the company says are softer and gentler and provide a more ecological approach to skin and body care and includes a respect for the environment.

RECYCLING CONTAINERS

Witt Industries expanded its line of GeoCube indoor recycling containers with a larger, 36-gallon capacity model, the addition of a recycle blue color as an option on all sizes, an improved bag holder retainer band and a new combination top for cans and paper. Also, the decals to identify the recycling stream for its cube has been changed to a new, more readable typeface design.

SELF-SERVICE YOGURT

Donper America introduced a new yogurt machine hotels can use for buffet areas, breakout sessions, free evening meals and other occasions. The model BH7480 is a freestanding unit that dispenses two flavors with a twist option housed in a slim-design stainless steel compartment. The machine is air-cooled, eliminating the need for it to connect to water and glycol systems.

CARPET

Bloom is a new carpet collection from Aqua Hospitality Carpets and Zeftron, a premium branded nylon 6 fiber system. The line is available in three nature-themed styles-Flora, Pure Petal and Just Leafy-and six colorways ranging from neutral earthtones to natural brights. Available in both broadloom and tile, the collection is suited for guestrooms, corridors and lobby areas.

HEARING AID

The Silent Servant Hotel Kit from Silent Call Communications is a complete package to meet the needs of guests who are deaf or hard of hearing while meeting applicable ADA regulations. The kit includes a receiver with built-in alarm clock, smoke detector with transmitter, sound monitor for the telephone, doorbell transmitter on a bracket, bed vibrator and a snap-on phone amp.

LAVATORY SYTEM

Bradley Corp. introduced the Advocate AV-Series Lavatory System, which it says is the first lavatory unit to include a sink, soap, faucet and dual-sided hand dryer in one unit. In addition to user convenience and functionality, the all-in-one design ensures all waste water goes down the drain, not on the floor or down the walls. Available in two- or three-user models, the lavatory is also ADA compliant, says the company.

SHOWERHEADS

Oxygenics has expanded its line of self-pressurizing showerheads to include four series. The Spa Series features the Evolution hand-held, rotating-head, multi-feature spray. The Power Series has the Power Massage Combo that offers 35 different sprays and a dual showerhead. The Rain Series is a wide (up to 10 inches) showerhead that has up to 54 power nozzles on each unit. The Classic Series includes simple and affordable models.

CLOCK RADIO

Sunbeam's new Elite CR1003 clock radio designed specifically for hotels is a "talking" product with a wide array of other features but is simple to operate, says the company. Features include voice, nap timer, USB charger, radio seek, iPod dock and white noise. It also has what Sunbeam calls a foolproof alarm setting system that incorporates an audible voice that instructs and confirms guest alarm settings. The unit also has a large, bright LCD display with easy-to-read time and clearly marked "alarm on/off" and "alarm time" indicators.

HAND DRYER

TRI-Umph is a new addition to American Specialties' Roval Collection of hand dryers. The company says the automatic high-speed dryer is a super-hygienic, fast-drying and competitively priced option for commercial washrooms. The unit's ergonomic design allows users to dry their hands in a natural position without water splash-back or water falling to the floor and creating a hazard. Its filter system is comprised of three layers of filter: HEPA, carbon and anti-microbial.

GUEST INTERNET SYSTEM

Eleven Wireless, provider of a cloud-based guest Internet platform, launched ElevenOS software, which is a new framework for advanced bandwidth management that includes package tiering, in-session upgrades, sharing across multiple guest devices and easy provisioning and prioritization for groups and conferences.

CLOUD-BASED PMS

At the recent HITEC trade show, Hotel Concepts-Brilliant introduced iTesso, a scalable, customizable and integrated cloud-based property management system, distribution platform and central reservations system. It also can be deployed as a direct connection between a hotel CRS and the global distribution system or as a distributed multi-property PMS with links to third-party CRS. The software is based and hosted on the Microsoft Azure cloud infrastructure.

TOOTHBRUSH HOLDER

The Stand and Stow toothbrush holder from Lightbulb LLC is a hotel amenity that provides guests with a clean place to stand their toothbrushes in the bathroom and a convenient place to store the brushes when they leave. A customization program from the company allows hotels to place their logos on the item.

HOSPITALITY LEGAL ISSUES

The fourth edition of Managing Legal Issues in the Hospitality Industry from Research and Markets Ltd. shows hotel owners and operators how to effectively and proactively manage the legal environment in their lodging properties. New to this edition are discussions of payment card industry compliance, revised ADA regulations, information on social media and more.

WIRELESS PA SYSTEM

The Loudmouth Wireless PA System from Ritron, Inc. allows hotels to use existing portable two-way radios, base stations or mobile radios to deliver live voice messages at a distance of up to two miles away, making the system suitable for general paging or announcements, weather emergencies, security announcements and more. The company says the system installs easily and virtually anywhere with no trenching or extensive wiring required.

STACKABLE SEATING

The Piper Chair from MTS Seating is contemporary and comfortable and takes stackable banquet seatings to "an elegant new level," says the company. The multi-contoured seat shell provides the comfort. The chair is stackable up to 10 high and comes with a 12-year structural frame warranty.

IPAD CHECK-IN

The xPress Check-In app from Northwind allows hotels to use iPads and other tablets for personalized mobile check-in and check-out services with seamless remote access to Northwind's Maestro Property Management Suite. Using the app, guest service agents can provide curbside service, upsell and change room assignments in real-time, complete group check-in and room blocking, remotely encode magstripe and RFID room keys, capture credit card info with PCI compliance and more.

SUSTAINABLE FURNITURE

The Plank Collection of furniture, developed by Pfeiffer Lab for furniture manufacturer Council, is made of Perennial Wood, a product made in the U.S. from domestically harvested Southern pine. The manufacturer says the wood undergoes a proprietary process that transforms its cell structure, leaving no toxic substances and providing a physical barrier that resists damage from outdoor elements for decades.

UPRIGHT VACUUM

The SC9050B lightweight commercial upright vacuum from Sanitaire features a more durable design in a lightweight, easy-to-maneuver frame, says the company. The frame is made of magnesium, which is 75% lighter than steel and 33% lighter than aluminum. A new design allows users to place their foot on the vacuum hood and release the vacuum from the upright position without the use of the foot pedal.

FLATWORK IRONER CLEANER

Tingue, Brown &Co. introduced a heavy-duty Continuous Belt Cleaner for flatwork ironers. Using an abrasive mesh strip design, the cleaner accesses difficult-to-reach areas directly under the ironer to remove large amounts of dirt, lint, grime, wax and other contaminants that accumulate over time.

AMENITY COLLECTION

Lather Hotel partnered with luxury bath and body brand Mistral to introduce the Mistral Verveine hotel amenity collection. The products draw on organic shea butter to soften, natural olive oil to hydrate and condition and the scent of verbena to energize and soothe, says the company. The collection includes shampoo, conditioner, shower gel, body lotion, body soap, face soap, bath salts, shea butter and hand cream.

LOCKING TECHNOLOGY

Enhancements to VingCard's RFID locking technology promise to nearly double the reading speed for its Classic RFID, Signature RFID and Signature RFID Remotus designs. In addition, the company says the new platform enables the RFID locks to read keycards from more than twice as far.

MATTRESSES

Jamison Bedding's new Town &Country mattress line comes in four models including one- and two-sided designs. ArmorPur technology repels water- and oil-based liquids and stains. It safeguards the bed from mold, mildew, algae, bacteria, odor-causing microbes and microbial deterioration.

CLEANING CHEMICALS

Signet Cleaning Chemical Service combines cleaning chemicals from Diversey with the delivery service of Cintas. The co-branded product line includes floor, hard surface and manual warewashing cleaners. The delivery service eliminates the need to carry inventory and provides properly diluted chemicals at the push of a button.

Frequency Dependence of Binaural Interaction in the Auditory Brainstem and Middle Latency Responses

Author: Fowler, Cynthia G; Horn, Jennifer H.

Publication info: American Journal of Audiology (Online) 21.2 (Dec 2012): 190-8.
ProQuest document link

Abstract: The primary purpose of this investigation was to determine the relative frequency representation of binaural function in the brainstem and cortex of adults. The secondary purpose was to compare adult responses to previously reported infant responses. Simultaneous auditory brainstem responses and auditory middle responses were recorded monaurally and binaurally in 20 young women. The binaural (BIN) response was subtracted from the summed monaural waves (L+R) to obtain the binaural interaction components (BIC) from waves V (peak A) and Pa (BIC-Pa). Amplitude ratios were calculated as BIC/L+R. Repeated-measures

analyses of variance evaluated responses to frequency (500 Hz vs. 4000 Hz), wave condition (L+R vs. BIN), and wave class (auditory brainstem response vs. auditory middle response). Waveforms were present for all conditions. The L+R responses were larger than the BIN responses, 500 Hz produced larger amplitudes than 4000 Hz, and Pa was larger than wave V. The largest response, overall, was the Pa(L+R) response to 500 Hz. For amplitude ratios, BIC-Pa/Pa(L+R) was larger than Peak A/[V(L+R)]. More neural resources are devoted to binaural function in the cortex than in the brainstem, andmore resources are devoted to lower frequencies than to higher frequencies. The adult data confirm that previously recorded infant data reveal binaural immaturity. Longitudinal data should characterize developmental characteristics of binaural function.

Purpose: The primary purpose of this investigation was to determine the relative frequency representation of binaural function in the brainstem and cortex of adults. The secondary purpose was to compare adult responses to previously reported infant responses.
Methods: Simultaneous auditory brainstem responses and auditory middle responses were recorded monaurally and binaurally in 20 young women. The binaural (BIN) response was subtracted from the summed monaural waves (L+R) to obtain the binaural interaction components (BIC) from waves V (peak A) and Pa (BIC-Pa). Amplitude ratios were calculated as BIC/L+R. Repeated-measures analyses of variance evaluated responses to frequency (500 Hz vs. 4000 Hz), wave condition (L+R vs. BIN), and wave class (auditory brainstem response vs. auditory middle response).
Results: Waveforms were present for all conditions. The L+R responses were larger than the BIN responses, 500 Hz produced larger amplitudes than 4000 Hz, and Pa was larger than wave V. The largest response, overall, was the Pa(L+R) response to 500 Hz. For amplitude ratios, BIC-Pa/Pa(L+R) was larger than Peak A/[V(L+R)].
Conclusion: More neural resources are devoted to binaural function in the cortex than in the brainstem, andmore resources are devoted to lower frequencies than to higher frequencies. The adult data confirm that previously recorded infant data reveal binaural immaturity. Longitudinal data should characterize developmental characteristics of binaural function.

Key Words: electrophysiology, adults, hearing, infants, physiology, acoustics, development

Binaural hearing allows people to understand speech in noisy backgrounds and to localize the direction of sounds in the environment. Deficits in binaural processing, however, can accompany aging, hearing loss, and some pathological conditions, all of which can reduce a person's communication ability. A better understanding of binaural processing may lead to improvements in communication for people who have binaural deficits. Binaural function has been studied extensively with psychoacoustics but not with physiological measures; the physiological measures provide the ability to determine function at various levels in the brainstem and cortex. Electrophysiological studies of binaural function have been done primarily with the auditory brainstem response (ABR) and, to a lesser extent, with auditory middle latency responses (AMLR) and auditory late latency responses (ALLR) responses (for a review, see Fowler, 2004). This study focuses on the electrophysiological measures of binaural interaction in the ABR and AMLR.

The first evidence of binaural interaction was provided in the ABR by Jewett (1970). Binaural stimulation of the auditory brainstem pathways produced a larger response than did monaural stimulation, but not twice as large, suggesting that the right and leftauditory pathways interacted in the brainstem. Dobie and Berlin (1979) formalized a method for investigating the difference, which they called the binaural interaction component (BIC) of the ABR. The BIC was defined as the amplitude difference between the summation of the leftand right responses (called the L+R or predicted binaural amplitude) and the binaural response amplitude (the BIN or true binaural response). The subtraction is done in one of two ways: Either the L+R response is subtracted from

the BIN response (e.g., Dobie &Berlin, 1979) or the BIN is subtracted from the L+R response (e.g., Fowler &Leonards, 1985; McPherson &Starr, 1993). The BICs from the two subtractions are mirror images, but the characteristics measured from each are not necessarily the same across studies.

The ABR has five waves, indicated by Roman numerals, and extends from the eighth nerve to the lateral lemniscus (Moller &Jannetta, 1983). The ABR-BIC waveform is centered around the generators of Waves IV-VI, which are thought to arise from the superior olivary complex to the lateral lemniscus (Moller&Jannetta, 1983). Binaurally innervated neurons within this pathway limit the amplitude of the binaural response as a cumulative effect of neural interactions involving excitations and suppressions within the auditory neural pathways. For click stimuli, the ABR-BIC amplitude indicates a 16%-25% reduction of the predicted (L+R) response (Dobie &Norton, 1980; McPherson, Tures, &Starr, 1989), thus suggesting overall suppression in neurons that are shared between the leftand right auditory brainstem pathways. These binaural neurons are localized between the trapezoid body and the lateral lemniscus (Polyakov &Pratt, 1994).

The BIC can be elicited from AMLR and ALLR as well, but less is known about the origins of the latter responses. The AMLR, of concern in the present study, consists of Na-Pa-Nb, which occur from 12 to 75 ms after click stimulation and arise from the thalamocortical radiations and primary auditory cortex. The click-evoked AMLR-BIC is associated with Na-Pa-Nb in adults (Dobie &Norton, 1980; McPherson &Starr, 1993; McPherson et al., 1989) and in infants (Cone-Wesson, Ma, &Fowler, 1997; McPherson et al., 1989). Click-evoked AMLR BICs indicate that binaural responses are nearly half the size of the predicted response (Dobie &Norton, 1980; McPherson et al., 1989), suggesting that more cortical resources are devoted to binaural processing in the cortex than in the brainstem. Comparable studies using tonal signals in adults have not been reported.

The binaural interaction components in the ABR and AMLR are currently being used for a variety of clinical purposes. For example, Delb, Strauss, Hohenberg, and Plinkert (2003) used the BIC to identify auditory processing deficits in children, whereas Leigh-Paffenroth, Roup, and Noe (2011) used the AMLR-BIC to evaluate adults with equal sensitivity but different auditory function between ears. He, Brown, and Abbas (2010) used the BIC to determine in a cochlear implant user the amount of current spread in the cochleae of both ears. Gordon, Valero, and Papsin (2007) used the binaural interaction component of the ABR to measure brainstem plasticity in young children who were fit with binaural cochlear implants with variable time delays between the fittings. These uses suggest the need for a better understanding of the BIC, including the responses to stimulus frequency.

Very few studies have investigated the effects of signal frequency on the BIC of either the ABR or the AMLR. In the ABR, the BIC has been recorded with tonal signals across the frequency range from 1000 to 6000 Hz in adults (Fowler, 1989; Fowler &Broadard, 1988; Fowler &Leonards, 1985; Ito, Hoke, Pantev, &Lutkenhoner, 1988) and with both 500 and 4000 Hz in infants (Cone-Wesson et al., 1997). In the AMLR, the BIC has been recorded with tonal stimuli from 500 Hz in adults (Zhou &Durrant, 2003) and with 500 and 4000 Hz in infants (Cone-Wesson et al., 1997). Cone-Wesson et al. (1997) concluded that the ABR-BIC and MLR-BIC elicited with tonal signals were immature in infants, but comparable data from adults have not been reported for verification of that supposition. Accordingly, the purpose of this investigation was to determine the relative frequency representation of binaural function in the brainstem and auditory cortex of adults and to compare the results with the frequency representation described in the previously reported responses in infants (Cone-Wesson et al., 1997).

Method

This study was approved by the University ofWisconsin- Madison Institutional Review Board, and all participants signed an informed consent prior to being enrolled in the study. Twenty young adult women (Mage = 24 years, range = 21-34 years) served as participants; only women were recruited for homogeneity across participants. Each participant passed a hearing screening at 20 dB HL for octave frequencies ranging from 250 Hz to 8000

Hz, a tympanometric screening using the norms of Margolis and Heller (1987), and acoustic reflexes present at both 500 and 4000 Hz at 90 dB HL. Participants were required to have no current or chronic history of middle-ear pathology. All testing was completed in a sound-treated booth that met standard requirements for ambient noise (American National Standards Institute, 1991). Stimuli were calibrated prior to testing each test day.We used a Quest Model 1800 Precision Impulse Integrating sound level meter (SLM) with a Model OB-300 1/3-1/1 octave filter set to calibrate 500-Hz stimuli and 4000-Hz stimuli to maintain a 100-dB peak sound pressure level (peSPL). The SLM was calibrated with an acoustic calibrator (Quest CA-22), then the insert earphones were calibrated.

ABR and AMLR were recorded simultaneously (Biologic EP, Version 5.64, Model 92). Stimuli were 500- and 4000-Hz tone bursts with a 2-ms rise-fall time and a 1-ms plateau in a Blackman-shaped envelope. Stimuli were presented at 100 dB peSPL and at a rate of 11.1 stimuli per second. Gold-cup surface electrodes (Grass, E5GH) were placed at the vertex (Cz) for the positive input, at the nape of the neck for the negative input, and on the forehead for ground. Impedance was <3,000 ohms and was balanced within 1,000 ohms across electrodes. Physiological filters were set to pass activity from 10 to 3000 Hz (3-dB down points) with a slope of 12 dB per octave.

Each participant was tested in one 3-hr session, with breaks as necessary. Participants reclined in a comfortable chair for the evoked potential tests and were asked to remain awake and quiet for the tests. Participant wakefulness was verified after each bank of 6000 sweeps by the examiner talking to the participant. The beginning stimulus frequency (500 or 4000 Hz) was alternated for successive participants. Two thousand stimuli were presented in each condition in the sequence of monaural right, monaural left, and binaural stimuli, and each sequence was repeated twice, for a total of 6,000 sweeps each.

Data were manipulated and analyzed offline. The leftand right monaural responses were added to yield the L+R response, after which the BIN was subtracted from the L+R response to yield the BIC. The BIC was considered present only if an independent observer and the second author both agreed on its presence. Latency and peak-totrough amplitudes were measured for waveforms in each of the replications in all stimulus conditions. For the ABR waveform conditions, wave V and Peak A were measured; for theAMLRconditions,wave Pa andBIC-Pawere measured. Amplitude ratios for peak A/V(L+R) and BIC-Pa/Pa(L+R) were calculated to control for amplitude differences in the parent waveforms.

For the statistical analysis, the latency and amplitude data used were the average of the three replications. Latencies, amplitudes, and amplitude ratios were analyzed with repeatedmeasures analysis of variance (RMANOVA; SPSS Version 20) with significance defined at the $p < .05$ level.

Results

The parent waveforms and the BIC were evident in all participants for both ABR and AMLR conditions and for both stimulus frequencies. A typical response to the 4000-Hz stimulus from a participant is shown in Figure 1, with the components of interest labeled. For the ABR, the peak Awas present in 100% of the BICs for both stimulus frequencies, whereas the peak B was present in 50% of BICs for 500 Hz and 60% of BICs for 4000 Hz. Hence, for the remainder of the study, we considered only peak A for the ABR-BIC.

Tables 1 and 2 contain the mean data (and SDs) for the latencies and amplitudes, respectively, for the wave components of interest (L+R, BIN, peak A, and BIC-Pa). As expected, the mean latencies for wave Vand Pa were longer in all conditions (monaural, binaural, L+R, and BIC) for 500 Hz than for 4000 Hz. The mean amplitudes of the wave V and Pa in the L+R and BIN conditions were greater for the 500-Hz stimuli than for the 4000-Hz stimuli. Overall, the largest BIC was the BIC-Pa elicited with the 500-Hz stimuli.

The latencies of waves V and Pa were analyzed with a three-way RM ANOVA to determine the significance of differences between class of potential (ABR V and AMLR Pa), stimulus frequency (500 Hz and 4000 Hz), and waveform condition (L+R and BIN); results are shown in Table 3. The only significant differences were between frequencies and between the wave classes. As expected, latencies were longer for waves elicited by 500 Hz

than 4000 Hz, and latencies were longer for the AMLR Pa than for the ABR wave V. The difference in latency between the L+R and BIN potentials was not significant, and interaction was significant.

The amplitudes of the L+R and BIN conditions for waves V and Pa for both frequencies are shown in Figure 2. Overall, the amplitudes for ABR wave V (leftpanel) are smaller than the amplitudes for AMLR wave Pa (right panel). The AMLR wave Pa in the L+R condition had the largest amplitude overall, and the difference in amplitudes between L+R and BIN conditions was large for the wave Pa in comparison with the wave V. The results were analyzed with a three-way RM ANOVA to determine the significance of differences between class of potential (ABR and AMLR), stimulus frequency (500 and 4000 Hz), and waveform condition (L+R and BIN); the results are shown in Table 4. The only significant main effect was waveform condition, with the L+R being larger than the BIN condition. Main effects for the stimulus frequency (responses to 500 Hz were greater than responses to 4000 Hz) and class of potential (Pa amplitude was larger than Vamplitude) were of marginal significance as a result of interactions between variables. The interactions are depicted in Figure 3. Panel A illustrates the interaction between frequency and wave condition. Whereas the 500-Hz frequency produced larger amplitudes than did the 4000-Hz frequency, the amplitude difference between the two frequencies was larger for the L+R condition (0.22 mV) than for the BIN condition (0.03 mV). Panel B illustrates the interaction between wave class and frequency, which indicates that amplitudes for Vand Pa are more similar (and larger) for 500 Hz than for 4000 Hz, as a result of reduced amplitudes for wave Vat 4000 Hz. Panel C illustrates the interaction between wave class and wave condition and indicates that in the L+R condition, wave Pa is much larger than wave V, whereas amplitudes for the two waves are similar for the BIN condition. In summary, the largest amplitudes were recorded for the Pa wave in the L+R condition with the 500-Hz stimulus frequency.

The BIC amplitudes and amplitude ratios (given in Table 2) are shown in Figure 4. In the figure, Panel A shows the absolute values for the BIC amplitudes, and Panel B shows the amplitude ratios. For both panels, the gray bars represent responses to 500 Hz, and the black bars represent responses to 4000 Hz. The pattern of responses is similar for the amplitudes and amplitude ratios. The amplitudes and the amplitude ratios were significantly correlated in three out of four cases (peak A at both frequencies and BIC-Pa at 4000 Hz), so the RM ANOVAwas confined to the amplitude ratios. The RM ANOVA indicated a significant difference for the class of potential, $F(1, 19) = 8.035$, $p = .011$, with the ratio for BIC-Pa being larger than the ratio for ABR peak A. There was a trend ($p = .074$) only for the interaction between wave class and stimulus frequency, suggesting that the BIC-Pa ratio was larger for 500 Hz than for 4000 Hz, whereas the ABR peak A ratio was not different for the two stimulus frequencies.

Discussion

The purpose of this study was to increase understanding of the way that binaural information is coded in the brainstem and auditory cortex as indicated by the BIC from the simultaneously recorded ABR and AMLR. All of the participants had the parent waveforms and the BIC for all stimulus and wave conditions. The AMLR provided BIC waveforms that were larger than those of the ABR, and the 500-Hz tone bursts provided larger BIC waveforms than did the 4000-Hz tone bursts. The results, therefore, are consistent with proportionately more resources being devoted to binaural function in the cortex than in the lower brainstem and suggest that more binaural resources are devoted to the lower frequencies than to the higher frequencies. The following discussion is divided into sections on class of potential, stimulus frequency, and comparison of adult and infant responses (Cone-Wesson et al., 1997) elicited by 500-Hz and 4000-Hz tone bursts.

Gender of the participants is not identified in most BIC studies in adults (e.g., Dobie &Norton, 1980; Ito et al., 1988; McPherson et al., 1989; McPherson &Starr, 1993) or infants (Cone-Wesson et al., 1997). When gender is identified in the participants (e.g., Zhou &Durrant, 2003), it is not analyzed. Participants in the Kelly-Ballweber and Dobie (1984) study were all men. Gender effects are not expected because the binaural interaction data are expressed as ratios, which normalize any amplitude differences across participants. Hence, to date, there are no demonstrated effects of gender on the BIC, and gender is not discussed below.

ABR Versus AMLR

Although no studies in adults can be directly compared with the findings in the present study, some observations can be made about the trends across studies. No previous studies evaluated adults with frequency-specific stimuli in both the ABR and AMLR paradigms, so comparisons can be made only with studies using click stimuli. McPherson and Starr (1993) recorded the ABR and AMLR individually with clicks at levels roughly equivalent to those used in the present study. McPherson et al. (1989) recorded ABR and AMLR simultaneously using click stimuli in adults and infants, but stimulus levels were substantially lower than those in the present study. Although both studies (McPherson &Starr, 1993; McPherson et al., 1989) reported wave V amplitudes from peak to trough, both studies reported amplitudes of P(30) and N(40) individually. In contrast, the present study measured both wave Vand wave Pa from peak to trough. Consequently, the comparisons to the studies by McPherson and colleagues use the summation of their P30 and N40 to approximate the Pa amplitude for comparisons to the present study.

In the present study, the tone bursts of 500 Hz and 4000 Hz produced wave V(L+R) amplitudes of 1.10 and 0.7 mV for 500 and 4000 Hz, respectively. For the same potential evoked with clicks, McPherson and Starr (1993) reported an amplitude of 0.984 mV, and McPherson et al. (1989) reported an amplitude of 0.960 mV-values that are between those elicited by the tone bursts. Dobie and Norton (1980) reported a wave V(L+R) amplitude of approximately 1.05 mV with a BIC peak A amplitude of about 0.40 mVor a ratio of about 0.25 (estimated from their graphs). The BIC peak A amplitude ratios for the present study were about 0.33 for both tone bursts, which were larger than any of the ratios reported for click stimuli (16%-25%).

The previous studies plus the present study are consistent in reporting that the AMLR BIC is substantially larger than the ABR BIC as a result of the L+R condition producing much larger amplitudes than the BIN condition (Dobie &Norton, 1980; McPherson &Starr, 1993; McPherson et al., 1989). The amplitudes of Pa(L+R) for clicks are approximately 1.73 mV and 1.55 mV (McPherson et al., 1989 and McPherson &Starr, 1993, respectively) and 1.55 mV and 1.44 mV for 500 Hz and 4000 Hz, respectively, in the present study; the values are quite consistent, considering differences in stimuli and recording parameters across studies. The BIC amplitude ratios in the present study also compare generally with the click-evoked AMLR BIC amplitude ratios that are near 50% in the two studies by McPherson and colleagues. The amplitude ratios in the present study were similar for 4000 Hz at 0.56 and somewhat larger for 500 Hz at 0.71. Thus, the 4000-Hz response is more like the click response than the 500-Hz response.

The data discussed above suggest substantial differences between the representations of binaural function in the cortex compared to the brainstem. The larger amplitudes for the BIC-Pa compared with the ABR peak A, as well as the larger BIC-Pa amplitude ratios compared with the ABR peak A ratios, confirm that the binaural responses command more neural resources in the cortex than in the brainstem, as previously reported with click stimuli (Dobie &Norton, 1980; McPherson &Starr, 1993; McPherson et al., 1989); the present findings extend those concepts to tonal signals and further suggest that low-frequency sounds command more neural resources than do higher frequency sounds. Further details concerning the frequency specificity of these responses are discussed below.

Frequency Differences

The BIC occurred in all participants for both stimulus frequencies in the present study as it does in most studies that use tonal signals presented at stimulus levels that are at least moderate. One unique finding in the present study was that at 4000 Hz, the BIN wave V was larger than the L+R wave V. The amplitude difference was 0.05 mV, with the BIN amplitude being the larger of the two. This difference was in the presence of SDs that were 0.25 mV for the BIN condition and 0.28 mV for the L+R condition, suggesting that this finding is probably a statistical anomaly resulting from the variability of the amplitude measurements. The computer additions and subtractions of the actual waveforms produce point-by-point comparisons between the involved responses. In contrast, the amplitudes of the individual components are measured from peak to following trough and do not

always coincide preciselywith the computerderived waveform differences.

Fowler and Leonards (1985) compared ABR BIC amplitudes resulting from stimulation with 1000 and 4000 Hz in participants with normal hearing and in those with highfrequency sensorineural hearing loss. Of interest here are the stimulus conditions at 100 dB peSPL for the listeners with normal hearing. Wave V(L+R) amplitudes were 0.86 mV for 1000 Hz and 0.78 mV for 4000 Hz, and the amplitude of peak A was larger at 1000 Hz than at 4000 Hz. At 4000 Hz, the amplitudes for the V(L+R) were slightly larger in the present study than those in Fowler and Leonards, but that is likely a result of the lower high-pass physiological filter used in the present study. Fowler (1989) evaluated binaural interaction with 1000-Hz and 3000-Hz tone pips and reported that wave V(L+R) amplitudes were larger for the lower frequency with amplitudes of 1.35 mV for 1000 Hz and 0.98 mV for 3000 Hz; ABR BIC peak A and amplitude ratios [A/V(L+R)] also were larger for the lower frequency. Despite the differences in recording and stimulus parameters, these three studies present the same pattern; the amplitudes of wave V(L+R) and peak A as well as the amplitude ratio associated with the lower frequencies consistently had the larger amplitude.

In a study with tonal signals with different parameters, Ito et al. (1988) recorded the binaural difference potential of the ABR to tonal signals from 1000 Hz to 6000 Hz and reported that the response amplitudes declined as the stimulus frequency increased. The present study extended the lowest stimulus frequency used for the ABR BIC to 500 Hz, thus confirming that the lower frequency stimuli provide larger BICs. These data are consistent with the supposition that the lower frequencies excite a wider frequency spread on the basilar membrane, which recruits a larger neural pool and results in the larger response amplitudes for the lower frequencies as compared with higher stimulus frequencies.

In the Ito et al. (1988) study, the click produced the largest amplitude overall, but the lowest frequency usedwas 1000 Hz, and 500 Hz is expected to produce a larger amplitude than did 1000 Hz. Ito et al. attributed the large amplitude of the click-evoked response to elicitation of the greatest amount of synchrony, but the stimulation of neural units over a wide frequency range also must have been a factor. Although higher frequency stimuli may elicit more synchronous responses than lower-frequency signals, the higher-frequency signals do not generally produce the larger BIC amplitudes. However, the signal parameters in the Ito et al. study were quite different from those in the two Fowler studies and, therefore, may explain at least some of the differences.

One other study (Zhou &Durrant, 2003) evaluated the binaural interaction in the AMLR with tone bursts in adults. The one signal parameter that was comparable to the stimuli in the present study was 500 Hz, which produced a binaural Pa amplitude ratio of 48%. That ratio is smaller than the ratio recorded as 0.71 in the present study, but the different signal parameters may account for some of the differences between studies.

Finally, some studies have investigated the frequencyspecific contributions to the ABR-BIC but with clicks in noise or filtered clicks as stimuli. DeVries and Decker (1988) used clicks in high-pass masking noise filtered at 500- 4000 Hz to evaluate the effects of frequency on the binaural interaction component of the ABR. Although they reported that the 500-Hz high-pass masked click produced the largest response, no statistically different results were found in their data. Polyakov and Pratt (1999) used filtered clicks but recorded responses using a three-channel Lissajous trajectory (3-CLT) to localize different components of the binaural interaction. They reported that some components were preferentially sensitive to high frequencies but also responded to lower frequencies. Additional studies using the same stimuli and similar recording parameters across participants will be necessary to confirm the effects of stimulus frequency on the binaural AMLR.

Adults Versus Infants

Maturation of binaural responses has been studied in several studies with click stimuli but in only one study with frequency-specific stimuli in neonates (see Cone-Wesson et al., 1997, for a complete description of those authors' methods). That study used some similar stimulus and recording configurations as in the present study to elicit the BIC simultaneously from ABR and theAMLRin neonates of both genders. Neonates were considered normal if their weight was 2800-4000 g, Apgar scores were >8 at 1 min and 5 min, the neonates had no risk

factors for hearing loss, and a normal ABR was obtained at 65 dB peSPL (Cone-Wesson et al.). A comparison between the results from 500- and 4000-Hz stimuli (rise-fall of 2 ms, plateau of 1 ms) in the two studies provides an opportunity to evaluate maturational changes in the BIC. Cone-Wesson et al. (1997) reported that not all infants had the BIC; the ABR peak A was present in 82% at 500 Hz and 74% at 4000 Hz, whereas the AMLR BIC-Pa was present in 62%at 500 Hz and 52%at 4000 Hz. In contrast, all of the adult participants in the present study had the BIC for both the ABR and AMLR, confirming that absence of binaural responses in some infants is consistent with immaturity. The tone pips were presented at 105 peSPL for the infants and 100 peSPL for the adults; these different levels suggest that the infants received approximately 10 dB higherlevel stimuli than did the adults. Based on Stapells, Picton, and Smith (1982), 100 pSPL is approximately 94 dB peSPL because of the different methods of calibration. Higher signal levels are consistently associated with more BICs, so the number of responses in the infants is a conservative estimate of the maturational stage of the binaural system at term birth.

Characteristics of the infants' and adults' responses also can be evaluated for signs of maturity. The mean amplitudes of the parent and BIC waveforms for the infants who had responses (Cone-Wesson et al., 1997) and the adults in the present study are depicted in Panel A of Figure 5, and the amplitude ratios are shown in Panel B. In the figure, the top panels include data from the 500-Hz stimuli, and the bottom panels include data from the 4000-Hz stimuli, whereas the leftpanels show data from the ABR and the right panels show data from the AMLR. The amplitudes of the parent waveforms are larger for the adults (black bars) than for the infants (gray bars) for both stimuli and both waveform classes. For the BIC, the ABR peak A is also similar for both frequencies for the infants and adults, but the BIC-Pa is substantially larger in the adults for both frequencies. Finally, the BIC amplitude ratios present a different pattern from that of the parent waveforms; the amplitude ratios are larger for the infants in all conditions except the Pa-BIC at 4000 Hz, for which it is equal for adults and infants. This overall pattern of the BIC suggests immaturity of the parent waveforms as well as for the BIC in the AMLR as described by Cone- Wesson et al. These differences confirm the immaturity of infants' binaural function, especially for the high brainstem/ cortical levels where the AMLR is generated. Longitudinal studies will be necessary to categorize the development of the waveforms throughout maturation.

The binaural system as described by the present study is only one of many ways in which the binaural system can be, and has been, studied electrophysiologically. A range of different stimuli and different response classes is necessary to provide a fuller analysis of binaural interaction. The short tone bursts with fairly rapid onset times were chosen for the present study because they were appropriate stimuli for both ABR and AMLR, and they facilitated an analysis of the processing that one type of signal undergoes between the brainstem and cortical levels. Similarly, clicks have been used for this purpose and can also be used for ALLRs if the goal is to evaluate widespread areas of the cortex, although different stimulation rates and physiological filters would be needed (e.g., McPherson et al., 1989). Other uses of short-duration stimuli (clicks and tone bursts) for binaural function include explorations of time and intensity trading (e.g., Furst, Eyal, &Korczn, 1990; Zhou &Durrant, 2003). The binaural masking level difference (MLD) is another type of binaural interaction; electrophysiological measures of the MLD require longer stimulus durations for the maximum benefit; an example can be found in Fowler and Mikami (1992), in which auditory late latency potentials were elicited with 500-Hz tone bursts with 5-ms riseand- fall times and a 25-ms plateau to record MLDs up to 14 dB. Even longer tonal signals (2000 ms) have been used to measure binaural beats in the cortical event-related potentials (Pratt et al., 2009). These studies exemplify only a few of the wide variety of stimuli and responses that researchers use to evaluate the binaural system.

Abstract: Individuals with low acceptable noise levels (ANLs) accept more noise than individuals with high ANLs. To determine whether ANL is influenced more by afferent or efferent cortical responsiveness, the authors measured differences in temporal masking responses between individuals with low versus high ANLs. If listeners with low ANLs have masked thresholds similar to those of listeners with high ANLs, low ANLs may be due to reduced afferent responsiveness affecting both the masker and signal. If, however, listeners with low ANLs have masked thresholds better than that of listeners with high ANLs, there may be a physiological basis for improved selective attention via stronger efferent inhibition of the "unwanted" sound. Participants were 19 listeners with normal hearing between the ages of 19 and 35. Ten listeners had low ANLs and 9 had high ANLs. All participants were compared using tone-in-noise simultaneous, forward, and backward masking tasks. Results revealed no observed differences in masked thresholds between the low versus high ANL group. The low ANL group, however, required significantly more threshold runs to achieve criterion necessary for threshold determinations. Findings suggest that low ANLs are associated with reduced afferent cortical responsiveness and, possibly, decreased sustained attention.

Purpose: Individuals with low acceptable noise levels (ANLs) accept more noise than individuals with high ANLs. To determine whether ANL is influenced more by afferent or efferent cortical responsiveness, the authors measured differences in temporal masking responses between individuals with low versus high ANLs. If listeners with low ANLs have masked thresholds similar to those of listeners with high ANLs, low ANLs may be due to reduced afferent responsiveness affecting both the masker and signal. If, however, listeners with low ANLs have masked thresholds better than that of listeners with high ANLs, there may be a physiological basis for improved selective attention via stronger efferent inhibition of the "unwanted" sound.
Method: Participants were 19 listeners with normal hearing between the ages of 19 and 35. Ten listeners had low ANLs and 9 had high ANLs. All participants were compared using tone-in-noise simultaneous, forward, and backward masking tasks.
Results: Results revealed no observed differences in masked thresholds between the low versus high ANL group. The low ANL group, however, required significantly more threshold runs to achieve criterion necessary for threshold determinations.
Conclusions: Findings suggest that low ANLs are associated with reduced afferent cortical responsiveness and, possibly, decreased sustained attention.
Key Words: acceptable noise level, masking, cortical responsiveness

Nabelek, Tucker, and Letowski (1991) developed a procedure for quantifying a listener's reaction to background noise while listening to speech. This measure has become known as the acceptable noise level (ANL; Nabelek, Tampas, &Burchfield, 2004), which is defined as the difference between the most comfortable level (MCL) for running speech and the maximum background noise level (BNL) that a listener is willing to accept or "put up with" while listening to running speech discourse. The higher the ANL, the less background noise the individual is willing to accept. Studies conducted by Nabelek and colleagues (Nabelek, Freyaldenhoven, Tampas, &Burchfield, 2006; Nabelek et al., 1991, 2004) showed that asANL increases, the chances of success in hearing aid use are reduced. A common finding with ANL is a large intersubject variability. This variability is not accounted for by intrasubject characteristics such as gender (Rogers, Harkrider, Burchfield, &Nabelek, 2003), age (Nabelek et al., 2006), audiometric thresholds (Nabelek et al., 1991), middle ear characteristics, or activity levels of the medial olivocochlear bundle system (Harkrider &Smith, 2005). Nor is ANL related to a speech performancein- noise task (Crowley &Nabelek, 1996; Nabelek et al., 2004, 2006). Although authors of earlier studies suggested that ANL is not dependent on type of noise (see, e.g., Nabelek et al., 1991), authors of subsequent studies (see, e.g., Johnson, Ricketts, &Hornsby, 2009) found that increasing the bandwidth of white noise increases the ANL, assuming that speech and noise are measured using the same frequency weighting. Studies by Harkrider and Tampas (2006) and Tampas and Harkrider (2006) compared physiological responses from individuals with low versus high ANLs using transientevoked otoacoustic emissions, auditory brainstem responses, middle latency responses (MLRs), and long latency responses (LLRs). The two groups showed physiological differences in responses from higher level regions of the central nervous system. Specifically, individuals with low ANLs had smaller peak-to-peak amplitudes of certain MLR and LLR waveforms versus individuals with high ANLs. Thus, differences in these responses between the two groups suggest that more central regions of the auditory system (at least, those beyond the superior olivary complex) may mediate acceptance of background noise. Tampas and Harkrider (2006) also found that listeners with low versus high ANLs generally have less change in component amplitude with changes in stimulus intensity, suggesting that listeners with low ANLs have either reduced afferent cortical responsiveness to sound or stronger efferent inhibition to unwanted background noise than do listeners with high ANLs. Stronger inhibition may be a factor in selective attention for auditory signals (see, e.g., Dempster, 1992; Harnishfeger &Bjorkland, 1994). A behavioral masking study may shed light on which of these alternatives is more correct. If, indeed, listeners with low ANLs

have less afferent cortical auditory responsiveness, then their masked thresholds should be similar to that of listeners with high ANLs, in that the reduced afferent responsiveness would affect both masker and signal. If, however, listeners with low ANLs have a physiological basis for improved selective attention, then their masked thresholds should be better than those of listeners with high ANLs because the stronger efferent inhibition of "unwanted" sound should allow the listeners with low ANLs to more easily detect the tonal target.

In the past, researchers suggested that simultaneous masking is peripheral in origin, whereas backward masking is mediated by higher order regions (Deatherage &Evans, 1969; Duifhuis, 1973; Elliott, 1962; Soderquist, Carstens, &Frank, 1981). The regions of the auditory system that mediate forward masking are still not known. The notion that forward masking is mediated more peripherally in the auditory system generally is accepted but not proven. Prolonged vibration or "ringing" effects of the basilar membrane may account for the persistent masking effect on the signal after offset of the masker (Moore, 1997). Other reasons might be that short-term adaptation in the central auditory system decreases its responsiveness just after the end of the masker-or, perhaps, the persisting neural-evoked activity is still there, somewhere along the auditory pathway higher than the auditory nerve, and it masks the signal (Moore, 1997). Backward masking thresholds are subject to greater individual differences for children and adults with normal hearing (Buss, Hall, Grose, &Dev, 1999) than those that are typically seen for simultaneous and forward masking. Likewise, large individual variability is seen when measuring ANL in an otherwise homologous population (see, e.g., Harkrider &Smith, 2005; Nabelek et al., 2006; Rogers et al., 2003). Because both ANL and backward masking appear to be mediated centrally and have high intersubject variability, different backward masking thresholds might be found between listeners with low versus high ANLs, whereas performance in forward and simultaneous masking may be similar between the two groups. To date, no known studies in the literature have investigated masking in relation to ANL.

In the current study, we used three psychophysical masking paradigms to investigate possible differences in responsiveness between listeners with low ANLs and listeners with high ANLs. We hypothesized that if afferent cortical responsiveness explained differences in ANLs, then performance between the two groups should be similar for all masking conditions. If efferent cortical responsiveness contributed to differences in ANLs, masking thresholds in all three conditions should be better for listeners with low versus high ANLs due to the benefit of selective attention from a stronger inhibitory system.

Method

Participants

Participants were volunteers with normal hearing (ages 19- 35 years) who were recruited from the student population at the University of Tennessee in Knoxville. Potential participants were excluded if they had hearing thresholds less than 15 dB HL (American National Standards Institute [ANSI] S3.6-2010) at octave frequencies between 250 Hz and 8000 Hz, bilaterally. Participants also were disqualified if, during an initial interview, they reported a history of ear infections, neurological disease, language impairment, attention-deficit/hyperactivity disorder, drug or alcohol dependency, mental illness, or any other central nervous system disorder. Of the initial 44 participants who volunteered, we included in the study only those participants who fell within low (≤ 6 dB) or high (≥ 16 dB) ANL groups. We did this in an attempt to obtain more distinct group differences (Harkrider &Tampas, 2006; Tampas &Harkrider, 2006).We excluded participants with mid ANLs (n = 20). Thus, the final study group consisted of 19 participants, 10 of whom had low ANLs and nine of whom had high ANLs. (Two additional participants with low ANLs and three additional participants with high ANLs were unable to complete the project.) The University of Tennessee Institutional Review Board approved all experimental protocols.

Procedure

ANL behavioral assessment. Participants completed the tests in an audiometric (Acoustic Systems) test booth that meets ANSI standards for permissible noise levels (ANSI S3. 1-1999/2008). The speech stimulus was a recorded monologue of a male speaker (Arizona Travelogue, Cosmos Inc.), and the competing background

noise was multitalker babble from the revised Speech Perception in Noise (SPIN) test (Bilger, Neutzel, Rabinowitz, &Rzeczkowski, 1984). We presented the target and noise via a compact disc with two tracks routed through an audiometer (GSI-61 clinical audiometer) that meets ANSI standards for audiometers (ANSI S3.6-2010), and then we routed both signals through the right insert earphone (Etymotic, ER-3A). In this manner, we measured ANL monaurally in the right ear, consistent with the presentation of temporal masking signals in the current study. To establish the MCL and BNL, we used a method of adjustment and bracketing that was based on procedures adapted from previous ANL studies (Franklin, Thelin, Nabelek, &Burchfield, 2006; Harkrider &Tampas, 2006; Nabelek et al., 1991; Tampas &Harkrider, 2006). We chose initial starting levels for finding MCL and BNL, and step sizes, to maximize efficiency of data collection while maintaining repeatability and reliability.

During each assessment, the participant signaled the examiner outside the booth to adjust stimuli levels. Instructions were presented verbally and in written mode to participants. Initially, the MCL for the participant was obtained. The level of the male speech was presented first at an attenuator setting of 40 dB HL on the audiometer and then was increased in 10-dB steps until prompted by the participant to reduce the level. Thereafter, the level of the male speech was adjusted up and down, first in steps of 5 dB and then in steps of 2 dB, until the MCL was established.

To establish the BNL, the level of the multispeech babble noise was adjusted, this time while the running speech was fixed at the MCL. The male discourse and noise were presented simultaneously. The participant was instructed to signal the examiner upon reaching the maximum level of background noise that he or she was willing to put up with while listening to the male discourse. The level of the multispeech babble was presented initially at 30 dB below the speech presentation level (at MCL) and then was increased in 10-dB steps until the participant indicated that it was above the level he or she could put up with for a long time while following the male discourse. Then, the level of the babble was adjusted down in 10-dB steps until the participant indicated that it was below the level that he or she could put up with for a long time while following the discourse. Finally, the level of the background noise was adjusted again up and down in 5-dB steps, and then in 2-dB steps, to the most noise that the participant was willing to put up with while still following the discourse and not becoming tense or tired. This level was marked as the participant's BNL.

We measured ANL by computing the difference between the MCL and BNL. Two complete ANL measurements (or trials) were conducted; thus, for each participant, we obtained two MCLs and two BNLs. For each participant, if the ANLs obtained from the two trials varied by more than 4 dB, the participant was reinstructed, and a third trial was obtained (Freyaldenhoven, Plyler, Thelin, &Hedrick, 2007; Freyaldenhoven, Thelin, Plyler, Nabelek, &Burchfield, 2005). The closest two ANL measures were averaged for each participant. A third trial was necessary for only two of 19 participants, emphasizing the previously documented test / retest reliability of ANL.

Masking procedures. Participants sat in a sound-treated booth (Industrial Acoustics Corporation [IAC]) that meets ANSI standards (ANSI S3.1-1999) for permissible noise levels. Each participant was asked to detect a brief tone in a background noise (masker) presented to his or her right ear (see, e.g., Hartley, Wright, Hogan, &Moore, 2000). All stimuli were generated digitally. The signal and the noise were passed through a separate computer-controlled attenuator and then were routed to the right-side headphone (Sennheiser HD 580). The stimuli were gated with a cosine-squared function that produces 10-ms rise and fall times (see, e.g., Wright et al., 1997). The tonal signal was a 1000-Hz tone with an overall duration of 20 ms as measured from the onset to the offset. The masker was a narrow-band noise that extended from 600 Hz to 1400 Hz, and its overall level was 70 dB SPL as measured in a 6-cc coupler (Bruel &Kjaer DB0161), with an all-in-all duration of 300 ms (see, e.g., Wright et al., 1997). There were three different masking conditions:

1. Simultaneous masking: The signal was temporally centered in the masker (Buss et al., 1999).
2. Backward masking: The 20-ms tone onset was initiated at 0, 20, or 40 ms before the onset of the 300-ms

noise (Wright et al., 1997).
3. Forward masking: The tone onset was initiated at 0, 20, 40, or 80 ms after the offset of the masker (Wright et al., 1997).
Temporal patterns of stimuli presentations are shown in Figure 1. The effect of forward masking for a broadband noise masker decays as the time interval between masker and signal is increased. There is little masking effect seen beyond a 200-ms signal delay (Jesteadt, Bacon, &Lehman, 1982). Soderquist et al. (1981) found no masking effects beyond 125 ms but did find relatively large masked threshold shifts when the signal-masker interval was less than 40 ms. In another study, Nishimura, Nakagawa, Sakaguchi, Hosoi, and Tonoike (2003) investigated forward masking at the level of the auditory-evoked N1m component. Results showed that the N1m amplitude was smallest for a signal delay of 40 ms. At shorter signal delays, the N1m amplitude actually increased, suggesting an integration of signal and masker neural activity. For signal delays greater than 40 ms, the N1m amplitude increased with increasing signal delay, as would be expected if masking occurred because of neural adaptation caused by the masker (Nishimura et al., 2003). Therefore, to include in the current study forward masking conditions that might be attributable to either temporal integration or neural adaptation mechanisms, we chose masker-signal delays at, above, and below 40 ms. These delays were varied at four conditions: 0 ms, 20 ms, 40 ms, and 80 ms.
Conversely, the signal-masker interval that elevates signal thresholds in backward masking seldom surpasses 25 ms (Fastl, 1976) but can reach 100 ms (Elliott, 1962). Nevertheless, in Soderquist et al. (1981), the greatest backward masking effects were found between 0 ms and -40 ms relative to the onset of the masker. For this reason, we chose signal-masker intervals of 0 ms, 20ms, and 40 ms in the backward masking paradigm. The noise level remained constant during threshold evaluation for all paradigms.
Data reported byWright et al. (1997) andMarler, Champlin, and Gillam (2001) show improvements in backward masking thresholds over the course of their study sessions, potentially complicating data interpretation. In an attempt to avoid a learning effect in the participants of the current study, we kept practice sessions and experimental sessions brief. Further, we compared performance within each participant across experimental sessions to document possible learning effects.
We obtained tone detection thresholds with a twoalternative, forced-choice (2AFC) procedure with a two-down, one-up tracking paradigm to estimate the 71% correct point on the psychometric function (Levitt, 1971). Data collection occurred online through the use of a commercially available software program (Psycho-Sig, Tucker-Davis Technologies). Because all listeners had normal hearing, the starting level for the adaptive procedure was fixed at 80 dB. Initial step size was 5 dB, with a final step size of 2 dB after two reversals. Runs were terminated after eight reversals, with threshold computation performed on the last six reversal points. The run standard deviation is the standard deviation across the last six reversal points. The listener was asked to listen for the signal tone and to indicate in which time interval the signal tone was presented.
During the task, the listener sat facing a computer screen. The two time intervals in which the signal tone might be present were represented on a computer screen as two blinking squares, one square for each time interval. One interval contained the noise only, and the other interval contained the tone. When the first interval of masker or masker + signal was presented, the left-most square would change shape as if pressed. Likewise, when the second interval of masker or masker + signal was presented, the right-most square would change shape as if pressed. After the second interval presentation, the participant used a mouse click to select which square (or interval) contained the signal tone. Because of the nature of the 2AFC task, the participant has to select an interval to proceed with the test, regardless of whether he or she hears the tone.
Response analysis. An individual threshold (or run) with a standard deviation of greater than 4.25 dB was discarded. These particular runs were discarded because wide tracking excursions within a run probably indicate that the participant lost concentration or, by chance, tracked too low, with many trials expended with signal level below threshold. In either case, we felt that such runs should be rejected as unreliable in the current

study. Three to six runs with individual standard deviations less than 4.25 were collected for each of the eight masking conditions. The value of 4.25 was selected on the basis of previous masking data using the paradigm of the current study, in which the largest standard deviations for a given run were 4.0 dB to 4.3 dB (Bacon &Grantham, 1989; Grantham &Bacon, 1991). For every condition, the average of the three to six runs was the masked threshold for that condition. Standard deviations were then computed across the runs used in threshold determination. All thresholds (runs) for each participant were obtained over two to three sessions; we did this to avoid participant fatigue. The order of obtaining thresholds (runs) for each condition was determined randomly. This method follows that of previous investigators examining masking (Bacon &Grantham, 1989; Grantham &Bacon, 1991).

Results

Masking Thresholds and Standard Deviations

The group means of all thresholds (in dB SPL) for each of the eight masking conditions are shown in Table 1. Average standard deviations across runs used to compute thresholds are shown in Table 2. A one-factor analysis of variance (ANOVA) was carried out on simultaneousmasking thresholds, where the factor was group (low vs. high ANL). The ANOVA revealed no significant difference between the two ANL groups, $F(1, 17) = 0.002$, $p = .966$.

We compared backward masking thresholds using a twofactor, repeated measures ANOVA. The factors were group and gap duration (repeated measures on 0 ms vs. 20 ms vs. 40 ms). Mauchly's test of sphericity was significant for the factor gap duration; therefore, degrees of freedom were corrected and reported using Greenhouse-Geisser estimates of sphericity for gap duration. (If the results of Mauchly's test of sphericity were significant in subsequent statistical analyses, the remaining statistical analyses were reported using Greenhouse-Geisser corrections.) The analysis showed a predictable significant main effect for gap duration, $F(1.451, 24.670) = 29.144$, $p < .001$, such that masking thresholds decreased as the duration of the gap increased. The analysis revealed neither a significant group difference, $F(1, 17) = 0.089$, $p = .769$, nor a significant Group ×Gap Duration interaction, $F(1.451, 24.670) = 0.220$, $p = .761$.

Forward masking thresholds also were compared through the use of a two-factor, repeated measures ANOVA. The factors were group and gap duration (repeated measures on 0 ms vs. 20 ms vs. 40 ms vs. 80 ms). Results showed a predictable main effect of gap duration, $F(2.011, 34.195) = 136.163$, $p < .001$, such that masking thresholds decreased as the duration of the gap increased. The ANOVA revealed neither a significant group difference, $F(1, 17) = 0.026$, $p = .874$, nor a significant Group ×Gap Duration interaction, $F(2.011, 34.195) = 0.628$, $p = .541$.

Discarded Runs

Mean discarded runs by masking condition for each of the two ANL groups are shown in Table 3. A one-factor ANOVA was carried out on the number of discarded runs collapsed across all masking conditions and durations, where the factor was group (low vs. high ANL). The ANOVA revealed a significant difference between the two ANL groups, $F(1, 17) = 8.241$, $p = .011$, such that individuals with low ANLs had more discarded runs than did individuals with high ANLs. To determine which masking conditions contributed to this significant group difference, three additional one-factor ANOVAs were computed for each masking condition. The factor was group (low vs. high ANL). The analyses revealed no difference between groups for the simultaneous masking condition, $F(1, 17) = 1.286$, $p = .273$; a difference between groups for the backward masking condition, $F(1, 17) = 5.614$, $p = .030$; and a difference between groups for the forward masking condition, $F(1, 17) = 5.752$, $p = .028$.

Discussion

Several reports have suggested that central structures of the auditory system contribute to the mediation of ANL (see, e.g., Harkrider &Tampas, 2006; Horne, 2010; Tampas &Harkrider, 2006). In a similar way, backward masking effects are likely mediated by structures above the brainstem, whereas it has been suggested that

simultaneous and forward masking effects are mediated more peripherally (see, e.g., Deatherage &Evans, 1969; Duifhuis, 1973; Elliott, 1962). Because listeners with low ANLs have smaller changes in central auditory evoked potential amplitudes with changes in stimulus intensity (Tampas &Harkrider, 2006), the authors hypothesized that these individuals have either less responsive cortical neurons or greater central efferent inhibition than do individuals with high ANLs. If listeners with low ANLs have reduced cortical auditory responsiveness, then their masked thresholds should be similar to those of listeners with high ANLs because the reduced responsiveness would be to both masker and signal. However, if listeners with low ANLs had a biological basis for stronger inhibition (or selective attention), then their masked thresholds should have been better across all masking conditions than those of listeners with high ANLs. Results of the current study indicated similar masking thresholds across the groups, supporting the hypothesis that listeners with low ANLs have reduced cortical auditory responsiveness.

There was a significant difference between the two ANL groups, and this difference manifested itself through the number of discarded runs that were omitted due to high standard deviations. The low ANL group required the completion of significantly more runs to obtain the targeted standard deviation per run (4.25 dB) for both forward and backward masking conditions. Temporal masking tasks require a steady effort that is related to attentional factors (Helzer, Champlin, &Gillam, 1996). Therefore, the number of trials needed to reach the criterion might be influenced by the listeners' focused or sustained attention to the masking task. The low ANL listeners in the current study may have been less attentive to the masking stimuli and, possibly, less conservative in their responses.

The differences in discarded runs between the low and high ANL groups may be related to central nervous system activation. For example, results from auditory evoked potential studies have shown that listeners with low ANLs have central auditory regions that are (a) less responsive to changes in auditory stimulation and/or (b) have greater cortical inhibition than those of listeners with high ANLs (Harkrider &Tampas, 2006; Tampas &Harkrider, 2006). Results from the current study suggest that listeners with low ANLs subjectively may be able to tolerate more noise not because of stronger cortical inhibition (i.e., they do not necessarily have better selective attention) but, rather, because of weaker afferent cortical activation. Less responsiveness may translate into less focused or less sustained attention-rather than better selective attention-by listeners with low ANLs.

In addition, results from the current study relate to the results of studies in which the authors found minimal correlation between ANL and speech performance-in-noise tasks (Crowley &Nabelek, 1996; Nabelek et al., 2004, 2006), suggesting that acceptance of background noise and perception of speech in noise are related but not identical phenomena. Results from the current study suggest that ANL may not merely reflect peripheral signal-to-noise ratio measures as those that might be measured from outputs of internal filters. Instead, ANL appears to be a more centrally mediated phenomenon.

In conclusion, the lack of significant differences in masking thresholds between the two ANL groups for any masking condition suggests that differences in ANLs are not due to temporal processing or selective attention abilities. Instead, differences in acceptance of background noise while listening to speech may be due-at least, in part-to overall afferent cortical responsiveness. These results are based on behavioral (not physiological) data, so there may have been variables other than cortical responsiveness that could have influenced the results. For example, the significantly larger number of discarded runs for the low versus high ANL group may suggest that, relative to individuals with high ANLs, reduced afferent cortical responsiveness is associated with reduced focused attention or reduced sustained attention in individuals with low ANLs. Because no explicit measures of attention were tested in the current study, additional research is needed to clarify how ANL measures and components of attention are related.

Abstract: The purpose of this work was to develop and evaluate a calibrated version of the Ling-6 sounds for evaluation of aided detection thresholds. Stimuli were recorded, and data from calibration values in dB HL were developed. Aided performance was characterized in adults and children. Stimuli were recorded, prepared, and transferred to a CD for testing. Initial testing was completed on 29 normally hearing young adults to determine typical responses in dB SPL and reliability. Corrections to dB HL were determined for each stimulus. Twenty-seven adults and 5 children with hearing losses were tested. Average normal sound field thresholds were 1 dB HL. Aided thresholds for adults varied with unaided hearing level and were better for low-frequency sounds. Adults and children performed differently, possibly because of greater hearing aid gain for children. Stimulus preparation and shaping resulted in a recorded, calibrated set of Ling-6 stimuli that provide flat normal thresholds in hearing level for normally hearing listeners. Typical performance ranges may vary with hearing level and prescription. More data are required to fully characterize this trend in the pediatric population.

Purpose: The purpose of this work was to develop and evaluate a calibrated version of the Ling-6 sounds for evaluation of aided detection thresholds. Stimuli were recorded, and data from calibration values in dB HL were developed. Aided performance was characterized in adults and children.
Method: Stimuli were recorded, prepared, and transferred to a CD for testing. Initial testing was completed on 29 normally hearing young adults to determine typical responses in dB SPL and reliability. Corrections to dB HL were determined for each stimulus. Twenty-seven adults and 5 children with hearing losses were tested.
Results: Average normal sound field thresholds were 1 dB HL. Aided thresholds for adults varied with unaided hearing level and were better for low-frequency sounds. Adults and children performed differently, possibly because of greater hearing aid gain for children.
Conclusions: Stimulus preparation and shaping resulted in a recorded, calibrated set of Ling-6 stimuli that provide flat normal thresholds in hearing level for normally hearing listeners. Typical performance ranges may vary with hearing level and prescription. More data are required to fully characterize this trend in the pediatric population.

Key Words: amplification or hearing aids, children, adults, efficacy, outcomes

Intervention for permanent childhood hearing impairment typically follows four stages: screening, assessment, intervention, and outcome evaluation (American Academy of Audiology, 2003). For families choosing an oral-aural approach, intervention may include the fitting and use of hearing aids and/or cochlear implants as well as intervention for communication development. Therapists, including speechlanguage pathologists and auditory-verbal therapists, may be trained to screen for appropriate aided hearing prior to therapy sessions using the Ling-5 or Ling-6 sound test (Ling, 1989). The Ling-6 sounds include /m/, /u/, /a/, /i/, /X/, and /s/ and were chosen to span the range of speech frequencies typically occupied by running speech. In addition, the vowels /u/, /a/, and /i/ span the vowel quadrangle in the English language (Stevens, 1998). Preceding a therapy session, these sounds may be delivered using the therapist's voice, and the child's ability to detect and/or recognize each sound may be monitored. This rapid check is done to confirm that the hearing devices are functional and to assist the therapist in estimating the child's aided speech sound detection, identification, and discrimination abilities.

Because the Ling sounds are commonly assessed by therapists who are clinical partners in providing intervention services, some audiologists also adopt the Ling-6 sound test in a variety of ways. Hearing aid fitting protocols for adults and children may include the use of Ling-6 sounds at the device validation stage as a rapid measure of speech sound reception (Cox, Mendel, &Bell, 2011; Smiley, Martin, &Lance, 2004). Anecdotal reports include either administration of the sounds as is done by therapists or measurement of aided detection thresholds by presenting each sound with the clinician's voice via a clinical audiometer. Users of this test have noted the need to define whether the test is used to evaluate speech sound detection, discrimination, or identification and the relative advantages and disadvantages of each type of evaluation (Smiley et al., 2004). The work described in this article was focused on the use of Ling-6 sounds for the evaluation of speech sound detection. A detection task was chosen to facilitate future work with infants, who may be able to perform an aided audiogram as an outcome measure. The present work focuses mainly on adults in this early evaluation of this procedure.

Aided Detection Thresholds in Device Evaluation

Aided detection thresholds have been used for various purposes in hearing aid fitting.Within historical comparative methods for hearing aid fitting, both unaided and aided sound field thresholds were measured at many frequencies and used to calculate the functional gain of the hearing aid under consideration (Skinner, 1998). Functional gain was used when shaping the hearing aid frequency response in lieu of electroacoustic hearing aid analysis. In modern practice, this time-consuming process for verification and shaping of hearing aid gain has largely been replaced by faster and more accurate electroacoustic procedures. In previous studies, authors have proposed a variety of factors that may limit the validity of functional gain measures, including head and body movement during testing, hearing aid noise floor, hearing aid response differences between speech and nonspeech test signals, off-frequency listening for participants with steeply sloping hearing losses, and interactions of compression attack and release times with stimulus onsets and/or offsets (Hawkins, 2004; Kuk, Keenan, Lau, &Ludvigsen, 2004; Scollie &Seewald, 2002; Stelmachowicz, Hoover, Lewis, &Brennan, 2002). These factors have led some authors to suggest that electroacoustic hearing aid analysis is a more appropriate tool for estimating hearing aid gain and frequency response, compared with functional gain measures (Hawkins, 2004; Stelmachowicz et al., 2002).

cochlear implants, or bone-anchored hearing devices are sometimes obtained, even for a small number of stimuli, as an outcome measure to determine the lowest level of sound that may be detectable (Bass-Ringdahl, 2010; Davidson et al., 2009; Hodgetts, Hakansson, Hagler, &Soli, 2010; Tharpe, Fino-Szumski, &Bess, 2004). This procedure is done to evaluate the fitting, and although it does not include computation of functional gain for shaping purposes, it may include comparison of unaided versus aided conditions as a benefit measure. This validation procedure has been deemed as having higher clinical utility when the hearing device cannot be assessed electroacoustically (e.g., bone-conducted or bone-anchored devices) or when information about whether a listener can detect aided sound is of clinical interest (Stelmachowicz et al., 2002). With either of these goals, interpretation of aided thresholds is difficult without knowledge of a "target" or "appropriate" aided threshold, which may vary with hearing threshold levels and/or hearing technology. Very little recent data exist, particularly regarding aided thresholds for speech stimuli with contemporary hearing devices. Typical performance with modern devices may be of interest for several reasons. First, contemporary devices may have increased wearable gain for low-level stimuli as a result of more effective feedback controls, increased processing bandwidth, and more frequency use of multichannel wide dynamic range compression, compared with early-era digital and linear analog devices. These changes may result in lower levels of sound being detected by the user. Second, modern prescriptive and fitting methods better account for the use of wide dynamic range compression and the different listening needs and preferences of adults and children (Keidser, Dillon, Flax, Ching, &Brewer, 2011; Scollie et al., 2005). For these reasons, characterization of typical

performance in users of modern hearing technologies, fitted using modern techniques, was of interest in this study.

Rationale for Current Study

In this article, we describe a set of stimuli and procedures for performing aided threshold evaluations, in dB HL, using prerecorded Ling-6 stimuli. The rationale for this study is fourfold. First, the Ling-6 stimuli span the speech frequencies by using only six test stimuli. Therefore, the use of Ling-6, rather than warbled tones or other narrowband stimuli, could probe a broad frequency range while requiring fewer measurements. Second, the Ling-6 stimuli are well understood by clinicians and have high face validity. Third, the Ling-6 stimuli are natural speech tokens and therefore support aided threshold evaluation with modern signal processing. Recent hearing aid efficacy studies have used aided Ling-6 thresholds as an outcome measure, with results indicating that this measurement is sensitive to frequency-specific differences between aided conditions (Glista et al., 2009; Wolfe et al., 2010, 2011). Finally, we speculated that clinical interpretation of detection thresholds for Ling-6 sounds would be supported if calibrated in the hearing level (HL) scale. Considering these arguments, the purpose of this study was to develop Ling-6 stimuli with calibration in dB HL and to characterize typical aided outcomes for these stimuli by using testing procedures that are feasible for use with commonly available clinical equipment.

Method

Pilot Stimuli and Procedure

The Ling-6 stimuli were spoken by a woman who was a native speaker of English. She was seated within a doublewalled IAC sound booth. Recordings were made with a pedestal microphone (AKG Acoustics) located approximately 30 cm from the talker's mouth and routed to a pre-amplifier (USBPre). Digitization was performed via sound card, and recordings were made with commercially available software (Spectraplus). The talker was instructed to produce each sound in isolation, with neutral vocal effort. The following orthographic representation of the Ling sounds was provided for her reference: "AH as in operate, EE as in beep, OO as in shoe, SH as in shoe, SS as in stop, MM as in man." Ten repetitions of each sound were recorded, and the token with the most neutral pitch contour and best sound quality was chosen and uploaded into editing software (Goldwave). Stimuli were excised from the original recordings and edited to preserve the naturally produced token as much as possible and to be approximately 1 s in duration (range: 0.89-1.25 s) and peak intensity (0.5 full-scale deflection). These edits required the shortening of only /X/ and /s/, which had naturally produced durations of about 1.5 s each. When shortening was required, the stimulus was clipped at a zero crossing, and an offset ramp in volume was imposed to prevent offset transients. The spectral characteristics of these stimuli are presented in Figure 1. The edited stimuli were embedded in a computer-assisted threshold search procedure, which used a two-alternative forced-choice adaptive tracking paradigm to assess sound field detection thresholds. Response choices were "heard it" and "didn't hear it." Thresholds on the adaptive track were estimated from the last four reversals, using a 5 dB step size and a 50% criterion. Sound field levels from this task were quantified in dB SPL, by calculating the reference calibration levels minus the attenuation levels at threshold.

Pilot Evaluation

Ten young adults (3 men, 7 women, ages 21-35 years) were recruited to participate in a pilot evaluation of these stimuli. Participants reported no hearing difficulties, had normal otoacoustic emissions, and had pure-tone audiometric thresholds in both ears at normal levels (at or below 15 dB HL) from 250 through 8000 Hz. Binaural sound field thresholds were measured twice for each participant. All measures were made in a double-walled sound booth. Noise levels within the booth met standards for maximum permissible ambient noise levels (MPANL) for the ears not covered condition, for testing at frequencies between 125 and 8000 Hz (Frank, 2000). Mean sound pressure levels at threshold ranged from 0 to 22 dB SPL across the Ling-6 sounds and formed a U-shaped curve across stimulus peak frequency similar to that of a minimum audible field curve. For example, the highest sound pressure levels at threshold were observed for the lowest frequency and highest frequency

stimuli (/m/ and /s/, respectively). These values were taken as interim reference equivalent threshold sound pressure levels (RETSPL; American National Standards Institute [ANSI], 2004) for these specific stimuli.

Clinical Stimuli and Procedure

On the basis of the pilot results, the levels of the stimuli were adjusted to approximate the pilot RETSPL per stimulus. As recommended by ANSI, a calibration tone was constructed that exceeded the peak levels of the highest level stimulus (ANSI, 2004). As well, a calibration noise was constructed that produced a target output level in the sound field, assuming that the field was calibrated for binaural listening at zero degrees azimuth. The intended purpose of the tone and noise was to permit replicable use of the CD, by providing the researchers with a tool to set the audiometer's input sensitivity for the CD on repeated uses, and to verify the sound field levels produced over time. Calibrated levels were monitored daily during data collection for this study, with the requirement of meeting calibration targets within 2 dB each day that data were collected.

The resulting calibration and Ling-6(HL) stimuli were placed on a CD for use with manual audiometric procedures via a clinical audiometer (GSI-61). The VU meter was adjusted to place the calibration tone at zero prior to use of the CD, and pilot testing with normally hearing listeners was attempted. However, recall that a 22 dB range existed among the stimuli in the pilot evaluation. Those that had been most attenuated within the resulting stimulus set could not be heard by the tester during manual audiometry. Therefore, a revised version was constructed that used minimal digital attenuation of stimuli, anticipating that a manual correction would be applied to convert the results to HL (see Appendix A). Specifically, the stimuli were adjusted by up to 5 dB, with values chosen to support the use of 5 dB step sizes in both manual audiometry and in correction factors. The RETSPL for each stimulus was compared with the RETSPL of /a/, which had the lowest detection thresholds. Stimulus levels were adjusted relative to this to the nearest 5 dB step. Any changes greater than 5 dB were saved for manual correction. For example, the /u/ stimulus had a pilot RETSPL greater than that of the /a/ stimulus and so was increased by 3 dB. In contrast, the /m/ stimulus had a pilot RETSPL that was 17 dB greater than that of the /a/ stimulus and so was adjusted by 2 dB, assuming that a correction factor would be applied for the remaining 15 dB. The root-mean-square digital levels of the resulting stimuli were within 12 dB of one another, which more readily allowed the tester to hear the stimulus during testing, compared with the first version.

Normative data for this version of the CD were gathered from a second group of normally hearing listeners, and clinical results were gathered on a group of adults with hearing impairment, as described below. Tracks on the CD included a calibration tone, a calibration noise, and six tracks of stimuli. Each stimulus track included 64 repetitions of the Ling-6 sound for use with conventional audiometric procedures. In the text below, this CD is referred to as the Ling-6(HL) test.

Participants

Twenty-nine normally hearing young adults (mean age: 24 years; age range: 20-28 years; 25 women and 4 men) participated in an evaluation of the Ling-6(HL) test. These participants reported no history of hearing problems and passed a hearing screening from 250 to 8000 Hz at 25 dB HL. Otoscopic examinations revealed no blockage of the external ear. Twenty-seven adults with hearing loss also participated (mean age: 68 years; age range: 21-87 years; 11 women, 16 men). Seventeen of these participants were regular users of hearing aids, all binaurally. Their hearing losses ranged from mild to moderate by pure-tone average (mean three-frequency pure-tone average [PTA]: 43 dB HL; PTA range: 31-60 dB HL). Audiometric slopes ranged from zero to 90 dB between 4000 and 500 Hz (mean slope: 40 dB). Figure 2 shows the mean and individual audiometric thresholds for the better ear of each participant. In addition, to illustrate the application of this test, we evaluated five children from a typical clinical caseload. These children ranged in age from 6 to 9 years and had moderate hearing losses in the better ear. One child had conductive hearing loss, and the remainder had sensorineural losses.

Hearing Aid Fitting Procedure

Adult participants were fitted with a pair of laboratory hearing aids, which were commercially available devices with multichannel wide dynamic range compression, no frequency lowering processing, and omnidirectional microphones. Venting was incorporated into earmolds on a case-by case-basis and ranged from 1 mm to 3.5 mm. All other features of the devices, such as digital noise reduction, were disabled during testing. Feedback cancellation was required and enabled for five participants. Hearing aids were fitted using the fifth version of the Desired Sensation Level (DSL 5) method (Bagatto et al., 2005), which includes a prescription for use with adults (Scollie et al., 2005), and verified using probe microphone measures of the Real Ear Aided Response (REAR) for running speech at 55 and 65 dB SPL and for 85 dB warbled tones, using a commercially available system (Audioscan Verifit VF-1). For the group as a whole, 81% of participants were fitted to within 5 dB of target at 4000 Hz in both ears. Five participants with steeply sloping hearing loss could not be fitted to within 5 dB of target, although most were fitted closely to target through 2000 Hz. This fitting profile is similar to those in a recently published study of clinically typical and beneficial fittings using the DSL 5 adult prescription (Polonenko et al., 2010).

The children in this study were tested while wearing their own hearing aids of varying makes and models. The hearing aids had been fitted using the DSL 5 method (Bagatto et al., 2005). These hearing aids were prescribed and verified by an experienced pediatric audiologist using simulated REAR measures, individually corrected using measured Real Ear to Coupler Differences. The fit to targets of each hearing aid was within 5 dB of targets for running speech at 65 dB SPL and for warble tones at 90 dB SPL.

Data Collection in dB HL

Each participant's detection thresholds were measured for each Ling-6(HL) stimulus with manual administration using 5 dB step sizes and a two-down, one-up bracketing procedure. Testing was completed within a double-walled audiometric booth (IAC) with a loudspeaker, placed at zero degrees azimuth, connected to an audiometer (GSI-61). Participants were seated in a height-adjustable chair with their heads located in a marked point within the booth. Each test was completed twice within one session. Participants with normal hearing were tested with ears uncovered, and they listened binaurally. Participants with hearing loss were tested in the binaurally aided condition. Testing was completed within the same booth used for pilot data, which exceeded the standards for MPANL for ears uncovered.

Results

Normative Values and Test-Retest Reliability

All twenty-nine normally hearing listeners completed the protocol, including the evaluation of test-retest reliability. Threshold values for each Ling-6(HL) stimulus were averaged across the two tests, and a final correction factor was determined that resulted in average thresholds near 0 dB HL across frequencies. Across stimuli and participants, corrected threshold values ranged from -12.5 to 15 dB HL. Table 1 displays the average corrected threshold per sound, as well as the 95% confidence interval for normal detection of each sound. In general, the upper limit of normal performance for this test was approximately 15 dB HL. Mean test-retest for this participant group was 2 dB across participants and stimuli and was one audiometric step size (5 dB) or less for all but two of 174 thresholds (99%) measured in the normally hearing group. The upper limit of the 95% confidence interval for test-retest difference was between 5 and 8 dB across stimuli (Table 1). Correlations between test and retest ranged from 0.71 to 0.90 in this group.

Characterization of Aided Results in Adults

As with the normally hearing listeners, adults with hearing loss completed two administrations of the Ling-6(HL) detection test but performed the test while wearing hearing aids. Test and retest aided thresholds were within 5 dB for all listeners and all stimuli. Test-retest correlations ranged from 0.89 to 0.97 across stimuli. Therefore, aided thresholds were averaged across test and retest for all participants in this group. The aided thresholds ranged from 0 to 47.5 dB HL. This range includes scores that fall outside the normal range of test performance, indicating that not all listeners had normal speech sound-detection abilities even though they were binaurally

aided. It is possible that the outcome of normalized versus nonnormalized aided detection thresholds might interact with the degree of unaided hearing loss, as normalization for all degrees of hearing loss is not a goal of the adult-based prescriptive method used in these fittings (Scollie et al., 2005). To determine the relation between unaided hearing levels and aided detection thresholds, we computed correlation coefficients between the magnitude of the unaided hearing loss and the aided Ling-6(HL) results. These correlations were computed both for each audiometric frequency in the better ear and also for the overall hearing loss, computed as the better ear four-frequency pure-tone average (BE4FPTA) of thresholds at 500, 1000, 2000, and 4000 Hz. The results, shown in Table 2, indicate several considerations that are important for interpreting test results. First, consider the predictive ability of the unaided pure-tone thresholds. In general, unaided thresholds are good predictors of performance when they are similar in frequency to the peak energy regions of the stimulus. For example, unaided thresholds at 250 and 500 Hz were the best two predictors of aided thresholds for /m/, /u/, and /i/. As shown in Figure 1, these stimuli had their highest spectral peaks in the low-frequency region. This trend occurred also for most stimuli, with /a/ correlated with low-and mid-frequency thresholds, and /s/ correlated with unaided hearing across frequencies, to 4000 Hz. However, both /X/ and /s/were also correlated with unaided hearing thresholds in the lower frequencies. This correlation might indicate that audibility of low-frequency energy in these fricatives contributed to detection, although the design of this study precludes direct evaluation of this. It may be the case that further sampling, a greater range of audiograms, or experiments with filtered stimuli would be necessary to determine the frequencyimportance function of these stimuli for detection. Another possible predictor of aided performance is the magnitude of hearing loss, represented here as the BE4FPTA. This predictor was also significantly, although more modestly, correlated with aided detection thresholds. Taken together with the frequency-specific results, this indicates that the magnitude and configuration of hearing loss are associated with aided detection thresholds with Ling-6(HL) stimuli. This result means that participants with better unaided hearing detected the Ling-6(HL) stimuli at lower levels than did listeners with poorer hearing, even in the aided condition. This relationship is depicted in Figure 3, which displays aided Ling-6(HL) thresholds for each stimulus and listener, against the listeners' unaided hearing levels by pure-tone average. Each Ling-6(HL) stimulus is indicated by a specific symbol in Figure 3, grouped with vowels and nasal stimuli on the leftpanel and fricatives on the right. Data from both listeners with normal hearing and listeners with aided hearing loss are shown. All data are plotted against the BE4FPTA, to facilitate visual comparison between nasals, vowels, and fricatives on a common scale. Confidence intervals for typical aided detection results are indicated for each group of stimuli (vowels and nasals versus fricatives) by solid lines. The derivation of these intervals is discussed further below.

For vowel and nasal stimuli, listeners with normal hearing had detection thresholds of about 15 dB HL or better. Adults with aided hearing loss performed both within or poorer than the normal range, depending on their degree of hearing loss. Adults with unaided thresholds of 30 dB HL or better had aided thresholds within the normal range and not significantly correlated with the BE4FPTA. Mean aided Ling-6(HL) thresholds for this group were 9.3 dB HL (SD = 5.12 dB). For listeners with hearing loss between 30 and 50 dB HL, average aided detection thresholds were poorer (M= 17.7 dB HL; SD = 7.2 dB) but not significantly correlated with varying unaided hearing levels. Above 50 dB HL, results indicated a significant trend for increasing aided nasal and vowel thresholds as hearing thresholds increased ($n = 40$, $r = .495$, $p = .001$). These participants detected nasal and vowel sounds at 25 dB HL on average (SD = 8.6 dB).

Detection thresholds for fricatives are shown as closed symbols in Figure 3. Results for the fricatives were somewhat poorer, with aided thresholds not within the normal hearing range but rather within a range of 15 to 50 dB HL. Aided detection thresholds were significantly associated with unaided better ear pure-tone averages for the fricatives ($n = 54$, $r = .522$, $p < .001$).

Correlations between better ear pure-tone average and each group of stimuli (nasals and vowels versus fricatives) were used to generate confidence intervals (solid lines in Figure 3). The BE4FPTAwas selected as

the predictor rather than frequency-specific thresholds, as it permits comparison of performance across stimuli using a single criterion. Accordingly, confidence intervals were computed as the mean aided Ling-6(HL) threshold in the range from 0 to 30 dB HL BE4fPTA, with a two standard deviation interval around the mean. Above 50 dB HL BE4fPTA, the range was computed as a linear regression of aided Ling-6(HL) thresholds versus unaided thresholds, with regressed values surrounded by two standard deviations. Between 30 and 50 dB HL BE4fPTA, the two previously described confidence intervals are joined by straight lines. This implies that aided threshold levels for the Ling-6(HL) stimuli may be related to the hearing loss of the listener, perhaps as a result of device-fitting differences for lesser versus greater hearing losses. This issue will be addressed in more detail below.

Illustrative Cases With Children

Aided detection of the Ling-6 sounds may assist pediatric audiologists in determining whether a child has auditory access to speech across a wide range of frequencies. In children, two other factors may also impact typical results. First, infants and younger children typically respond to a slightly suprathreshold minimum response level (MRL) rather than responding at true threshold for audiometric tasks (Sabo, Paradise, Kurs-Lasky, &Smith, 2003; Widen et al., 2000). Responses for young children on a Ling-6(HL) detection task may also be at MRL rather than at true threshold. Recall that average normal thresholds for the Ling-6(HL) stimuli were between 0 and 15 dB HL. The upper limit of the normative adult range may therefore differ from the upper limit of normal hearing commonly used to interpret visually reinforced audiometry (VRA) results for younger children (i.e., 25 dB HL; Sabo et al., 2003). Second, children who use hearing aids may be provided with more gain than would be given for an adult with the same audiogram, using recent versions of some prescriptive formulae (Keidser et al, 2011; Scollie et al., 2005). This may allow children who use hearing aids to detect the Ling-6(HL) sounds at a lower level than was typical of the adult data presented in this study. To illustrate this second issue, we examined five pediatric cases in the course of normal clinical practice. As described above, these children were between the ages of six and nine years of age and wore hearing aids fitted to within 5 dB of the DSL 5 child target. Aided Ling-6(HL) thresholds were measured with good withintest reliability by using standard audiometric procedures, as judged by the clinician. The results from these children are shown alongside adult data in Figure 3. It is evident that these children had lower (better) aided thresholds than were measured for adults with similar degrees of hearing loss. Two factors may have contributed. First, the DSL 5 child prescription requires more gain than does the DSL 5 adult prescription. Therefore, the children wore devices with approximately 7 dB more gain for a 50 dB HL audiogram (Scollie et al., 2005). Second, three of the children used frequency compression hearing aids. One of these children had aided detection thresholds for /s/ and /X/ at 15 dB HL or better despite having unaided high-frequency thresholds in the severe range. This result for DSL 5 child fittings using frequency compression is consistent with results in published studies using a non-HL version of this Ling-6 test (Glista et al., 2009). Finally, the best-performing child had a flat moderate conductive hearing loss and aided thresholds well below 0 dB HL for all six stimuli. Further data would be required to determine whether this type of result is consistently associated with aided conductive hearing loss.

Discussion

This article presents a set of prerecorded Ling-6 stimuli, implemented on a CD, with clinical calibration procedures and normative data for use as a speech sound detection test in the sound field. Data on a sample of adults with hearing loss and illustrative cases of children with hearing loss provide preliminary characterization of test performance as an aided outcome measure. These results indicate that typical performance on this test varies with the unaided hearing loss and the prescription type. These factors will be discussed in more detail below.

Test-retest reliability for both normally hearing listeners and for listeners with hearing aids was within one audiometric step size for the majority of test cases in this study. This is consistent with reports of aided sound field thresholds using warbled tone stimuli to assess listeners with nonlinear hearing aids (Kuk et al., 2004) and

either similar to or slightly better than well-recognized reports in which aided thresholds were measured on adults and children with hearing loss (Hawkins, Montgomery, Prosek, &Walden, 1987; Humes &Kirn, 1990; Stuart, Durieux-Smith, &Stenstrom, 1990). In general, the procedures used across these studies were similar, and they are similar to those used in the current study. Two differences warrant discussion. First, the data presented by Kuk and colleagues (2004) were gathered within a sound booth that had been modified to include absorptive fabric panels to further reduce standing waves, and the listener's head was resting against a headrest to minimize head and body movement. To represent clinical conditions during testing, we did not incorporate these procedures into the current study. Second, the stimuli used in the present study are broader in bandwidth than the warbled tones used in the previous studies cited above. The broader bandwidth could reduce the effects of standing waves, which may be an advantage for test-retest reliability. The broader bandwidth also prevents this test from being highly frequency specific and prevents their use in characterizing aided hearing on a frequency-by-frequency basis, compared with testing with narrowband stimuli, such as pure tones. Test performance was characterized in a sample of adults with hearing loss, all of whom were fitted with a modern, commercially available hearing aid with multichannel wide dynamic range compression. The hearing aids were fitted using the DSL 5 method and verified in the ear canal of each participant using a probe tube microphone system. With these fittings, adults with better ear pure-tone averages of up to 30 dB HL achieved aided thresholds in the upper half of the normal range for the low-frequency stimuli in this test. For losses above this or for high-frequency stimuli, aided detection was not within the normal range and was related to the degree of hearing loss, characterized either by frequency-specific thresholds or by the overall magnitude of the hearing loss. This is consistent with the prescriptive goals and calculations of the DSL 5 method, which prescribes aided listening levels for adults that are significantly lower than those prescribed for children (Scollie et al., 2005). Clinically, this means that expected aided performance on this test ranges between about 0 and 50 dB HL, depending on the frequency content of the stimulus and the unaided hearing loss and gain of the hearing aid. Adult performance was compared with illustrative cases of five older children who were tested while wearing their own hearing aids. These devices had also been fitted using the DSL 5 method, which prescribes more gain for children with early childhood hearing losses than is prescribed for adults with acquired losses. Specifically, DSL 5 uses a modified normalization algorithm for children, in which gain targets attempt to normalize audibility if the input is above the compression threshold (Scollie et al., 2005). Accordingly, the children had lower aided thresholds than did the adults, and their scores fell largely within the normal range. The current data set on children serves to illustrate that adults and children may have different test performance if they are fitted with a prescription that uses age-dependent gain. In addition, some of these children used frequency-lowering hearing aids, which may have been a factor in their aided thresholds for the higher-frequency stimuli. The current data set on children is not adequate to fully characterize typical children's responses across hearing loss or technology type, and further work on this is recommended.

Considering the results presented here, it appears that the Ling-6(HL) stimuli support reliable estimation of sound field speech sound detection thresholds in several participant groups, using clinically available equipment such as a CD player and commercial audiometer. This test may support reliable test results across time and tester, compared with a live voice administration during aided threshold testing, although this was not studied directly in this research. Limitations of either the test or our current knowledge of the test include the following: First, the performance of this test is not yet fully characterized on children who use hearing aids, particularly children in the developmental range for testing with VRA. The use of a VRA-based protocol for assessing aided Ling sound detection in infants and toddlers has been suggested in previous reports (Winter &Kuk, 1998). However, the test-retest, normative, and clinically typical test performance for VRA is unique (Hawkins, 2004; Sabo et al., 2003; Widen et al., 2000). We would therefore expect that a VRA procedure with the Ling-6(HL) stimuli would require specific evaluation to determine normative properties, clinical patterns of outcome, and appropriate application with test azimuths other than those used in this study. Second, the relative advantages

or disadvantages of using Ling-6 sounds rather than warbled tones or narrow bands of noise for aided detection threshold evaluation is not addressed by the current study. Third, recalling that all data used here were measured using zero degrees azimuth, normative test properties with other azimuths have not yet been assessed. Fourth, the variation and importance of frequency content across the Ling-6 stimuli is not fully exploited by a detection task such as is presented here. Consider the spectral properties of the four low-frequency stimuli (/m/, /u/, /a/, /i/) in this set (Figure 1) against the typical test performance in hearing aid users (Figure 3). These stimuli have similar peak spectral levels yet different spectral properties. This detection test would likely have been driven by the primary spectral peaks between 200 and 500 Hz, where the stimuli have similar peak levels. This is consistent with the results, in which aided detection thresholds across these stimuli occupy essentially the same range in the aided adult listeners. Therefore, is testing all six stimuli necessary? This may be an important clinical consideration regarding test time. It also highlights the different test considerations when Ling-6 stimuli are used either for a detecion task or for a more complex task such as speech sound discrimination or identification (Smiley et al., 2004). Whereas the former may be related to peak levels, the latter may be affected by other properties of the stimuli, including formant structure. Literature on vowel recognition indicates that audibility, frequency, frequency change, and frequency ratios of formats likely affect vowel identification (Hillenbrand, Getty, Clark, &Wheeler, 1995; Monahan &Idsardi, 2010). The present work addresses the use of the Ling-6 stimuli for detection purposes in decibel hearing level but does not address the suprathreshold tasks of discrimination or identification. Finally, the results presented here were gathered using the DSL 5 fitting method and nonlinear hearing aids. It is possible that typical performance with other fitting methods or technologies may vary from the results shown here.

The clinical use of the Ling-6(HL) detection test requires use of the calibration tone to adjust the input sensitivity of the audiometer to the correct level and verification that the target calibration levels are achieved using a sound level meter. These requirements are typical of CD-based tasks that are routed to audiometers. If they are, use of the correction factors shown in Appendix A may be appropriate. As with other tests that are used across a variety of sound fields (e.g., Cox &Gray, 2001), site-specific verification of the corrections on a sample of otologically normal listeners is recommended either to ensure that the corrections are appropriate or to develop site-specific corrections. Although correction factors are perhaps inconvenient, the advent of computer-assisted audiometers may facilitate automation of such corrections in the future.

Appropriate clinical applications of this version of the Ling-6 stimuli may include measurement of aided speech sound detection thresholds as a measure of hearing device outcome. This application is not a replacement for electroacoustic hearing aid analysis, specifically real ear measurement, as a method for ensuring that the gain and frequency shaping of a hearing aid is appropriate for a particular hearing aid user. Real ear measurement is more precise and provides more detailed and robust information about hearing aid response across frequency and level, compared with measures of either functional gain or aided thresholds. Therefore, aided Ling-6(HL) detection thresholds use may have greatest utility (a) for devices that cannot be evaluated with real ear measurements (e.g., cochlear implants, bone-anchored or -conducted hearing devices, middle ear implants); or (b) when confirmation that the listener is receiving the aided signal is of clinical interest (e.g., for children, when measurement of aided thresholds is done to validate that aided speech sounds are detected by the child). This latter use is best considered an outcome measure as opposed to a verification measure. Either of these applications may assist in postfitting evaluations or provide information for further discussion with patients, caregivers, teachers, or speech-language pathologists. The score sheet presented in Appendix B displays the normal range measured in this study, based on the 95% confidence intervals measured for each group of listeners, and allows plotting of unaided and/or aided detection thresholds on a case-by-case basis.

Acknowledgments

The development of this test was financially supported by the Natural Sciences and Engineering Research Council/Canadian Institutes of Health Research Collaborative Health Research Program, the Canadian

Language and Literacy Research Network Summer Studentship program, and the Hearing Foundation of Canada. Ongoing support for clinical evaluation of the test in children is provided by the American Academy of Audiology New Investigator Award (2012-2013) and in partnership with the Network of Pediatric Audiologists of Canada and Sheila Moodie. The Ontario Research Foundation's support of the National Centre for Audiology Translational Research Unit supported this project through access to participants. The authors thank Richard Seewald for comments on an earlier version of this article and KellyMattingly for assistance with figure preparation.

An audio CD is available with the stimuli used in this study, along with support documents that provide instructions and scoring sheets. Contact Phonak (www.phonak.com) for more information.

An Evidence-Based Systematic Review of Directional Microphones and Digital Noise Reduction Hearing Aids in School-Age Children With Hearing Loss

Author: McCreery, Ryan W; Venediktov, Rebecca A; Coleman, Jaumeiko J; Leech, Hillary M.

Publication info: American Journal of Audiology (Online) 21.2 (Dec 2012): 295-312.
ProQuest document link

Abstract: The purpose of this evidence-based systematic review was to evaluate the efficacy of digital noise reduction and directional microphones for outcome measures of audibility, speech recognition, speech and language, and self- or parent-report in pediatric hearing aid users. The authors searched 26 databases for experimental studies published after 1980 addressing one or more clinical questions and meeting all inclusion criteria. The authors evaluated studies for methodological quality and reported or calculated p values and effect sizes when possible. A systematic search of the literature resulted in the inclusion of 4 digital noise reduction and 7 directional microphone studies (in 9 journal articles) that addressed speech recognition, speech and language, and/or selfor parent-report outcomes. No digital noise reduction or directional microphone studies addressed audibility outcomes. On the basis of a moderate level of evidence, digital noise reduction was not found to improve or degrade speech understanding. Additional research is needed before conclusions can be drawn regarding the impact of digital noise reduction on important speech, language, hearing, and satisfaction outcomes. Moderate evidence also indicates that directional microphones resulted in improved speech recognition in controlled optimal settings; however, additional research is needed to determine the effectiveness of directional microphones in actual everyday listening environments.

Full text: Headnote

Purpose: The purpose of this evidence-based systematic review was to evaluate the efficacy of digital noise reduction and directional microphones for outcome measures of audibility, speech recognition, speech and language, and self- or parent-report in pediatric hearing aid users.
Method: The authors searched 26 databases for experimental studies published after 1980 addressing one or more clinical questions and meeting all inclusion criteria. The authors evaluated studies for methodological quality and reported or calculated p values and effect sizes when possible.
Results: A systematic search of the literature resulted in the inclusion of 4 digital noise reduction and 7 directional microphone studies (in 9 journal articles) that addressed speech recognition, speech and language, and/or selfor parent-report outcomes. No digital noise reduction or directional microphone studies addressed audibility outcomes.
Conclusions: On the basis of a moderate level of evidence, digital noise reduction was not found to improve or degrade speech understanding. Additional research is needed before conclusions can be drawn regarding the impact of digital noise reduction on important speech, language, hearing, and satisfaction outcomes. Moderate evidence also indicates that directional microphones resulted in improved speech recognition in controlled optimal settings; however, additional research is needed to determine the effectiveness of directional microphones in actual everyday listening environments.
Key Words: children, evidence-based systematic review, digital noise reduction, directional microphones, amplification

The negative perceptual consequences of background noise on speech understanding have been established across numerous studies with children (Elliott, 1979; Johnson, 2000). Children with and without hearing loss experience greater degradation in speech recognition than do adults in background noise (McCreery et al.,

2010; Stelmachowicz, Pittman, Hoover, &Lewis, 2001); furthermore, children with hearing loss may experience even greater degradation in speech understanding than do their peers with normal hearing (Crandell, 1993; Finitzo-Hieber &Tillman, 1978). Interference from background noise not only influences speech understanding but can also have substantial effects on learning and academic achievement, including reading and mathematics (Shield &Dockrell, 2003, 2008). Classroom noise levels are frequently observed to exceed recommended levels of noise and reverberation, often reaching levels that are likely to degrade speech recognition and make learning more difficult. Whereas the recommended signal-to-noise ratio (SNR) for educational environments is +15 dB to +30 dB, SNRs in most classrooms are only between -6 dB and +6 dB (Knecht, Nelson, Whitelaw, &Feth, 2002; Nelson, Bougatsos, &Nygren, 2008). Frequency modulation (FM) systems can be coupled with hearing aids (HAs) to limit the effects of background noise on speech understanding and learning in classrooms (Lewis &Eiten, 2011); yet, FM systems may not be practical in all listening situations, such as learning environments like classroom discussions with multiple talkers of interest. When FM systems are impractical or not available, HA features such as directional microphones and digital noise reduction (DNR) may help to minimize the negative perceptual consequences of background noise. Directional microphones and DNR are HA features that were developed to minimize the negative effects of background noise for HA users. DNR includes a wide range of signal processing strategies designed to classify the input to the HA as primarily speech input or noise input, and then reduce gain when the input to the HA is predominantly noise. DNR can be implemented using a wide range of algorithms, including modulation detection and complex filtering. Significant differences in the implementation of DNR between manufacturers and within manufacturers' different products make general predictions about the effect of DNR and related outcomes difficult (Hoetink, Körössy, &Dreschler, 2009).

Directional microphones also have been developed to limit the negative effects of noise on speech understanding and comfort. Directional microphones maintain amplification for sounds originating in front of the listener while limiting amplification for sounds arriving from the sides and behind the listener. Spatial processing is accomplished by having multiple microphones at different locations on the HA or a single microphone with multiple ports. Directional microphones can be assigned to a specific program in the HA, which requires the listener to switch the device to a directional setting for situations with background noise. More recently, manufacturers have developed directional microphone systems that switch automatically from omnidirectional to directional response when the input to the HA has spectral, modulation, and/or level characteristics consistent with background noise. This process often relies on a similar classification signal processing to DNR. Directional microphones can also be fixed, where the direction pattern of the microphones does not change, or be adaptive, where the directional pattern of the microphone changes in response to the location of a speech or noise source in the environment. The advent of programmable directional microphone and DNR settings, as well as adaptive features that change automatically in response to the environment, create novel challenges for clinicians who must decide whether these features should be activated as well as how to verify any impact their use may have on audibility. Recent data support the idea that school-age children can reliably change their HA program in response to changes in the environment (Scollie, 2010), but the efficacy and effectiveness of adaptive signal processing features have yet to be determined.

Although research with pediatric HA users is becoming more prevalent, most DNR research to date has been conducted in the adult population. In general, adult DNR studies reveal that speech recognition typically is not affected by DNR (Bentler, 2005). However, adults can experience improved ease of listening in noise with DNR compared to conditions without DNR (Boymans &Dreschler, 2000; Ricketts &Hornsby, 2005). For example, Mueller, Weber, and Hornsby (2006) documented that while DNR did not change speech recognition for adults, DNR did result in listeners being able to tolerate a higher acceptable noise level in comparison to conditions without DNR. The lack of improvement or degradation in speech understanding for adults with DNR is not surprising given that most algorithms use modulation detection to reduce gain only for periods of the signal

where only noise is present (Kates, 2008). Some DNR algorithms may selectively reduce gain only in frequency regions where noise is the primary signal; however, the spectral characteristics of speech and noise in realistic environments often overlap significantly. Therefore, when both speech and noise are present in the environment, many DNR algorithms do not make significant changes to the signal in order to preserve the audibility of speech (Peeters, Kuk, Lau, &Keenan, 2009). Even if DNR were active when both speech and noise were present in the environment, any reduction in gain would be applied to the combined speech in noise signal, making it unlikely that SNR improvements would be sufficient to improve speech understanding. Therefore, as with adults, the primary objective for using DNR with children should be to maintain speech understanding while limiting the negative impact of background noise on listening effort, cognitive processing, and the child's listening comfort. In cases where DNR does result in decreased speech audibility, the negative effect on speech recognition would likely be greater for children than what would be expected with adults, as children require more audibility to reach the same levels of speech recognition as adults (Stelmachowicz et al., 2001).

Unlike DNR, directional microphones have the potential to improve the SNR for the listener, particularly in situations where the signal of interest and noise sources are spatially separated (Boymans &Dreschler, 2000; Gravel, Fausel, Liskow, &Chobot, 1999). The benefits of directional microphones for improving speech understanding in noise for adults who use HAs have been previously documented in three systematic reviews (Agence d'évaluation des technologies et des modes d'intervention en santé [AETMIS], 2003; Amlani, 2001; Bentler, 2005). Whereas the magnitude of improvement observed with directional microphones varied across studies, reviews by AETMIS (2003), Amlani (2001), and Bentler (2005) all reported that overall directional microphones did provide a statistically significant improvement in speech recognition across studies with adults. In general, the largest improvements in speech recognition were observed for experimental conditions where the stimuli are presented in front of the listener and the noise source was fixed behind the listener. The presence of reverberation, diffuse noise sources, or other more realistic acoustic conditions resulted in smaller improvements in speech recognition in adults.

Although existing studies can provide clinicians with support for using these advanced HA signal processing strategies with adults, the findings are difficult to generalize to children in school-age populations due to the ongoing development of auditory, speech, and language skills coupled with the unique, acoustically complex environments in which they must access auditory information. Changes in audibility that result from DNR and directional microphones may have different effects on children than those previously reported with adult listeners. Since children experience greater degradation in speech understanding from background noise than adults, the degree to which the negative consequences of background noise can be limited may have a greater impact on children than has been observed in adults. Additionally, differences in listening behavior between adults and children have the potential to affect the degree to which similar results can be observed with children. Unless the talker of interest and sources of noise are stationary, improvements in the SNR with directional microphones are predicated on the ability to orient the head toward the signal of interest. Ching and colleagues (2009) evaluated listening behavior in infants and young children with normal hearing and hearing loss in simulated realistic listening situations. These children looked at the speaker of interest more than 40% of the time, which suggests that young children are able to orient toward a speaker in realistic environments, but may not do so consistently.

Evidence-based systematic reviews (EBSRs) and guidelines of HA signal processing for children are necessary to provide objective, nonbiased summaries of empirical evidence and recommendations for HA selection and clinical management based on empirical evidence. The American Academy of Audiology Pediatric Amplifications Guidelines Task Force has announced a soon-to-be published evidence-based guideline that will likely include information on directional microphones and DNR. Currently available pediatric HA articles, clinical guidelines, and protocols (American Academy of Audiology Task Force, 2003; Bagatto, Scollie, Hyde,

&Seewald, 2010; King, 2010; Scollie, 2010) are not based on systematic reviews of the evidence. Additionally, as pointed out by Scollie (2010), current clinical guidelines provide conflicting recommendations regarding the use of HA features with children. Whereas Bagatto and colleagues (2010) recommended decisions about selecting HA features be conducted on an individual basis using clinical judgment, King (2010) recommended that features such as directional microphones and DNR be routinely used with children. Therefore, the purpose of the current EBSR is to systematically review the current research evidence regarding the effect of directional microphones and DNR on relevant hearing, speech, and satisfaction outcomes for school-age children with hearing loss.

Beginning in 2010, ASHA's National Center for Evidence- Based Practice in Communication Disorders began a systematic search of the current, peer-reviewed research to determine the impact of several HA signal processing features on select communication outcomes in school-age children, including: directional microphone response, noise reduction, amplitude compression, and frequency lowering. The results of the literature search are presented in a series of three EBSR reports. This review focuses on the impact of directional microphone response and noise reduction; two additional reviews address frequency lowering and amplitude compression. This series of EBSRs is intended to inform clinical decisions pertaining to the selection and management of the aforementioned HA technology for school-age children.

We developed clinical questions for this review in consideration of the population, intervention, comparison, and outcome. Our population of interest is school-age children, and our intervention comparisons include the use of DNR in HAs versus the use of HAs without DNR and omnidirectional response as compared to directional microphone response. Four categories of outcome measures have been suggested to evaluate the efficacy of HA features with children: audibility, speech recognition, speech and language outcomes, and subjective measures (Hogan, 2007). Audibility, the ability to hear sounds directly, impacts an individual's ability to recognize, learn, and interpret speech. Audibility outcome measures are objective measures of speech audibility, including sound-field testing, real ear measures (gold standard), real-ear-to-coupler difference, Articulation Index (AI; ANSI S3.5-1969) scores, and Speech Intelligibility Index (SII; ANSI S3.5-1997) scores. Because children with hearing impairments are more likely to have limited exposure to audible speech (Arlinger, 2001), they are at increased risk for language difficulty in areas such as vocabulary acquisition (e.g., Briscoe, Bishop, &Norbury, 2001; Pittman, 2008), which is important in developing context for academic subject areas (e.g., Maynard, Pullen, &Coyne, 2010; Myers &Botting, 2008; Scarborough, 1998). Speech recognition outcome measures are objective measures of speech stimuli identification, including phoneme, nonword, word, and sentence materials. The accurate perception of speech underlies the development of spoken and written language skills (Bavin, Grayden, Scott, &Stefanakis, 2010; DesJardin, Ambrose, Martinez, &Eisenberg, 2009). Speech and language outcome measures include standardized measures of communication development. Ultimately, the impact of hearing ability on social interaction becomes a primary focus and is often captured by self-report or parent-report questionnaires. The impact of these outcomes on school-age children fitted with hearing devices is an important consideration for audiologists who provide services to that population.

Two clinical questions were developed as the focus of this EBSR:

1. What are the effects of DNR technology as compared to HAs without DNR on audibility outcomes, speech recognition outcomes, speech and language outcomes, and HA self-report or parent-report outcomes for schoolage children with hearing loss?
2. What are the effects of directional microphone response as compared to omnidirectional response on audibility outcomes, speech recognition outcomes, speech and language outcomes, and HA self-report or parent-report outcomes for school-age children with hearing loss?

Method

Literature Search

We obtained articles for this series of reviews from a literature search of HA processing features. The fourth

author, experienced in conducting systematic literature searches (e.g., Frymark et al., 2010), developed a search strategy. We searched 26 databases (e.g., PubMed, CINAHL, PsycINFO, ERIC) from January to April 2010 using keywords related to hearing loss, children, and amplification (e.g., hearing aid, hearing instrument, amplification, child, frequency compression). A full list of the searched databases and search terms are included in a concurrent review within this series, McCreery, Venediktov, Coleman, and Leech (2012). We examined reference lists of all full-text articles retrieved from the initial search to identify additional relevant articles. One author looked for articles citing the studies accepted for inclusion (see McCreery et al., 2012) and searched in the EBSCO database for literature published by 26 prolific authors. The overarching search for the series of reviews was initially completed from January to April 2010; however, given the size and scope of the review series as well as the lapse of time with report of results, the search was updated to include studies published through July 2011.

Study eligibility was based on the following inclusion criteria: (a) experimental or quasi-experimental research designs addressing one or more of the clinical questions; (b) studies written in English that were published in a peerreviewed journal after 1980; (c) studies including school-aged children between the ages of 5 and 17 years with documented conductive, mixed, or sensorineural hearing loss; (d) studies using wearable HAs and signal processing approaches that are currently available in commercial HAs; and (e) studies providing comparative data on HAs with and without the target technological features. Studies including participants outside of the target age range were excluded unless the mean age fell within the target age range or if the data could be split for separate analyses. Operational definitions of signal processing strategies and outcomes are included in McCreery et al. (2012). Two authors independently applied the inclusion criteria to determine study eligibility based on abstracts. A second independent review of preliminarily accepted full-text articles was completed by the same authors to determine final inclusion. We calculated interrater reliability using the kappa statistic (k) and percent agreement. Interrater disagreements were resolved by consensus or the advisement of the first author, who also reviewed the final list of included and excluded literature for accuracy and completeness. Landis and Koch's (1977) labels describing relative strength of agreement were applied to k statistics: <.00 = poor, .00-.20 = slight, .21-.40 = fair, .41-.60 = moderate, .61-.80 = substantial, and .81-1.00 = almost perfect.

Critical Appraisal

Individual studies. Full-text versions of each included study were independently reviewed by the second and third authors, who have educational training and previous experience (e.g., Gosa, Schooling, &Coleman, 2011; Roush, Frymark, Venediktov, &Wang, 2011); these authors appraised experimental research for quality. Each author rated the quality of the study on up to seven appraisal criteria using an adaptation of the ASHA levels-of-evidence scheme (Cherney, Patterson, Raymer, Frymark, &Schooling, 2008; Fey et al., 2010; Mullen, 2007). The levels-of-evidence scheme was developed by the ASHA National Center for Evidence-Based Practice in Communication Disorders along with the ASHA Advisory Committee for Evidence-Based Practice and was piloted prior to its adoption in 2008. The scheme was adapted for evaluation of within-subject repeated measures designs with special consideration for threats to internal validity arising from these study designs (Portney &Watkins, 2009) and with input from the first author regarding the applicability of each appraisal point to HA research. We calculated interrater reliability using κ (weighted as appropriate) and percent agreement. Neither rater had an extensive audiological background; therefore, they requested the knowledge and experience of the first author as necessary to provide background information to clarify any instances of uncertainty during the quality appraisal process. Individual studies received one point for each appraisal criterion met, and quality ratings were determined for each study on the basis of the total number of points. Appraisal points were awarded for (a) an adequate description of study protocol (i.e., sufficient detail provided for replication), (b) assessor blinding, (c) an adequate description of random sampling of participants, (d) randomization to condition or sequence of conditions, (e) counterbalancing of the order of conditions (applicable only to within-subject designs), (f) reporting of p values (or the provision of data to calculate that statistic), and

(g) reporting of effect sizes and their confidence intervals (or the provision of data to calculate those statistics).
Body of evidence. We used the Cincinnati Children's Hospital Medical Center body of evidence grading scheme (Cincinnati Children's Hospital Medical Center, 2011a) to evaluate the strength of the evidence for the body of literature for each clinical question. This scheme was selected because it considers several important domains: hierarchy, bias, quantity, magnitude of effect, and consistency of evidence (Coleman, Talati, &White, 2009), and offers a clear and objective approach to evaluating bodies of evidence. The second and third authors independently evaluated the quality of individual studies using the Cincinnati Children's Hospital Medical Center Controlled Clinical Trial Appraisal worksheet (Cincinnati Children's Hospital Medical Center, 2011b) to arrive at a quality level for each study. Interrater agreement was calculated using k and percent agreement. These two authors then independently evaluated the body of evidence for each clinical question using the Cincinnati Children's Hospital Medical Center evidence grading worksheet to arrive at a grade of high, medium, or low. A high grade of evidence is based on a high-quality systematic review, more than one high-quality randomized controlled trial or more than five high-quality nonrandomized controlled trials or cohort studies. If a body of evidence was graded as high, it suggests that future research is not likely to change confidence in the answer to the clinical question. A moderate grade was based on a high-quality randomized controlled trial or multiple high- or low-quality systematic reviews, randomized and nonrandomized controlled trials, cohort studies, or more than five case-control studies. Moderate evidence suggested that future research is likely to have an important impact on answers to the clinical question. A low grade of evidence indicated that there is consensus but no research to answer the question. A grade was not assignable if there was insufficient evidence to answer a clinical question. Questions and interrater disagreements were resolved by consensus or advisement of the first author.

Data Extraction and Analysis

With the advisement of the first author, a list of disciplinespecific data extraction points was developed. The second and third authors summarized these critical features of each study, including study design, characteristics of the population, previous HA usage, test HA features, HA settings (including volume control and equalization), study protocol, outcome measures, findings, and limitations. The first author reviewed summaries for accuracy and completeness. This information is located throughout the text and tables of this review.

Effect size, r, was calculated for all studies providing sufficient data. In studies providing raw data in which the independent variable was dichotomous and the dependent variables were continuous, the point-biserial correlation coefficient (rpb) effect size was calculated using an online calculator (Lowry, 2010). If raw data were not presented, an approximated effect size, r, was calculated from F-statistics with corresponding degrees of freedom (dfs; Garbin, n.d.) or from paired t values and df (Rosenthal &DiMatteo, 2001). The number of participants in each study was entered into an online calculator (Garbin, n.d.) to calculate the confidence interval (CI) surrounding each effect size. Effect sizes favoring the experimental technology (i.e., HAs with DNR or a directional microphone response) investigated in each study were assigned a positive value, whereas effect sizes favoring the control condition (i.e., HAs with DNR deactivated or an omnidirectional response) were assigned a negative value. The magnitude of the r effect sizes was interpreted as follows: small (.10 to .29), moderate (.30 to .49), and large (above .50; Cohen, 1992). P values were calculated in several studies in which raw data were provided but statistical significance for our sample of interest was not reported. We used the Wilcoxon signed ranks test due to the small number of participants.

We discuss the statistical significance of included study findings throughout the text of this review. A finding was considered to be statistically significant if the confidence interval surrounding the effect size did not include the null value and/or if the p value was less than or equal to .05. For each clinical question, we further analyzed results to determine whether any data trends were apparent that suggested an impact of study design or study quality on the results.

Results

Study Selection

Of the 376 studies identified, 168 were eliminated during the abstract review and an additional 171 were subsequently excluded after review of the full text. Of the 37 remaining studies, 14 were eliminated after further scrutiny. This process resulted in a total of 23 articles, nine of which are included in this review. Reasons for exclusion were that the study did not directly address a clinical question for this or another review in the series, did not provide sufficient data for analyses, or reported the use of a technology no longer available in commercial HAs. See McCreery et al. (2012) for a flow chart depicting this process.

Ten studies from nine articles were included in this review. Four studies (Auriemmo et al., 2009; Pittman, 2011a, 2011b; Stelmachowicz et al., 2010) provided data to address Clinical Question 1 (DNR) and seven studies (Auriemmo et al., 2009; Gravel et al., 1999; Hawkins, 1984; Kuk, Kollofski, Brown, Melum, &Rosenthal, 1999; Ricketts, Galster, &Tharpe, 2007, Experiments 1 and 3; Wouters, Litière, &van Wieringen, 1999) addressed Clinical Question 2 (directional microphones). One study (Auriemmo et al., 2009) investigated both directional microphone response and DNR.

Interrater Reliability

Overall interrater reliability for the inclusion/exclusion process indicated substantial agreement and moderately high percent agreement between raters (k = .67, 87.9%). The interrater reliability for the critical appraisal of individual studies and bodies of evidence was also calculated using the k statistic (weighted as appropriate) and percent agreement. Perfect interrater agreement (k = 1.00, 100%) was obtained for three appraisal criteria: blinding, sampling, and random allocation to condition/sequence. Interrater agreement was moderate for the counterbalancing and effect size appraisal criteria (k = .60, 80%; k = .62, 90%, respectively) and substantial for the statistical (p value) reporting criterion (k = .48, 70%). Interrater reliability was poor (k = 0) for one appraisal criterion, protocol description, despite a high percent agreement between raters (i.e., 80%). The skewed distribution of responses created a paradox in which the k statistic was very low despite a fair percentage of agreement (see Feinstein &Cicchetti, 1990, for further explanation). Interrater reliability and percent agreement for individual study quality determinations, conducted as a step in the process of grading the body of evidence for each question, was substantial (k = .62, 90%). Individual ratings are included in the supplementary materials associated with this article.

DNR

Clinical Question 1: What is the effect of DNR technology as compared to HAs without DNR on audibility outcomes, speech recognition outcomes, speech and language outcomes, and HA self- or parent-report outcomes on school-age children with hearing loss?

Four studies (Auriemmo et al., 2009; Pittman, 2011a, 2011b; Stelmachowicz et al., 2010) that included a total of 65 participants met the inclusion criteria for this clinical question. Participants ranged in age from 5 to 12.8 years and presented with mild to moderately severe hearing loss. The majority of participants had a sensorineural hearing loss and were experienced HA users. Additional details are presented in Table 1. Four different HA models with varying DNR algorithms were identified across the four studies and included the Widex Diva SD9M/19M, Siemens Explorer 500, Starkey Destiny (Model 1200), and a test HA with modulation-based DNR algorithm and Wiener filter. Researchers in two studies (Auriemmo et al., 2009, Stelmachowicz et al., 2010) provided speech recognition outcomes, two (Pittman 2011a, 2011b) provided speech and language outcomes, and one (Auriemmo et al., 2009) also provided HA self- or parentreport outcomes. Additional details regarding HA features and experimental procedures are located in the appendix. As a result of the heterogeneity (e.g., differences in specific outcome measures used, differences in severity of hearing loss, differences in compression thresholds and stimulus input levels) and small number of included studies for each clinical question, effect sizes were not averaged across studies.

Speech recognition outcomes. Speech recognition outcomes consisted of nonsense syllable, word, and

sentence recognition scores measured at several SNRs. Auriemmo et al. (2009) tested word recognition in quiet and at +5, 0, and -10 dB SNR. Stelmachowicz et al. (2010) measured recognition of nonsense syllables, words, and sentences at SNRs of 0, +5, and +10 dB. As shown in Table 2, two (of five) effect sizes yielded a small magnitude of effect (favoring DNR); however, no statistically significant mean differences in speech recognition were reported between conditions with DNR compared to those without DNR in either study at any SNR.

Speech and language outcomes. As reported in Table 3, Pittman, in two studies (2011a, 2011b), examined language outcomes for children with hearing loss using DNR. Pittman (2011b) measured children's ability to appropriately categorize words heard in noise while completing a simultaneous visual task with DNR activated versus deactivated. In Pittman (2011a), children's ability to learn novel words was investigated by exposing children to nonsense words presented in noise with DNR activated versus deactivated. In both studies, effect sizes were small and nonsignificant with the exception of one finding, in which the p value just reached significance ($p = .047$) and favored HAs with DNR for novel word learning in older children (11-12 years; Pittman, 2011a). The magnitude of this effect was large.

HA self-report or parent-report outcomes. Auriemmo et al. (2009) used the parent version of the Abbreviated Profile of Hearing Aid Performance (PA-PHAP; Kopun &Stelmachowicz, 1998) to assess parents' perceptions of their child's response to a range of listening situations after each 6-week trial with the HA with DNR versus without DNR. Parents did not report any significant difference between HA conditions on the PA-PHAP. Children in this study also were asked to respond to a directional subscales questionnaire (Ricketts, Henry, &Gnewikow, 2003) designed to evaluate the child's perceived amount of difficulty hearing in different listening environments. The children did not report any significant differences between settings with DNR and those without DNR for the "sound front" scale; however, significant differences ($p = .03$) were reported for the "sound back" scale, which favored the setting with DNR enabled.

Trend analysis by study design and quality. Individual study quality scores ranged from 4/7 to 5/7 across the four studies. All of the studies were within-subject, repeated measures designs, and three studies counterbalanced conditions, further distinguishing them as crossover designs. In the fourth study, Pittman (2011b) randomized participants to a sequence of conditions, also reducing the potential for order effects. None of authors of these studies reported use of random sampling, and only one indicated that assessors were blinded. However, researchers in all four studies did provide adequate protocol descriptions and reported or provided sufficient information to calculate statistical significance (see Table 4). Results from these studies were analyzed to determine whether variations in study quality or study design were associated with variations in effect size. However, because there were only minimal discrepancies among the included studies in quality and design, no conclusions were possible. The ability of users to control the volume of the HA, although not included as an appraisal point, may significantly impact study findings. Study authors indicated that volume control was deactivated in all but one study (Auriemmo et al., 2009), which did not provide information regarding the volume control.

Overall quality of body of evidence for DNR. The authors of one low-quality RCT (Pittman, 2011b) and three lowquality controlled clinical trials (Auriemmo et al., 2009; Pittman, 2011a; Stelmachowicz et al., 2010) provided information to address Clinical Question 1. Findings from these studies were generally consistent and suggested that DNR did not have a significant impact on speech recognition, speech and language, or parent /child report outcomes. Using the Cincinnati Children's Hospital Medical Center grading scheme, this constitutes a moderate body of evidence, which means that further research is likely to impact the answer to this clinical question.

Directional Microphones

Clinical Question 2: What is the effect of directional microphone response as compared to omnidirectional response on audibility outcomes, speech recognition outcomes, speech and language outcomes, or HA self-report or parent-report outcomes for school-age children with hearing loss? Seven studies were found to

address this clinical question (Auriemmo et al., 2009; Gravel et al., 1999; Hawkins, 1984; Kuk et al., 1999; Ricketts et al., 2007 [Experiment 1, Experiment 3]; Wouters et al., 1999). These studies included a total of 97 participants (ages 4.8-17 years) with hearing loss severity ranging from mild to severely profound. As shown in Table 1, the majority of participants were experienced HA users with a sensorineural hearing loss. Experimental directional response systems included adaptive automatic or fixed systems that used either dual microphones or a single two-port directional microphone. Additional details pertaining to the HA features and experimental procedures are presented in the appendix. All seven studies included speech recognition outcomes and three (Auriemmo et al., 2009; Kuk et al., 1999; Ricketts et al., 2007, Experiment 1) also included HA self- or parent-report outcomes.

Speech recognition outcomes. Speech recognition outcomes were reported for word or sentence recognition accuracy at set SNRs as well as SNRs necessary to achieve 50% accurate speech recognition (see Table 5). Effects of directionality are heavily dependent on the azimuth of the signal and noise in relation to the listener. Therefore, results are discussed in the context of the signal/noise azimuth.

Presentation of signal to front and noise to back. Two studies (Auriemmo et al., 2009; Kuk et al., 1999) assessed accuracy of word recognition for directional response and omnidirectional response at several positive and negative SNRs. Although Kuk et al. did not provide sufficient information to calculate effect sizes, p values were reported revealing statistical significance across all SNRs and favored use of HAs with a directional response over the participants' own omnidirectional HAs ($p < .05$). Auriemmo et al. reported large and statistically significant findings at SNRs of 0 dB ($r = .56$, 95% CI [.14, .81], $p < .05$) and -10 dB ($r = .67$, 95% CI [.31, .86], $p < .05$) in favor of the directional HAs. Findings in quiet and at +5 SNR failed to reach statistical significance; however, the magnitude of the effect at +5 SNR was moderate. Two studies (Gravel et al., 1999; Hawkins, 1984) measured SNRs necessary to achieve 50% accuracy on tests of word or sentence recognition. All p values from these two studies were statistically significant and favored directional response over omnidirectional response ($p < .05$); yet only one of the three effect sizes was significant. Gravel et al. (1999) reported a large and statistically significant effect size for words and sentences combined ($r = .86$, 95% CI [.67, .94], $p < .0001$). Hawkins (1984) examined the effects of omnidirectional and directional microphones in both monaural and binaural conditions. Neither condition produced a statistically significant effect size, although the magnitude of effect was moderate in the monaural condition and large in the binaural condition.

Presentation of signal to front and noise to side. In one study, Wouters and colleagues (1999) presented stimuli to the front (0°) of participants and noise to the side (90°) and measured the SNR necessary to achieve 50% accuracy on tests of word and sentence recognition. Effect sizes ranged from small ($r = .22$) to large ($r = .63$) for words or sentences presented in several types of noise. However, the statistical significance of these effects could not be determined because confidence intervals were not reported or calculable. All p values were statistically nonsignificant.

Presentation of signal to front in diffuse noise. Ricketts and colleagues (2007) simulated several classroom environments within which three different experiments were conducted. Only data from Experiments 1 and 3 provided information to determine the effect of directional response with stimuli and noise coming from various directions. In Experiment 1, omnidirectional and directional response was measured in five simulated conditions: "teacher front," "teacher back," "desk work," "discussion," and "bench seating." The azimuths of stimuli and noise for each condition are provided in Table 5. The SNRs necessary to achieve 50% accuracy on a sentence recognition test were recorded. An overall effect size, calculated across all five listening conditions, was large and statistically significant and favored directional response ($r = .58$, 95% CI [.25, .79], $p < .0017$). Post-hoc analysis revealed a statistically significant interaction of listening condition and directionality. "Teacher front," "desk work," and "discussion" conditions were statistically significant and favored directional response ($p < .05$). "Teacher back" was statistically significant and favored omnidirectional response ($p < .0375$). "Bench seating" was not statistically significant. In Experiment 3, omnidirectional and directional response were

measured in a "multiple talkers" condition in which the stimuli were directed to the front, back right, or back leftof the participant and noise was presented from four speakers in corners of the room. The overall effect size for this condition was large and statistically significant and favored omnidirectional response (r = -.79, 95% CI [-.90, -.58], p <.0012). Post hoc analysis revealed a significant interaction between stimuli source and directionality. No statistically significant differences were noted between directional and omnidirectional responses when the stimuli were presented to the front of the listener; although, significant differences (p <.01) favoring omnidirectional response were present when the stimuli were presented to the back leftand back right of participants.

Summary of speech recognition outcomes. The overall findings indicate that directional microphones were more effective for speech recognition when the signal was presented directly in front (0° azimuth) of the listener and when the noise was presented directly behind the listener (180° azimuth). Use of omnidirectional microphones, however, resulted in better speech recognition when the signal deviated away from the front of the listener.

HA self-report or parent-report outcomes. In three studies (Auriemmo et al., 2009; Kuk et al., 1999; Ricketts et al., 2007, Experiment 1), researchers evaluated HA self- or parent-report outcomes in the children's daily environments using subjective questionnaires administered to children, parents, and/or teachers. No effect sizes were calculable for these studies; however, p values were reported in Auriemmo et al. (2009) and Ricketts et al. (2007). The p values reported in the Kuk et al. study were based at a .10 significance level, and, therefore, could not be interpreted as significant at the .05 level. The Kuk et al. findings suggested that overall students favored the use of directional microphones over their own omnidirectional HAs for the majority of listening situations. No differences were found for the following situations: group discussion, teacher moving, and talking while hanging coats. Auriemmo and Ricketts and their coauthors found no statistically significant differences between directional and omnidirectional response for children or parents.

Trend analysis by study design and quality. As depicted in Table 4, individual study quality scores ranged from 2/7 to 5/7. All of the studies were within-subject, repeated measures designs. Three (Auriemmo et al., 2009; Gravel et al., 1999; Ricketts et al., 2007, Experiment 1) were designed to control for order effects by counterbalancing conditions and were therefore classified as crossover studies, whereas in another study, Hawkins (1984) controlled for order effects by randomizing participants to a sequence of conditions. Authors of all studies reported or provided sufficient data to calculate statistical significance, and the majority of studies provided an adequate description of protocol and sufficient data to calculate effect sizes. For many studies, researchers did not indicate assessor blinding, random sampling, randomization and/or counterbalancing procedures. The results of these studies were further analyzed to determine whether study design or quality impacted findings. Despite multiple similarities in study design and quality among select studies, no overall conclusions can be drawn; effect sizes were unavailable or the significance of the effect size was questionable for some of the studies. Although not included in the study critical appraisal, potential confounding variables including volume control settings, frequency response, and use of different devices are important to consider when evaluating study findings. With the exception of two studies in which sufficient information was not provided (Kuk et al., 1999; Wouters et al., 1999), studies did equalize the frequency response between omnidirectional and directional conditions. Only one study (Hawkins, 1984) reported that volume control was fixed for both conditions; all other studies did not provide this information. One important confound noted by Kuk et al. (1999) was the use of different devices to assess omnidirectional and directional response. Outcomes from directional microphone HAs were compared to outcomes with the children's own omnidirectional HAs.

Overall quality of body of evidence for directional microphones. The body of evidence to answer this clinical question consisted of one low-quality randomized controlled trial (Hawkins, 1984) and six low-quality controlled clinical trials. Findings from these studies were generally consistent across similar signal/noise listening configurations. This constitutes a moderate level of evidence that suggests that future research is likely to impact the answer to the clinical question.

Discussion

The purpose of the current EBSR was to evaluate the impact of DNR and directional microphone technology on a range of communication outcomes for school-age children with hearing loss who use HAs. Our aim in this review as well as the findings from two additional reviews in this series was to inform clinical decisions pertaining to the selection and management of these technologies in the school-age population. DNR and directional microphones are both designed to minimize the negative perceptual consequences of background noise on comfort and perception. Because school-age children listen and learn in environments with significant levels of competing background noise (Knecht et al., 2002), these technologies have the potential to benefit children with hearing loss. We identified four studies that evaluated DNR and seven studies that evaluated directional microphones were identified and analyzed as part of the review.

DNR

DNR is a signal processing strategy designed to reduce the negative perceptual consequences of background noise by lowering the gain of the HA when the input signal is classified as noise. Because DNR typically relies on gain reduction, speech recognition can at best be maintained and may potentially be degraded if the processing significantly alters the audibility of the speech signal (Stelmachowicz et al., 2010). The results of two studies included in this EBSR on the effect of DNR on speech recognition with school-age children with mild to moderately severe hearing loss (Auriemmo et al., 2009; Stelmachowicz et al., 2010) indicated that mean speech recognition was not improved or degraded with DNR. Although the younger group of children (ages 5-8 years) in Stelmachowicz et al. (2010) showed considerable individual variability in speech recognition in conditions with and without DNR, none of the participants showed constant patterns of improvement or degradation across nonsense syllables, monosyllabic words, or sentences. Auriemmo et al. (2009) also included parent and child ratings of listening difficulty, which were found to improvewith DNR for the children's ratings only when sound was located behind them. Although such a finding would be anticipated with directional microphones, it is unexpected for a condition with only DNR activated because DNR adjusts the SNR in a nonlocalized manner. Results from these two studies support the conclusion that the DNR algorithms used in these two studies did not improve or degrade speech recognition in school-age children, but did result in a reduction in the difficulty rating for sounds from behind the listener. These findings are generally congruent with previous studies of the impact of DNR on speech recognition and sound quality in adults with hearing loss.

The author of two other studies included in this EBSR (Pittman, 2011a, 2011b) examined the influence of DNR on complex listening tasks, including word categorization and novel word learning tasks. The outcomes in these two studies were categorized as speech and language outcomes because the tasks were dependent on perceptual and cognitive processes important for spoken and written language development, in addition to speech recognition. For the word categorization study (Pittman, 2011b), participants heard words that were to be categorized as person, food, or animal while also completing a complex connect-the-dots visual task. No improvement or degradation in word categorization was observed when comparing conditions with and without DNR for children with hearing loss. In another study, Pittman (2011a) analyzed the effect of DNR on novel word learning at 0 dB SNR. Whereas there was no improvement or degradation in word learning for 8- to 9-year-old children with hearing loss, 11- to 12-year-olds experienced an enhancement in word learning in the DNR condition only. The age-related differences in DNR benefit were attributed to the higher overall nonword recognition scores in the older group; the process of novel word learning in part is dependent on the accuracy of speech recognition. Because speech recognition in noise has rarely shown improvement with DNR in previous studies, an enhancement in novel word learning may be unlikely to occur if the effect is dependent on DNR improving perception. Collectively, these two studies suggest that DNR does not negatively impact complex listening and word learning tasks and has the potential to improve performance in some conditions and age groups of children. Although word categorization and novel word learning have not been specifically explored in DNR studies with adult listeners, investigators have reported positive outcomes for reduced listening effort at

very poor SNRs (Sarampalis, Kalluri, Edwards, &Hafter, 2009) and acquisition of novel speech contrasts (Marcoux, Yathiraj, Côté, &Logan, 2006) for DNR with adults. While further research is needed to specify the underlying mechanisms that result in reduced effort and improved performance on complex tasks in the absence of observable benefits for speech perception, the limited data to date suggest that DNR will not negatively impact learning processes in school-age children. Given the documented negative consequences of noise on academic and learning outcomes in children (Shield &Dockrell, 2008), the use of DNR in classroom settings may help to minimize potential problems.

Overall, a moderate level of evidence from four studies of DNR with school-age children identified in the current review suggest that DNR does not affect speech recognition or complex listening tasks and may result in reduced ratings of difficulty for specific situations (sounds behind the listener) and improved novel word learning in older (11- to 12-year-old) children. Evidence that DNR does not result in reduced outcomes in conjunction with its potential for improvements in sound quality, listening effort, and complex listening and learning tasks provides preliminary support for the use of DNR with school-age children. Further studies of DNR should attempt to replicate the findings from these studies with different DNR algorithms because the characteristics and implementation of DNR vary considerably across manufacturers and devices (Hoetink et al., 2009). The four studies of DNR in the current review also included only children with mild to moderately severe hearing loss. Children with greater degrees of hearing loss may have more limited audibility and experience greater degradation in outcomes with background noise that could lead to different results with DNR.

Three of the four studies addressing this clinical question used the desired sensation level (DSL; Scollie et al., 2005) fitting prescription to determine HA gain and output. Auriemmo and colleagues (2009) used a proprietary approach. Differences in audibility for different fitting prescriptions across studies may limit the generalizability of these findings and ability to compare results across studies using different prescriptive methods. The use of proprietary fitting approaches without quantification of aided audibility prevents accurate predictions regarding the magnitude and pattern of differences that might be observed for different outcome measures in children with hearing loss.

The state of the evidence in any given area of research is suggested to move through several distinct phases including exploratory, efficacy, effectiveness, and cost-effectiveness (see Robey, 2004, for further discussion of stages of research). The DNR studies included in this review were all in the efficacy stage of research, meaning that research was conducted in a controlled manner to maximize the internal validity of the findings. As efficacy has not been established for speech recognition and speech and language outcomes, additional efficacy research examining these outcomes, as well as the effect of DNR on users' self-reported ease of listening and performance on complex listening tasks, is needed to establish the benefit of DNR. Also, as advancements in DNR algorithms are achieved, additional efficacy research on all outcomes will continue to be necessary. Longitudinal studies with children using DNR may provide insight into the effects of experience and acclimatization, and long-term impacts on language and learning processes. Research that addresses these questions would help clinicians to determine the appropriateness of this technology for children because preference ratings have been found to favor DNR for adult listeners in previous studies (Ricketts &Hornsby, 2005). Once efficacy has been established, additional research may focus on effectiveness and cost-effectiveness research.

Directional Microphones

We identified seven studies with school-age children and adolescents that compared an omnidirectional microphone, which is equally sensitive to sounds regardless of their location relative to the listener, to directional microphones for school-age children. Speech recognition in noise was consistently improved when the signal of interest was in front of the listener (Auriemmo et al., 2009; Gravel et al., 1999; Hawkins, 1984; Kuk et al., 1999; Ricketts et al., 2007), but was poorer for conditions where the signal of interest was behind the listener (Ricketts et al., 2007). Improvements for speech originating in front of the listener were observed across

a wide range of SNRs, stimuli, and configurations of noise: diffuse noise as in Ricketts et al. (2007) and fixed noise behind the listener in Gravel et al. (1999). Because speech recognition is improved when the talker of interest is in front of the listener and is either maintained or degraded for conditions when the talker of interest is beside or behind the listener, the benefit of directional microphones for schoolage children is dependent on the ability of the child to orient toward the signal of interest. This ability to orient is particularly important in classroom situations where the speaker of interest may move or change, such as a teacher moving through the classroom or during a class discussion with multiple talkers; it may be dependent on the age of the listener. Ricketts and Galster (2008) demonstrated that school-age children with hearing loss were able to accurately orient toward the signal of interest in classroom settings, indicating that amplification can be maintained using directional microphones in classroom environments. These findings suggest that directional microphones may be beneficial for school-age children in classrooms in situations where an FM system would be impractical, including classroom discussions with multiple talkers of interest.

Despite improvements in speech recognition across multiple studies, no significant differences were observed for subjective measures of sound quality for directional versus omnidirectional responses (Auriemmo et al., 2009; Ricketts et al., 2007, Experiment 1). This disparity is counterintuitive considering the importance of speech understanding to communication in everyday situations. However, there are several potential explanations for this difference between objective measures of speech recognition and subjective ratings of satisfaction and sound quality:

1. The amount of improvement from directional microphones in real-world environments may be much smaller than the improvements in a controlled speech recognition task in a laboratory, an explanation that has been mentioned in systematic reviews of directional microphones for adults (Amlani, 2001).
2. Because directional microphones maintain amplification for whatever signal the child is oriented toward, the benefits of directional microphones may be less apparent to the users because they may use visual cues to orient toward the signal of interest throughout the day, which studies with adults have demonstrated can influence the degree of observed directional benefit in the laboratory (Wu &Bentler, 2010).
3. Although in at least one study (Auriemmo et al., 2009) researchers used a questionnaire (from Ricketts et al., 2003) that contained items that specifically probed listening situations that would be expected from directional microphones, the overall difference between speech recognition and subjective satisfaction outcomes in the current review may reflect the need for different tools to assess the benefits of this technology in real-world environments and more realistic laboratory outcome measures.

Another important consideration regarding the use of directional microphones in real-world environments is the influence that reduced sensitivity from sounds arriving from the sides or behind the child may have on their ability to use overhearing. Akhtar (2005) suggested that overhearing may be an important mechanism to support novel word learning in young children. By definition, incidental learning through overhearing involves the child's ability to hear and attend to stimuli that may not be directly in front of them. Children with hearing loss are at risk for delays in the acquisition of new vocabulary compared to their peers with normal hearing (Pittman, 2008). Preliminary data from Moeller (2010) suggests that children with hearing loss may face additional challenges using overhearing to support novel word learning compared with children with normal hearing. Although studies that directly evaluate how directional microphones may affect overhearing have not been conducted, potential limitations on children's ability to learn new vocabulary could limit the efficacy of this technology with young children.

Most of the studies relating to this clinical question used a version of the DSL (Scollie et al., 2005) prescriptive formula to prescribe HA gain and output for their participants. Two studies (Auriemmo et al., 2009; Kuk et al., 1999) used a proprietary prescriptive approach other than DSL and one study (Wouters et al., 1999) used POGO. The DSL is the most widely used prescriptive method for children, but the extent to which results obtained with one specific prescriptive formula can be generalized to other approaches cannot be determined.

As mentioned previously, the use of manufacturer proprietary prescriptive approaches without documenting audibility over a range of input levels limits the ability to determine whether differences in outcomes are related to audibility or the signal processing contrast of interest.

The included studies contribute to a moderate level of evidence that suggests efficacy for the use of directional microphones in school-age children in well-controlled laboratory environments when the sound is directed to the front of the child; however, methodological weaknesses limit our ability to confidently form conclusions without further research. Despite the need for additional high-quality efficacy research, the state of research for directional microphone studies is progressing through a later stage of efficacy and into the realm of effectiveness. Effectiveness research investigates the impact of an intervention when it is implemented in realistic situations, and, often, in typical daily environments. One study (Ricketts et al., 2007) investigated efficacy in several simulated environments, where the configuration of speech and noise signals more realistically approximated classrooms and other important environments. Authors of three studies (Auriemmo et al., 2009; Kuk et al., 1999; Ricketts et al., 2007, Experiment 1) also included real world HA satisfaction measures. The equivocal findings from these later stage investigations highlight the need for additional late efficacy and effectiveness studies that use real world or simulated environments and outcomes. Also, since most HA manufacturers incorporate multiple signal processing techniques into the same device, children may be using DNR and directional microphones simultaneously, whereas most of the current research focuses on the independent effects of these technologies. Future efficacy and effectiveness research should investigate how these strategies may interact to affect listening and satisfaction outcomes.

Limitations of the Current Review

Several limitations of this systematic review should be considered. First, the search criteria for this review were restricted to studies available in English, which likely reduces the quantity of relevant information that could have otherwise been included. Also, although the exclusion of unpublished findings and findings published in non-peer-reviewed journals was intentional to ensure that all included studies were previously vetted in a peer-review process, it has been suggested that this practice increases the likelihood of publication bias and may overrepresent positive treatment effects (McAuley, Tugwell, &Moher, 2000). In addition to the studies discussed in this review, the reader should consider research that was published after completion of the specified dates of this literature search. It is anticipated that future updates to this review will capture evolving research findings. Finally, due to the limited number of studies and differences in technologies and outcome measures used, the effect sizes obtained in this EBSR were not pooled. It is expected that as additional research becomes available, meta-analysis of the findings will be possible, reliable, and meaningful.

Conclusion

When making clinical decisions, clinicians should always use their own expertise to consider the needs and desires of the client in addition to the quality of research evidence, expert consensus opinion, potential benefits/harms, and costeffectiveness. DNR processing did not improve or degrade speech understanding in school-age children in two studies included in the current review, and outcomes during complex learning tasks were largely unaffected by DNR. There was limited evidence from one study suggesting a potential impact on HA satisfaction; however, additional research is needed to evaluate different DNR processing schemes as well as the influence of these features on comfort and ease of listening in realistic listening situations. Based on these preliminary results from a moderate body of evidence, DNR algorithms that do not reduce the audibility of speech could be used to increase listener comfort in school-age children. Research with younger children and greater degrees of hearing loss are needed before broader evidence-based recommendations can be made.

Based on a moderate body of evidence, HAs with a directional microphone response were found to improve speech recognition in noise in controlled situations where the target signal is located in front of the listener. However, decreased performance with directional response was noted in one article (Ricketts et al., 2007) when the target signal was located to the side or behind the listener, which highlights the importance of counseling

and the ability of the listener to orient toward the target signal for the benefits of this technology to be fully realized. Equivocal real-world satisfaction ratings also call attention to the need for additional research in this area to better understand the use of this technology in typical daily environments. Directional microphones have the potential to improve speech understanding in background noise in specific configurations of talker and background noise. Given the number of potential acoustic environments that a school-age child might experience in home, academic, and social situations, directional microphones may be beneficial in some situations and equivocal or detrimental in others. Therefore, recommendations regarding directional microphones with school-age children should be based on the child's ability to change the directional setting and the specific acoustic environments encountered by the child.

Acknowledgments

This evidence-based systematic review was supported by ASHA's National Center for Evidence-Based Practice in Communication Disorders (N-CEP). We thank Laura Cannon for updating the literature search and the following individuals for comments on an earlier version of this article: Patricia Stelmachowicz, Brenda Hoover, Ruth Bentler, Tracy Schooling, Tobi Frymark, and Rob Mullen. No author had any paid consultancy or any other conflict of interest with this document, and all authors agreed to declare no competing interests.

Sidebar

This systematic review was conducted under the auspices of the American Speech-Language-Hearing Association; however, this is not an official position statement of the Association.

An Evidence-Based Systematic Review of Frequency Lowering in Hearing Aids for School-Age Children With Hearing Loss

Author: McCreery, Ryan W; Venediktov, Rebecca A; Coleman, Jaumeiko J; Leech, Hillary M.

Publication info: American Journal of Audiology (Online) 21.2 (Dec 2012): 313-328.
ProQuest document link

Abstract: We developed 1 clinical question for this review, which addressed the comparison of hearing aids using frequency lowering compared to conventional processing amplification for outcomes of audibility, speech recognition, speech and language, and self- or parent-report for children with hearing loss. We systematically searched 26 databases for studies addressing a clinical question and meeting all inclusion criteria. We evaluated studies for methodological quality and reported or calculated effect sizes when possible. The literature search resulted in the inclusion of 5 studies. We implemented several different frequencylowering strategies across studies; 2 studies used nonlinear frequency compression, 2 used frequency transposition, and 1 used frequency compression with dynamic consonant boost. Whereas methodological limitations of the included studies preclude the formulation of strong conclusions, findings were generally positive across frequency-lowering strategies and outcomes. Additional high-quality research is needed in this area.

HA and Procedural Details

The primary goal of providing early and appropriate amplification for children is to provide access to the acoustic cues needed to support the acquisition of speech and language abilities. Although children who receive amplification and early intervention before 6 months of age generally have better communicative outcomes than cohorts who are identified or fit with hearing aids (HAs) after 6 months of age (e.g., Nelson, Bougatsos, &Nygren, 2008), children who receive early amplification still exhibit delays compared to their peers with normal hearing. Further, Moeller and colleagues (2007) found that children who received amplification before 6 months of age had significantly delayed phonological development for the fricative class of phonemes, despite acquiring other classes of speech sounds later than, but at a rate similar to, children with normal hearing. The authors attributed delayed fricative acquisition to the limited bandwidth of conventional processing (CP) HAs. Additional research supports the notion that early phonological delays may impact the acquisition of morphosyntax (Moeller et al., 2010) as well as having implications for speech perception in school-age children with hearing loss. Stelmachowicz, Pittman, Hoover, and Lewis (2001) demonstrated that audibility of a frequency range from 2 to 4 kHz was important for perception of fricatives in male speakers and a range from 2 to 8 kHz in female and child speakers. Given that hearing amplification is typically restricted to approximately 5 kHz (Stelmachowicz, Pittman, Hoover, Lewis, &Moeller, 2004), children with hearing loss may not adequately perceive high-frequency sounds such as /s/ and /z /, especially when listening to female speakers or their own productions. Several studies have examined the impact of extending bandwidth into the 9-10 kHz region. These studies suggest that extended bandwidth may improve word learning (Pittman, 2008; Pittman, Lewis, Hoover, &Stelmachowicz, 2005; Stelmachowicz, Lewis, Choi, &Hoover, 2007) and perception of important fricative sounds, such as /s/, which serve multiple linguistic functions in language (Stelmachowicz et al., 2001). Providing amplification for frequencies above 6 kHz is also supported by studies that showed improved speech recognition (Hornsby, Johnson, &Picou, 2011), listener preference (Ricketts, Dittberner, &Johnson, 2008), and acceptable noise level (Johnson, Ricketts,&Hornsby, 2009) in adult listeners.

The most obvious strategy for providing a broader bandwidth through HAs would be to develop HAs that can provide better high frequency audibility. Killion and Tillman (1982) reported on a HAwith bandwidth that extended up to 16 kHz, demonstrating that extended bandwidth hearings aids were technologically feasible. However, the extended bandwidth in that system had a limited output that would have only been appropriate for listeners with mild hearing losses. Despite this potential, the bandwidth of most digital HAs has been limited to

approximately 5 kHz. Evidence of incremental improvements in HA bandwidth has started to surface (Kreisman, Mazevski, Schum, &Sockalingam, 2010), but numerous barriers to extending the bandwidth of amplification up to 10 kHz in digital HAs have prevented more substantial progress. In regard to determining bandwidth, the Nyquist theorem states that in order to adequately capture the signal, the sampling rate must be at least two times higher than the frequency desired in the input signal. Therefore, to capture inputs up to 10 kHz, a 20 kHz minimum sampling rate is needed (Kuk &Baekgaard, 2009). The extension of bandwidth into higher frequencies can also constrain low-frequency amplification and output power as well as increase distortion and acoustic feedback (Boothroyd &Medwetsky, 1992; Kuk &Baekgaard, 2009). The relatively low level of speech energy at high frequencies means that greater gain is required at higher frequencies to achieve consistent audibility. Moore, Stone, Fullgrabe, Glasberg, and Puria (2008) documented that only approximately 40% of adults with mild to moderate high-frequency hearing loss could achieve audibility at 10 kHz due to the limited speech energy at frequencies above 4 kHz and the significant gain requirements for making those softsounds audible. An alternative to extending HA bandwidth is to use signal processing to lower the output frequency of the speech spectrum to overcome HA design and speech energy limitations at higher frequencies. Multiple signal processing approaches, collectively known as frequency lowering, shiftor compress high-frequency sounds into a lower frequency range, thus making previously undetectable high-frequency sounds perceptible to the hearing-impaired listener. Several different approaches to frequency lowering are currently available in wearable HAs such as nonlinear frequency compression (NLFC), frequency transposition (FT), and dynamic speech recoding systems that use a combination of frequency compression (FC) and temporal consonant enhancement, such as dynamic consonant boost (DCB). In NLFC, inputs to the HA above a specified start frequency are lowered in frequency by a specific compression ratio, preserving the frequency of signals below the start frequency (Glista et al., 2009). HAs with FT extract a spectral peak above a start frequency down one octave to preserve harmonic relationships in the input signal (Auriemmo et al., 2009). Devices that use FC with DCB compress the entire input spectrum of the HA and also provide additional gain to sounds with the temporal and spectral characteristics of fricative phonemes. Unlike extending the bandwidth of the HA, frequency lowering involves alteration of the distribution of speech energy as a function of frequency, which has raised concerns about potential negative impacts due to distortion of acoustic cues necessary for speech recognition and speech and language learning. Whereas audibility of highfrequency sounds has been demonstrated to be important for supporting speech and language development, novel word learning, and speech perception in children, questions remain about whether those developmental processes can be facilitated with frequency-lowering strategies.

Prior to the advent of cochlear implants, frequencylowering strategies were developed to be implemented with individuals with severe to profound hearing loss and limited potential for aided audibility (Braida et al., 1979). The resulting frequency-lowering strategies applied significant signal processing to the entire speech spectrum to maximize audible speech energy, often leading to significant distortion of acoustic speech cues. The initial use of frequency lowering across the entire speech spectrum was necessary for these listeners with extremely limited residual hearing to maximize the potential for making the speech spectrum audible. Consequently, early studies of frequency lowering using techniques of vocoding (Lippmann, 1980; Posen, Reed, &Braida, 1993) or slow playback (Beasley, Mosher, &Orchik, 1976; Bennett &Byers, 1967) demonstrated limited improvement and even degradation in speech intelligibility with hearing impaired users. Subsequent expansion of the candidacy recommendations for pediatric cochlear implantation has reduced the number of individuals with profound hearing loss who utilize HAs and has thus resulted in a greater proportion of HA users with mild to severe hearing loss. Consequently, the focus of the implementation of frequencylowering strategies has shifted to address the audiological and communication goals of these individuals who typically have adequate low- to mid-frequency audibility. More specifically, newer frequency-lowering algorithms, including NLFC (Glista et al., 2009) and FT (Kuk, Keenan, Korhonen, &Lau, 2009), are applied over a more limited frequency range, typically in the

high frequencies, with the goal of extending audibility to frequencies greater than the bandwidth of CP HAs. Because these more recent strategies are often applied only at higher frequencies, the significant spectral distortion that occurred with noise vocoders and slow playback systems is likely reduced. As a result, current frequency-lowering strategies, applied in a population of children with lesser degrees of hearing loss, may show more favorable results than previous approaches.

Studies of frequency-lowering devices are becoming more prevalent in both the pediatric and adult populations. Studies of frequency lowering with adults have shown mixed results depending on the subjects' degree of hearing loss and specific outcome measures used to establish benefit (Bohnert, Nyffeler, &Keilmann, 2010; Glista et al., 2009; Simpson, Hersbach, &McDermott, 2005, 2006). The effects of frequency lowering for children have the potential to be different than in adult studies for several important reasons. First, previous studies have demonstrated that children show larger improvements in speech understanding as the bandwidth of HAs is extended to higher frequencies (Stelmachowicz et al., 2004). The extent to which frequency lowering increases the audibility of high-frequency speech cues may result in more consistent improvements in speech understanding in children than have been observed in adults. Alternatively, children's speech understanding is more susceptible to spectral distortion than adults (Eisenberg, Shannon, Martinez, Wygonski, &Boothroyd, 2000), who are more easily able than children to use their knowledge of phonology and language to support speech understanding under conditions of significant distortion. Manufacturer data suggest that frequency lowering may be activated in as much as 80% of one company's pediatric HA fittings (Jones &Launer, 2010), supporting the need for an evidence-based systematic review (EBSR) to help clinicians understand the potential effects of this technology on outcome measures of HA efficacy in school-age children with hearing loss.

The purpose of this EBSR is to document the current, peer-reviewed research evidence pertaining to the use of frequency-lowering HA signal processing features in schoolage children with hearing loss. This review is part of a series of three reviews of current HA signal processing approaches for children. Other reviews in this series address directional microphone response/noise reduction and amplitude compression.

The clinical question was formulated for this review in consideration of the population, intervention, comparison, and outcome. The population under review is school-age children with hearing loss. The intervention is HAs with frequency-lowering signal processing, and the comparison is HAs without frequency lowering. Outcomes of audibility, speech recognition, speech and language, and self- or parentreport (subjective measures) are all important to consider in HA research (Hogan, 2007). There is an inherent relationship between these outcomes such that the level of audibility achieved will impact an individual's ability to recognize speech, an individual's ability to recognize speech will affect his or her expressive and receptive speech and language skills, and the degree to which the HA is able to improve audibility and speech recognition will likely influence the individual's satisfaction with the device. Ideally, one would hope to affect change in all four of these outcome areas, but research may demonstrate that a given HA signal processing strategy impacts one outcome category more or less than another. This research is valuable to understand the strengths and limitations of a hearing device. Audibility outcomes are objective measures of speech audibility (e.g., sound-field testing, real ear measures, articulation index scores [ANSI S3.5-1969], and Speech Intelligibility Index [SII] scores [ANSI S3.5-1997]. Speech recognition outcomes include objective measures of speech stimuli identification at the phoneme, nonword, word, and sentence level. Speech and language outcomes consist of formal and informal measures of receptive and expressive speech and language skills (e.g., Goldman-Fristoe Test of Articulation-Second Edition; Goldman &Fristoe, 2000; mean length of utterance). Finally, self- and parent-report outcomes include subjective measures such as satisfaction surveys and listening questionnaires.

Robey (2004) suggested that clinical research moves through five distinct phases beginning with exploratory research (Phases I and II) and progressing to efficacy (Phase III) and effectiveness research (Phase IV) prior to the investigation of cost-effectiveness (Phase V). Exploratory research typically comprises case studies and discovery-oriented small studies, whereas efficacy research usually includes controlled laboratory trial research.

Effectiveness research is often conducted in typical environments to determine the extent to which therapeutic benefit is attainable in realistic situations; cost-effectiveness research typically consists of cost-benefit analysis and is usually targeted to regulators, policy makers, and legislative bodies. In consideration of the known research literature associated with frequency-lowering signal processing and the current availability of this technology, we anticipated that the majority of research would fall into the efficacy phase of research. As such, the following clinical question was formulated for this EBSR: What are the effects of frequency-lowering technology as compared to standard HA bandwidth on audibility outcomes, speech recognition outcomes, speech and language outcomes, and HA self-report or parent-report outcomes for school-age children with hearing loss?

Method

Literature Search

This review is based on a systematic literature search conducted with a combined search strategy of several HA signal processing strategies. In addition to frequency lowering, the search also pulled studies addressing directional microphone response, noise reduction, and amplitude compression. The results of studies addressing these other HA signal processing features are discussed in separate reviews within this series (i.e., directional microphone/digital noise reduction and amplitude compression). The search strategy was developed by the fourth author, who has experience in conducting systematic literature searches (e.g., Frymark et al., 2010). We initially searched 26 databases (e.g., PubMed, CINAHL, PsycINFO, ERIC) for peer-reviewed literature published from 1980 to April 2010 using key words related to hearing loss and children (e.g., hearing aid, hearing instrument, amplification, child, frequency compression). In addition, we searched reference lists of all full-text articles to identify articles for potential inclusion and conducted specific searches based on prolific authors and accepted articles. After an extensive time lapse prior to publication, we updated the literature search in July 2011 to capture the most recently published information. Specific details pertaining to the literature search and update, including a list of databases, key words, and search dates, can be found in McCreery, Venediktov, Coleman, and Leech (2012).

The inclusion criteria required studies to have an experimental or quasi-experimental design, to address the clinical question, and to have been published in English. The sample must have included children between the ages of 5 and 17 years with a documented hearing loss. Studies including participants outside of the target age range were excluded unless the mean age fell within the target age range or if the data could be split for separate analyses. To be included, study authors must have provided comparative data of outcomes with and without the target HA feature using wearable devices and using signal processing approaches that were currently available in commercial HAs. Operational definitions are included in McCreery et al. (2012). The second and third authors independently read abstracts and full-text articles to determine articles for final inclusion. Interrater reliability was calculated using the kappa statistic (k) and percent agreement, and disagreements were resolved by consensus or with the advisement of the first author (R.W.M.). Landis and Koch's (1977) labels describing relative strength of agreement were applied to k statistics: <.00 = poor, .00-.20 = slight, .21-.40 = fair, .41-.60 =moderate, .61-.80 = substantial, and .81-1.00 = almost perfect.

Critical Appraisal

Individual studies. The second and third authors critically and independently appraised the quality of each accepted article using up to seven appraisal criteria modified from the ASHA levels-of-evidence scheme (Cherney, Patterson, Raymer, Frymark, &Schooling, 2008; Fey et al., 2010; Mullen, 2007). This scheme was developed by the ASHA National Center for Evidence-Based Practice in Communication Disorders along with the ASHA Advisory Committee for Evidence-Based Practice. It was piloted prior to its adoption in 2008. The scheme was adapted for evaluation of within-subject repeated measures designs in consideration of the common threats to internal validity (Portney &Watkins, 2009). The first author provided input regarding the appropriateness of the scheme as it pertained to HA research. The raters both had previous experience (e.g.,

Gosa, Schooling, &Coleman, 2011; Rousch, Frymark, Venediktov, &Wang, 2011) and training evaluating the methodological quality of scientific literature. The appraisal criteria were as follows: (a) an adequate description of study protocol (i.e., sufficient detail provided for replication), (b) assessor blinding, (c) an adequate description of random sampling of participants, (d) randomization to condition or sequence of conditions, (e) counterbalancing of the order of conditions (applicable only to within-subject designs), (f) reporting of p values (or the provision of data to calculate that statistic), and (g) reporting of effect sizes and their confidence intervals (or the provision of data to calculate those statistics). One point was awarded for each appraisal criterion fully met. Interrater reliability was calculated using k (weighted as appropriate) and percent agreement. Neither rater had an extensive audiological background. As such, the knowledge and experience of the first author was requested in instances of uncertainty to clarify background audiological concepts.

Body of evidence. The strength of the body of evidence available to address the clinical question posed in this review was evaluated using an evidence grading scheme developed by the Cincinnati Children's Hospital Medical Center (2011a). This scheme considers domains of hierarchy, bias, quantity, magnitude of effect, and consistency of evidence, all considered to be important for evaluating bodies of evidence (Coleman, Talati, &White, 2009), and provides an objective and straightforward grading system. The second and third authors independently evaluated the quality of individual studies using the Cincinnati Children's HospitalMedical Center controlled clinical trial appraisal worksheet (Cincinnati Children's Hospital Medical Center, 2011b) to arrive at a quality level for each study. Agreement was calculated using k and percent agreement. Next, the two raters independently evaluated the body of evidence for the clinical question using the Cincinnati Children's Hospital Medical Center evidence grading worksheet (Cincinnati Children's Hospital Medical Center, 2011a). Evidence was graded high, medium, low, or grade unassignable. A high grade of evidence was based on a high quality systematic review, more than one high quality randomized controlled trial or more than five high quality nonrandomized controlled trials or cohort studies. Highly graded bodies of evidence indicate that further research is not likely to change the level of confidence in the answer to the clinical question. A moderate grade is based on a high quality randomized controlled trial or multiple high or low quality systematic reviews, randomized and nonrandomized controlled trials, cohort studies, or more than five casecontrol studies. Moderate evidence suggests that further research is likely to have an important impact on the answer to the clinical question. Low evidence is based on local or published consensus but not research evidence. The grade was unassignable if there was insufficient evidence and lack of consensus. Questions and interrater disagreements were resolved by consensus or under the advisement of the first author.

Data Extraction and Analysis

The second and third authors summarized the critical features of each study including study design, characteristics of the population, previous HA usage, test HA features, study protocol, outcome measures, findings, and limitations. The first author reviewed summaries for accuracy and completeness. This information is located throughout the tables and text of this review.

Effect size, r, was calculated for all studies providing sufficient data. For studies providing raw data, the pointbiserial correlation coefficient, rpb, was determined using an online calculator (Lowry, 2010). Effect size, r, was also approximated for several studies providing F statistics or paired t values and corresponding degrees of freedom (df; Garbin, n.d. [online calculator]; Rosenthal &DiMatteo 2001, respectively). The confidence interval surrounding each effect was determined from the sample size and effect size estimate using another online calculator (Garbin, n.d.). Effect sizes favoring the experimental technology (i.e., frequency lowering) investigated in each study were assigned a positive value, whereas effect sizes favoring the control condition (i.e., HAs with inactivated or unavailable frequency lowering) were assigned a negative value. Effect size magnitudes were labeled small, medium, or large according to the scale suggested by Cohen (1992) such that r = .10 is a small effect, r = .30 is a medium effect, and r = .50 is a large effect. The p values were calculated in several studies in which raw data were provided but statistical significance for our sample of interest was not

reported. The Wilcoxon signed ranks test was used due to the small number of participants.

We discuss the statistical significance of included study findings throughout the text of this review. A finding was considered to be significant if the confidence interval surrounding the effect size did not include the null value and/or if the p value (provided by the author or calculated as indicated above) was less than or equal to .05. For each clinical question, results were further analyzed to determine if any data trends were apparent which may suggest an impact of study design or study quality on the results.

Results

Study Selection

Of the 376 citations retrieved, we rejected 168 after reading the abstract, 171 after reading the full text, and 14 after detailed analysis (see McCreery et al., 2012, for flow chart and reasons for rejection).We fully accepted 23 articles for inclusion in the series of EBSRs; six articles (five studies) pertained to frequency lowering, and the remaining studies addressed either directional microphones/digital noise reduction or amplitude compression and are discussed in separate reviews. The authors of one study (Wolfe et al., 2010) included in this review provided follow-up data in a separate article (Wolfe et al., 2011).

Interrater Reliability

Interrater reliability for sifting articles for inclusion or exclusion was substantial (k = .67; percent agreement = 87.9%), and all interrater disagreements were resolved by consensus. Interrater reliability for the critical appraisal of individual studies and the body of evidence was also calculated using the k statistic (weighted as appropriate) and percent agreement for each of the seven appraisal points based on the raters' agreement across the five studies. These values ranged from substantial agreement ("effect size," k = .62; 80%) to perfect agreement ("assessors blinded," "sampling," "allocation," "counterbalancing," k = 1.00; 100%) with the exception of two appraisal points related to the adequacy of study protocol description and availability/calculability of p values for which interrater reliability was poor (k = 0; 80%). For the first appraisal point, raters agreed that there was an adequate description of study protocol for four of the five studies. For the remaining study, the authors disagreed on the adequacy of the protocol description and resolved by consensus that the study provided an inadequate description. For the appraisal point regarding the reporting or calculation of p values, the raters agreed that the p value was reported or calculable in four of five studies. The one p value disagreement was resolved via consensus to have been reported or calculable as well. The raters arrived at full independent agreement (k = 1.00; 100%) when identifying the individual study quality levels as the first step in determining the grade of the body of evidence. Individual rater responses are included in the supplementary materials associated with this article.

Study Findings

We obtained five studies that addressed the clinical question posed for this review. Two sets of researchers (Auriemmo et al., 2009; Smith, Dann, &Brown, 2009) studied the use of FT, two (Glista et al., 2009; Wolfe et al., 2010, 2011) investigated NLFC, and one (Miller-Hansen, Nelson, Widen, &Simon, 2003) used FC with DCB. As a result of the heterogeneity (e.g., differences in specific outcome measures used, differences in severity of hearing loss, differences in compression thresholds and stimulus input levels) and small number of included studies for each clinical question, effect sizes were not averaged across studies.

Frequency Compression With DCB

Miller-Hansen and colleagues (2003) used FC with DCB and collected audibility outcomes for 19 children and speech recognition outcomes for 16 children who had previous outcome data with CP HAs. This study was a repeated measures design with a quality appraisal score of 2/7 (see Table 1 for full list of appraisal criteria and quality scores). As noted in Table 2, children were experienced HA users and had hearing losses ranging from mild-moderate to profound. Outcome measures were obtained 1 month post-fitting of the frequency-lowering device and compared to previous measures with the children's CP HAs. Whereas effect sizes were not calculable for any outcomes in this study, aided thresholds significantly favored the use of the

frequencylowering device over CP at 500, 1000, and 2000 Hz ($p < .0001$); word recognition outcomes also favored the use of frequency lowering ($p = .006$).

Frequency Transposition

Two studies (Auriemmo et al., 2009; Smith et al., 2009) investigated the effect of FT as found in the Widex Inteo 9 and 19 HAs compared to CP in the same or a previously worn device. Both studies were repeated measures design studies with quality appraisal scores of 2/7 (see Table 1). The children in these studies ranged from 6 to 14 years of age with sloping sensorineural hearing losses. They were all experienced HA users (see Table 2). In Auriemmo et al. (2009), speech recognition, speech production, and self-report outcome measures were collected for the study HAs in CP and FT settings at baseline and/or after 3- or 6-week acclimatization and training periods. In the study by Smith and colleagues (2009), speech recognition and speech production outcome measures were obtained after 12 and 24 weeks, respectively, for the study aids in FT mode as compared to the children's previous performance with their own CP HAs.

Speech recognition outcomes. Auriemmo and colleagues (2009) reported no statistically significant differences for a nonsense syllable test presented at 30 dB HL and 50 dB HL between FT and CP at baseline and after 3 weeks of training with each type of processing. There was a significant difference ($p < .05$) between scores after 6 weeks of training in the FT program compared to CP at baseline and after 3 weeks of training at 30 dB HL for consonant recognition and after 3 weeks of training compared to CP at baseline for vowel recognition. Additionally, scores after 6 and 3 weeks of training with the FT settings were significantly better than scores with FT at baseline for consonant and vowel recognition at 30 dB HL (see Table 3). Smith et al. (2009) found statistically significant differences ($p \leq .01$) on tests of word and phoneme perception for participants using frequency lowering after 12 weeks over previous scores with CP HAs.

Speech and language outcomes. Both Auriemmo et al. (2009) and Smith et al. (2009) investigated differences in speech production outcomes after use of FT. Smith et al. noted significant differences ($p = .01$) in the children's scores on the Goldman-Fristoe Test of Articulation-Second Edition (Goldman &Fristoe, 2000) after 24 weeks of HAs with FT as compared to their previous scores without FT. Children in the Auriemmo et al. study also demonstrated significantly better ($p < .05$) production of /s/ and /z/ in reading and conversation after 6 weeks of auditory training with FT as compared to their previous productions after 3 weeks of training without FT.

Self- or parent-report outcomes. Investigators of both studies (Auriemmo et al., 2009; Smith et al., 2009) addressed HA self-report, teacher-report, or family-report outcomes for children using frequency-lowering devices. No measures of effect size were reported or calculable for either study. In Auriemmo et al. (2009), significant differences on subjective questionnaires favoring FT were reported after 6 weeks of training ($p < .05$) compared to 3 weeks of training with CP. Also, the majority of children reported a preference for the FT setting over the default HA setting when listening to bird songs, music, and female discourse. Smith et al. (2009) investigated family perceptions of HA benefit. Only four of the six families responded to the researcher-generated questionnaire. Of those who responded, all reported increased responses to specific high-frequency sounds, observed some degree of change in their child's speech production, and noted that their child heard better during one-on-one conversations. Some families also noted that their child requested repetition less frequently.

Frequency Compression

Outcomes using NLFC were reported in two studies (Glista et al., 2009; Wolfe et al., 2010, 2011). Glista et al. (2009) used a repeated measures design and received a quality appraisal score of 2/7. Wolfe et al. (2010, 2011) randomized and counterbalanced study conditions and was therefore classified as a crossover design with a quality appraisal score of 5/7 (see Table 1). Children in these studies were between the ages of 6 and 17 years and demonstrated sloping sensorineural hearing loss that was either moderately severe to profound (Glista et al., 2009) or mild-moderate to moderately severe (Wolfe et al., 2010, 2011; see Table 2). The

acclimatization period ranged from 3 weeks to 1.3 years in Glista et al. and 6 weeks in each condition in Wolfe et al. Both studies provided audibility and speech recognition outcomes, and Glista et al. also provided self- or parent-report outcome measures.

Audibility outcomes. Glista et al. (2009) and Wolfe et al. (2010, 2011) provided audibility outcomes consisting of aided thresholds using tones and/or high frequency speech sounds (i.e., /s/ and /sh/) for both NLFC and CP conditions. Effect sizes were calculable for Wolfe et al.; all were large and significant (they ranged from r = .60, 95% CI [.13, .85] to r = .82, 95% CI [.53, .94]; see Table 4). These findings favored the use of NLFC over CP conditions. Wolfe et al. (2011) also provided follow-up data at 6 months which revealed no significant change from audibility measures after 6 weeks of use. Although effect sizes were not available for the study by Glista et al., aided thresholds for at least one phoneme, /s/ or /sh/, were significantly ($p < .05$) better for 2 of 10 participants with NLFC as compared to CP. Group level statistical analysis was not completed for the child data in isolation from the adult data; results of a repeated measures analysis of variance (ANOVA) completed with combined adult and child data revealed a significant main effect of processor type, favoring NLFC over CP. Glista et al. included age group as a between-subjects variable and did not indicate a main effect of age. Further, results from the multiple linear regression analysis indicate that age group was not significantly correlated to the results.

Speech recognition outcomes. Both studies provided efficacy data pertaining to speech recognition outcomes; however, effect sizes were available only in Wolfe et al. (2010, 2011). Wolfe et al. measured discrimination of plurals and several phonemes in tokens, that is, /asa/, /ada/, /afa/, /aka/, /asha/, and /ata/, as well as performance on a speech-in-noise test. A large and statistically significant effect was noted on the University of Western Ontario Plurals Test (Glista &Scollie, 2012), favoring NLFC (r = .81, 95% CI [.51, .93]). Two tokens, /asa/ and /ada/, revealed large and statistically better outcomes for NLFC over CP (r = .57, 95%CI [.03, .85], $p < .05$; r = .56, 95% CI [.07, .83], $p < .05$, respectively). Effect sizes were not calculable for tokens /ada/, /afa/, /aka/, or /asha/, and effect sizes were not significant for tokens /ata/ and /asa/ at 6000 Hz. None of these tokens were statistically significant. Performance on the Bamford-Kowal-Bench Speech-in-Noise Test (Etymotic Research, 2005) was neither clinically nor statistically significant. There were no statistically significant differences on any speech recognition outcomes at 6 month follow-up with the exception of a large and significant improvement in discrimination of tokens /ada/ (r = .68, 95% CI [.26, .88], $p < .01$) and /asa/ (r = .62, 95%CI [.13, .87], $p < .05$) filtered at 6000 Hz for the frequencylowering condition compared to results at 6 weeks. Glista and colleagues (2009) measured participants' scores on a speech recognition test using a HA with NLFC activated or deactivated. Group-level analysis was not performed for child data in isolation; a repeated measures ANOVA completed with adult and child data combined revealed that speech recognition scores were significantly higher in the NLFC condition as compared to the CP condition for consonant and plural stimuli. However, scores were not significantly different for vowels. Age group was included as a betweensubjects variable, and it was not indicated that there was a main effect of age. The authors' results of the multiple linear regression indicated no significant correlation of age group on the results for consonant recognition but a significant correlation for plural recognition. Those findings revealed that the children in the study received greater benefit associated with the NLFC condition for the plural recognition task than adults. Visual depiction of the child data support that, on average, children's speech recognition scores were higher in the NLFC condition than the CP condition for consonant and plural stimuli, although the statistical significance and magnitude of this effect are unclear. As noted in Table 4, individual analysis of the child data indicated a statistically significant ($p < .05$) difference in speech recognition scores favoring NLFC for consonants and plurals for 4/10 participants and 7/11 participants, respectively. There was not a statistically significant difference between the processing types for any children with the vowel stimuli.

Self- or parent-report outcomes. No effect sizes or p values were reported or calculable in either study; however, Glista et al. (2009) noted that 64% of children preferred the NLFC device over CP, 9% preferred CP

over NLFC, and 27% preferred neither of the processing conditions.

Trend Analysis by Study Design and Quality

Table 1 depicts the specific appraisal points met or unmet for each study as well as the total quality score. Repeated measures designs were used in four studies. One study used a crossover design (Wolfe et al., 2010, 2011). In that study, participants were randomly allocated to the sequence of conditions and counterbalanced. Study quality scores ranged from 2/7 (Auriemmo et al., 2009; Glista et al., 2009; Miller-Hansen et al., 2003; Smith et al., 2009) to 5/7 (Wolfe et al., 2010, 2011). Although the majority of these studies did provide an adequate description of study protocol and provided measures of statistical significance (or sufficient data to calculate statistical significance), studies did not collect a random sample of participants and in many instances did not randomize to a sequence of conditions or counterbalance to avoid practice effects or blind assessors. The findings were further analyzed to determine whether there were any apparent effects of study design and study quality on results. Visual inspection does not suggest that differences in study quality were responsible for trends in the results. Auriemmo et al. (2009) explained that counterbalancing was not used due to the ethical implications of providing the children with new technology and subsequently removing it as would be necessary in a crossover design. Glista et al. (2009) used a withdrawal study in order to eliminate uncertainty that significant findings in favor of the experimental treatment were erroneously attributed to practice or acclimatization effects. The methods used to quantify high-frequency audibility varied across studies. For example, Glista and colleagues completed a test for cochlear dead regions in their participants to optimize audibility of frequency-lowering settings, whereas Auriemmo et al. did not attempt to provide amplification above 3000 Hz. These decisions could have resulted in differences in high-frequency audibility between the different frequency-lowering strategies. Another consideration is that confounding variables within a study may significantly impact the results. Potential confounds noted in this review included unequal amounts of total training time provided in the frequency lowering and CP conditions in Auriemmo et al. and the use of different HA devices (children's own HAs were used to assess CP) in Miller-Hansen et al. (2003).

Overall Quality of Body of Evidence

This body of evidence consists of one low-quality randomized controlled trial (Wolfe et al., 2010, 2011) and four low-quality controlled clinical trials. Findings across these studies were generally consistent and favored the use of frequency lowering over CP amplification for outcomes assessed. This body of evidence is graded moderate, which suggests that further research is likely to have an important impact on conclusions regarding this clinical question.

Discussion

We included five studies in the current review that examined outcome measures for HAs with frequency lowering. Two of the included studies evaluated FT (Auriemmo et al., 2009; Smith et al., 2009), two studies evaluated NLFC (Glista et al., 2009; Wolfe et al., 2010, 2011), and one study evaluated FC with DCB (Miller-Hansen et al., 2003). Overall, studies of frequency lowering reported equivalent or positive results across studies and outcome measures.

Frequency Compression With DCB

Limited evidence from the one study (Miller-Hansen et al., 2003) that reported outcomes for FC with DCB indicated significantly improved audibility and speech recognition outcomes for children using this technology compared to their previous performance with CP HAs. This study suggests that the 1-month acclimatization period was sufficient for children to adapt successfully to these devices. It is unclear whether additional acclimatization would continue to result in significantly improved audibility and speech recognition outcomes. A notable limitation of this study is the use of two different devices (i.e., the experimental frequency compression device and the children's own CP HAs) to assess the two different conditions. We cannot be certain that the study findings were a result of frequency compression and not a result of other uncontrolled differences between the two devices. Also, lack of a control group and lack of counterbalancing reduce the internal validity

of the study and ability to control the influence of maturation on speech recognition outcomes. Further, the magnitude of the effect of FC with DCB is unknown because effect sizes were not presented and we were unable to calculate effect sizes from available data. Additional research with FC with DCB is necessary in order to draw meaningful conclusions regarding the impact of this technology for children with hearing loss.

Frequency Transposition

Evidence from two studies (Auriemmo et al., 2009; Smith et al., 2009) addressed the use of FT in theWidex Inteo 9 and 19 HAs. Neither study provided sufficient data comparing audibility outcomes with FT to outcomes with CP amplification for statistical analysis; however, visual analyses of four audiograms in Auriemmo et al. (2009) depicting sound-field thresholds with FT and without FT in the right and leftears clearly suggest lower thresholds for all participants in both ears with FT. Neither study provided speech recognition, speech and language, or self- or parent-report outcomes.

Although no differences in speech recognition were noted in Auriemmo et al. (2009) after 3 weeks of training in each condition, significant differences were noted for consonant recognition after 6 weeks of training in the FT condition compared to outcomes after 3 weeks in the CP amplification condition. Further, scores after 3 weeks and 6 weeks of training with FT were significantly better than baseline FT scores. Similarly, Smith and colleagues (2009) noted a significant difference between phoneme perception scores in favor of FT following a 12-week acclimatization period in comparison with scores associated with previous use of CP amplification. Findings from Auriemmo et al. and Smith et al. suggest that length of acclimatization may have a significant impact upon speech recognition outcomes and warrants further systematic evaluation. Unfortunately, the lack of a control group and counterbalancing in both of these studies does not allow us to rule out practice, training, or maturational effects. Also, the duration of the training was a confounding variable because unequal amounts of training were provided in each condition. We cannot be certain that study findings reflect differences caused by FT and not additional auditory training. Auriemmo et al. noted that auditory training alone was unlikely to have been responsible for the findings because outcomes on a nonsense syllables test were similar at time of fitting with the default condition and after 3 weeks of training.

Speech and language outcomes are consistent with speech recognition findings from both studies. Smith et al. (2009) noted significantly higher scores on an articulation test after 24 weeks of FT use as compared to previous scores associated with the use of CP amplification. Auriemmo et al. (2009) noted significantly better production of /s/ and /z/ in the study participants after 6 weeks of training with FT as compared to previous scores after 3 weeks of training with CP amplification. As with speech recognition outcomes, practice effects, training, and maturation (i.e., the passage of time between the two speech and language measurement periods in each condition), all threats to internal validity and potential confounding variables, such as differences in the length of training between CP and FT, may account for the significant difference in findings.

Limited evidence from one study (Auriemmo et al., 2009) indicated a child preference for FT after 6 weeks of acclimatization compared to CP amplification. In the study by Smith and colleagues (2009), families noted improvements in children's auditory functioning with FT. The lack of effect sizes for the majority of these findings limits the characterization of the magnitude of the effect of FT in these studies. Because blinding was not used in these studies, results of subjective preference measures should be viewed with caution. Without blinding children, parents, and teachers to the experimental processing, positive effects may be related to expectations of improvement related to labeling, and negative effects may be moderated by the same expectations. Such effects have been documented in HA outcomes research with adults (Bentler, Niebuhr, Johnson, &Flamme, 2003) and can significantly impact listeners' perceptions and expectations about benefit.

Frequency Compression

Authors of two studies (Glista et al., 2009; Wolfe et al., 2010, 2011) investigated the use of NLFC on audibility and speech recognition outcomes in children (and adults: Glista et al., 2009) with hearing loss. Although significant findings were reported for audibility outcomes and consonant and plural speech recognition

outcomes in Glista et al. (2009), these findings included both adult and child data combined. Additional statistical analyses indicated that there was not significant variability between adult and child findings for /s/ and /sh/ detection and consonant recognition, and that the variation in plural recognition resulted from larger improvement with NLFC for children as compared with adults. However, it is uncertain whether statistical analysis of the child data in isolation would have sufficient power to produce a statistically significant result or a large effect size. Individual audibility and speech recognition data from Glista et al. indicated that some, but not all, participants had significantly better outcomes with the use of NLFC.Wolfe et al. (2010, 2011) reported statistically significant findings favoring the use of NLFC for all tested thresholds (4000-8000 Hz) and phonemes /s/ and /sh/. Additionally, significant speech recognition outcomes were noted, favoring NLFC for plurals and some speech tokens (/asa/, /ada/, /ata/), but not for sentences in noise. The magnitudes of these effects were all medium to large. Unlike the previous study designs discussed, Wolfe et al. used a counterbalanced crossover design with equal (6 week) acclimatization periods for each condition, thereby eliminating the concern for practice, order, training, and maturation effects noted in previous studies.

Implications of Findings

The purpose of frequency-lowering strategies is to increase the audibility of the high frequencies to minimize the negative consequences of limited HA bandwidth. The authors of the studies included in this review evaluated three different frequency-lowering strategies and overall contribute to a moderate body of evidence, suggesting that additional research evidence may have an important impact on conclusions regarding the use of this technology. Across frequencylowering strategies, audibility, as measured by aided puretone thresholds and /s/ and /sh/ detection thresholds, was consistently improved by frequency lowering. Aided detection of pure tones in quiet has limited utility for predicting audibility for speech in realistic listening environments (Stelmachowicz &Lewis, 1988) because thresholds are measured at levels significantly below the average level of speech sounds as processed by hearing aids. Improvements in the detection of fricative sounds would be expected to translate more directly into measurable improvements in speech recognition. Therefore, if clinicians are interested in documenting changes in audibility with frequency lowering, differences in the detection of specific phonemes or phonemic contrasts may be a more valid approach than aided pure tone thresholds in sound field. Specifically, aided pure tone thresholds are likely to be strongly affected by other signal processing systems in the HA, such as amplitude compression or feedback management. Additionally, the researchers who examined NLFC (Glista et al., 2009; Wolfe et al., 2010, 2011) and FC with DCB (Miller-Hansen et al., 2003) used a version of the desired sensation level (DSL; Scollie et al., 2005) prescriptive formulas to verify the gain and maximum output of the HA, which is widely used in pediatric HA fitting. In both of the studies of FT, investigators used the manufacturer's proprietary prescriptive approach (Sensogram). Differences in prescriptive formulae for the types of frequency lowering included in the current review could have resulted in variations in audibility that were related to the prescriptive approach rather than the frequency lowering. Discrepancies in the prescriptive approach make comparisons across studies and types of frequency lowering difficult to attribute to frequency lowering alone. Additionally, generalization to other prescriptive approaches is also not possible.

For studies in the current review, speech recognition outcomes were also generally more favorable with the use of frequency lowering as compared to CP amplification; however, due to methodological weaknesses in the majority of studies, we cannot be sure that the benefit is truly a result of the frequency lowering or that it is clinically significant. The authors of one study (Wolfe et al., 2010, 2011) that was of relatively higher methodological quality did show meaningful and statistically significant benefit of NLFC for some, but not all, speech recognition subtests. These differences across stimuli may have been impacted by varying degrees of sensitivity to the morphosyntactic cues, such as plurality. Specifically, since frequency-lowering strategies are most likely to facilitate detection and understanding of highfrequency speech sounds (such as /s/ and /z/), the largest benefits of these strategies should be realized in tests that are sensitive to morphology at the word level. Speech recognition tests that provide more opportunities to identify plurals, such as the University ofWestern

Ontario Plurals Test (Glista &Scollie, 2012), allow direct assessment of morphology at word level contrasts that are likely to be affected by frequency lowering. Speech recognition tests that include sentence-level syntactic cues, such as the Bamford-Kowal-Bench Speech-in-Noise Test (Etymotic Research, 2005), or do not contain a sufficient number of high-frequency phonemes (Phonetically Balanced Kindergarten words; Haskins, 1949) may not accurately reflect the impact of frequency lowering on all aspects of speech understanding. Additionally, sentences may provide listeners with semantic and syntactic cues that support speech recognition even when acoustic cues are limited. Because current frequency-lowering strategies are applied primarily to the high frequencies where speech energy may be limited, standardized estimates of audibility such as the SII (ANSI S3.5-1997) do not predict large improvements in the overall speech recognition score if the audibility of high-frequency bands is enhanced. The limitations of the SII for predicting speech recognition was highlighted in work by Gustafson and Pittman (2010), who reported variability in speech recognition for adults and children with normal hearing between conditions with varying bandwidth but matched for audibility on the SII. Given the significance of high-frequency audibility for the development of phonological (Moeller et al., 2007) and morphosyntactic (Moeller et al., 2010) skills as well as novel word learning (Pittman, 2008), the limitations in enhancing the audibility of high-frequency sounds for speech recognition should not be interpreted as being insignificant to a child's development.

Speech and language outcomes were reported only in the two studies that investigated FT (Auriemmo et al., 2009; Smith et al., 2009). As previously indicated, we cannot conclude that the improvements noted in these outcomes were a result of FT because maturation and practice effects were not addressed by appropriate control conditions. Whereas measures of audibility and speech recognition are more directly linked (i.e., less impacted by factors external to hearing) than speech and language measures to HA signal processing, speech and language measures are also important to investigate because these outcomes have enormous impacts on a child's academic abilities and social well-being.

Measures of user satisfaction are also critical in HA research because the perceptual benefits of amplification do not always correspond to increased listener satisfaction. For example, in studies of digital noise reduction with adult listeners, speech recognition was not altered by the signal processing, but significant improvements in ratings of sound quality were observed (Ricketts &Hornsby, 2005). Limited findings provided in several studies included in this review suggest that many children prefer frequency-lowering devices to CP amplification and that subjective improvements in hearing are noted by many children and their families with the use of frequency lowering.

Directions for Future Research

The current research with frequency-lowering signal processing strategies is in the efficacy phase of research, meaning that the outcomes were primarily measured in controlled laboratory environments. The frequency-lowering strategy of interest in these studies was the independent variable; other signal processing variables generally were controlled for or deactivated. These studies all implemented repeated measure designs to compare children's outcomes related to CP amplification to outcomes associated with frequency-lowering amplification. Although one study (Wolfe et al., 2010, 2011) controlled for potential order effects by counterbalancing amplification conditions, the majority of studies did not. Future efficacy research in this area should carefully control for order effects by randomization and counterbalancing to ensure that all results can be attributed to the use of frequency lowering and not accounted for by practice or, in studies of extended duration, maturation. As the length of the acclimatization period and differences in individual participant characteristics appear to influence outcomes, additional research to determine ideal candidacy and training/acclimatization periods may be warranted. Future research should also include measures of effect size in order to evaluate the magnitude of the impact of frequencylowering strategies compared to CP amplification.

Once the efficacy of different frequency-lowering strategies is established with additional research, subsequent research may focus on comparative efficacy and effectiveness research. Comparative efficacy research will be

necessary to determine whether one type of frequency lowering is more beneficial than others, which includes consideration of the influence of the hearing characteristics of the child or other external variables. Also, since most HAs incorporate more than one signal processing strategy into the same device, efficacy and effectiveness research will be needed to investigate how audibility, speech recognition (especially morphosyntax), speech and language, and satisfaction outcomes are affected by the interaction of multiple signal-processing strategies (e.g., directional microphones, wide dynamic range compression, and FT) in real-world environments.

Although several of the studies included in the current review examined the influence of acclimatization on speech recognition outcomes (Auriemmo et al., 2009; Smith et al., 2009; Wolfe et al., 2010, 2011), variations in the time course and degree of improvement over time suggest that factors related to the acclimatization process should be examined. Immediate improvements in audibility are anticipated to support long-term benefits for speech recognition and speech and language outcomes. Therefore, the influence of acclimatization on speech and language outcomes should also be examined, preferably using control groups or other methodological approaches to minimize the influence of maturational and practice effects on outcomes. Two studies that included measurements at two different time intervals (Auriemmo et al., 2009; Wolfe et al., 2010) demonstrated that initial improvements in speech recognition outcomes were either maintained or increased after varying periods of experience (with or without additional auditory training) with the signal processing. Until further research into the time course of improvements related to frequency lowering can be reported, clinicians should anticipate that improvements in outcomes may be observed as listening experience increases over time.

The studies included in the current review also include a heterogeneous sample of hearing impaired children with variations noted in age as well as severity of hearing loss, extent of experience with CP amplification, length of exposure to aided audibility, and other variables that could influence the degree to which frequency-lowering benefits may be observed. These differences across studies are not conducive to developing consistent candidacy for frequency lowering in general or for the three specific implementations of frequency lowering used in different studies. The extent to which these and other variables influence outcomes with frequency lowering should be explored to assist clinicians in making decisions about whether or not frequency lowering is appropriate and, if so, what parameters should be selected to optimize audibility.

Limitations

There are several limitations to the current review. One is the inclusion criterion, which restricted accepted articles to those reporting on a signal processing strategy that is currently implemented in commercial HAs. This restriction eliminated studies that used frequency vocoding and outdated forms of FT, which may have provided a historical background of the earlier outcomes of frequency lowering. In addition, only studies that were published in English were included, which likely reduced the total number of studies that could have been evaluated. Also, the decision was made to accept only studies published in a peer-reviewed journal in order to ensure that all studies received initial vetting and to reduce the likelihood of including biased studies; however, it has been suggested that the exclusion of nonpublished research may introduce publication bias into the systematic review. Because research on this topic continues to be conducted and published, the reader is encouraged to consider all literature published after the systematic search conclusion dates specified in this EBSR. We expect that future updates to this review will capture additional published research. The results of the systematic review were not pooled in a meta-analysis due to the variations across frequency-lowering strategies and the limited number of effect sizes available. Direct comparisons between types of frequency lowering were not possible due to multiple methodological differences between studies as well as the fact that studies of FT used the manufacturer's proprietary prescriptive approach, whereas studies of NLFC and FC with DCB used the DSL prescriptive approach to determine HA gain and maximum output levels. Differences in audibility between prescriptive approaches that are unrelated to frequency lowering confound potential comparisons across frequency-lowering strategies for all of the outcomes in the current review.

Conclusion

Based on a moderate body of evidence, current research provides preliminary support for the use of frequency-lowering strategies for school-age children with sloping hearing loss of at least moderate degree in the high frequencies. The majority of research in this area contains methodological limitations that restrict our ability to draw strong conclusions; however, outcomes were generally positive across outcome measures. Additional research is needed in order to draw confident conclusions regarding the use of frequency lowering. For example, individual variation in observed benefit from frequency-lowering strategies, as reported in one study, may reflect differences in audibility. Given the potential heterogeneity of outcomes across school-age children, clinicians should use clinical outcomes to monitor children's auditory development milestones and aided speech recognition to support clinical decisions about the implementation of frequency lowering with their pediatric patients. Future research should attempt to resolve issues surrounding candidacy for frequency-lowering strategies as well as the timeframe and extent of any acclimatization that may occur.

Acknowledgments

This evidence-based systematic review was supported by ASHA's National Center for Evidence-Based Practice in Communication Disorders (N-CEP). We thank Laura Cannon for updating the literature search and the following individuals for comments on an earlier version of this article: Patricia Stelmachowicz, Brenda Hoover, Ruth Bentler, Tracy Schooling, Tobi Frymark, and Rob Mullen. No author had any paid consultancy or any other conflict of interest with this document, and each author agreed to declare no competing interests.

Sidebar

This systematic review was conducted under the auspices of the American Speech-Language-Hearing Association; however, this is not an official position statement of the Association.

The Effects of Aging on Auditory Processing and Cognition

Author: Tun, Patricia A; Williams, Victoria A; Small, Brent J; Hafter, Ervin R.

Publication info: American Journal of Audiology (Online) 21.2 (Dec 2012): 344-50.
ProQuest document link

Abstract: To briefly summarize existing data on effects of aging on auditory processing and cognition. A narrative review summarized previously reported data on age-related changes in auditory processing and in cognitive processes with a focus on spoken language comprehension and memory. In addition, recent data on effects of lifestyle engagement on cognitive processes are reviewed. There is substantial evidence for age-related declines in both auditory processes and cognitive abilities. Accumulating evidence supports the idea that the perceptual burden associated with hearing loss impacts the processing resources available for good comprehension and memory for spoken language, particularly in older adults with limited resources. However, many language abilities are well preserved in old age, and there is considerable variability among individuals in cognitive performance across the life span. The authors discuss how lifestyle factors and socioemotional engagement can help to offset declining abilities. It is clear that spoken language processing in adulthood and old age is affected by changes in perceptual, cognitive, and socioemotional processes as well as by interactions among these changes. Recommendations for further research include studying speech comprehension in complex conditions, including meaningful-connection spoken language, and tailoring clinical interventions based on patients' auditory processing and cognitive abilities along with their individual socioemotional demands.

Purpose: To briefly summarize existing data on effects of aging on auditory processing and cognition.
Method: A narative review summarized previously reported data on age-related changes in auditory processing and in cognitive processes with a focus on spoken language comprehension and memory. In addition, recent data on effects of lifestyle engagement on cognitive processes are reviewed.
Results: There is substantial evidence for age-related declines in both auditory processes and cognitive abilities. Accumulating evidence supports the idea that the perceptual burden associated with hearing loss impacts the processing resources available for good comprehension and memory for spoken language, particularly in older adults with limited resources. However, many language abilities are well preserved in old age, and there is considerable variability among individuals in cognitive performance across the life span. The authors discuss how lifestyle factors and socioemotional engagement can help to offset declining abilities.
Conclusions: It is clear that spoken language processing in adulthood and old age is affected by changes in perceptual, cognitive, and socioemotional processes as well as by interactions among these changes. Recommendations for further research include studying speech comprehension in complex conditions, including meaningful-connection spoken language, and tailoring clinical interventions based on patients' auditory processing and cognitive abilities along with their individual socioemotional demands.
Key Words: aging, cognition, speech

As most older adults know all too well, aging is associated with changes and challenges in many areas. Research has provided ample evidence for age-related changes in sensory abilities (Gordon-Salant, Frisina,

Popper, &Fay, 2010), cognitive abilities (Craik &Salthouse, 2007), and socioemotional processes (Urry &Gross, 2010), yet much remains to be understood about how these myriad changes interact in the individual.We will discuss briefly each of these areas in turn and provide recommendations for directions of future research and clinical implementation.

Age-Related Changes in Auditory Processing

As adults age, changes occur that can influence auditory processing. Age-related changes within the auditory system from both animal and human studies have been well documented and show degradations in anatomic, physiologic, and audiologic structures and functions (e.g., Chisolm, Willott, &Lister, 2003; Frisina &Walton, 2001; Schneider, 1997; Stach, Hornsby, Rosenfeld, &DeChicchis, 2009; Willott, 2001). Starting with the most peripheral anatomic structures, there are minimal age-related changes in the outer and middle ear, such as loss of stiffness in the cartilaginous portion of the external auditory meatus and increased prevalence of arthritis of middle ear joints (Schneider, 1997; Weinstein, 2000). Age-related changes in the outer or middle ear structures do not produce significant hearing deficits in older individuals; however, changes in the inner ear and neural pathways are known to have dramatic effects on auditory processing (Chisolm et al., 2003; Schneider, 1997; Schneider &Pichora-Fuller, 2000).Within the cochlea, a loss of outer and inner hair cells and ganglion cells is observed. There are also overall blood supply changes that can reduce audiologic functionality by affecting the three arteries that innervate the auditory system, along with a decrease in vascularization in the layers of the stria vascularis. This decrease in vascularization causes degenerative changes by limiting blood flow and possibly affecting metabolic processes that maintain the various cochlear potentials (Schneider, 1997; Schuknecht, 1993). Evidence of age-related changes is noted beyond the cochlea, throughout the brainstem and into the auditory cortex. A loss of neural synchrony is considered another influential change that occurs as age affects auditory processing (Schneider &Pichora-Fuller, 2000). Depending on stimulus parameters, such as frequency, intensity, or spatial location, auditory neurons are either excited or inhibited. Older adults show a lack of inhibition (Tremblay, Piskosz, &Souza, 2003; Willot, 1996) and decrease in excitatory synchronization (Anderson &Kraus, 2010; Schneider &Pichora-Fuller, 2000), resulting in the degradation of neural coding throughout the central auditory nervous system (e.g., Frisina, 2001; Lister, Maxfield, Pitt, &Gonzalez, 2011; Tremblay et al., 2003).

In summary, there are progressive degenerations of sensory, strial, neural, and supportive cells within the cochlea and a reduction of neural inhibition and synchrony abilities as a result of aging that lead to deficits in functionality. Loss of pure-tone sensitivity with age is one of the most extensively documented age-related decreases in functionality. Many have described the typical hearing loss configurations of the aging adult (e.g., Chisolm et al., 2003; Schuknecht &Gacek, 1993; Willott, 1991), where the higher frequencies are more affected and continue to decline with increased age. Although pure-tone detection quantifies the audibility component of hearing loss, and audibility is a major predictor of auditory processing difficulties (Houtgast &Festen, 2008; Humes, 1996; Sommers &Humes, 1993), there are, however, physiological, histological, and psychoacoustic studies that have shown a weak relationship between real-life auditory processing and pure-tone sensitivity (Houtgast &Festen, 2008; Killion, 2002; Plomp, 1978; Schneider, 1997; Wilson &McArdle, 2008).

Under the umbrella of perceptional processing and in addition to declines in pure-tone sensitivity, other factors that are thought to influence auditory processing difficulties and also are known to decline with age include frequency and intensity discrimination, temporal resolution, and binaural processing. Impaired frequency discrimination has been observed by the broadening of auditory filters (Glasberg, Moore, Patterson, &Nimmo-Smith, 1984; Patterson, Nimmo-Smith, Weber, &Milroy, 1982; Sommers &Humes, 1993) and an increase in frequency difference limens (Abel, Krever, &Alberti, 1990; Konig, 1957; Moore &Peters, 1992) that lead to decreased frequency selectivity. Indeed, the ability of the auditory system to differentiate the spectral components of a complex sound into its component frequencies is reduced for older listeners. Additionally, older individuals with hearing loss exhibit impaired intensity discrimination, resulting in poor intensity resolution and

increased intensity difference limens (Schneider &Pichora-Fuller, 2000). Similarly, impaired temporal resolution has been demonstrated by elevated gap detection, gap discrimination, and duration discrimination thresholds in older listeners independent of hearing loss (e.g., Fitzgibbons &Gordon-Salant, 1994; Moore &Peters, 1992). Decreased temporal resolution may also influence the observed reduction in binaural processing in older adults. Here, older adults show impaired binaural release from masking, where interaural time and level differences are used to locate and separate the signals (Koehnke &Besing, 2001; Pichora-Fuller &Schneider, 1998).

Because of these perceptual declines, older adults have greater difficulty localizing sound sources and discriminating spectral and temporal transitions in a signal. Such declines in peripheral auditory processing significantly impact the ability to understand speech in difficult listening environments (Baer &Moore, 1993; Helfer, 1991; Koehnke &Besing, 2001; Patterson et al., 1982; Schneider, 1997). With these difficulties, older listeners struggle with processing complex signals, such as rapid speech presented in background noise and reverberation (Bergman et al., 1976; Helfer, 1991). Indeed, the most common complaint of older listeners is difficulty understanding speech, particularly in less than optimal listening situations. Older listeners, independent of hearing loss and with similar thresholds, vary in their ability to understand speech in the presence of noise; therefore, a more advantageous signal-to-noise ratio is needed to reach a given level of performance (Helfer, 1991; Helfer &Freyman, 2008; Killion, 2002; Wilson &McArdle, 2008). Adverse listening conditions that add perceptual difficulty and reduce performance in these situations have been demonstrated experimentally with time-compressed speech (e.g., Tun, 1998; Wilson, Preece, Salomon, Sperry, &Bornstein, 1994), speech embedded in background noise (e.g., Helfer &Freyman, 2008; Pichora-Fuller, Schneider, &Daneman, 1995), and reverberated speech (e.g., Moncur &Dirks, 1967; Wilson et al., 1994). Older listeners' performance in these adverse listening conditions shows large individual differences that cannot be fully explained by perceptual deficits.

Although the perceptual predictor variables, such as the above-described declines in perceptual processing (i.e., audibility, temporal and intensity discrimination, frequency resolution, and binaural processing), are the major predictor of performance by older listeners (Houtgast &Festen, 2008; Humes, 1996), there are still undefined secondary influences. Emerging evidence shows that the perceptual and cognitive systems form a highly integrated information-processing system (Arlinger, Lunner, Lyxell, &Pichora-Fuller, 2009; Lin, 2011; Lindenberger &Baltes, 1994; Pichora-Fuller, 2007; Schneider &Pichora-Fuller, 2000), and the remaining variance not explained by the age-related changes in the perceptual domain provides support that cognitive factors are also influencing older adults' auditory processing abilities (Akeroyd, 2008; Arlinger et al., 2009; Houtgast &Festen, 2008; Humes, 2005; Rabbit, 1991; Schneider &Pichora-Fuller, 2000). We now turn to age-related changes in cognitive processes that may impact auditory processing.

Age-Related Changes in Cognitive Processes

Although there is substantial variation across individuals, aging is commonly associated with declines in cognitiveprocessing resources in the areas of attention (McDowd &Shaw, 2000), working memory, and executive function (Baddeley, 2002; Verhaeghen &Cerella, 2002; West, 1996), as well as with a general decline in mental processing speed (Salthouse, 1996). All of these abilities play a critical role in speech processing, and so we might expect age-related declines to interact with the changes in auditory processing described above in a way that affects the older listener's ability to comprehend and remember spoken language (Benichov, Cox, Tun, &Wingfield, 2011). Speech places a substantial burden on attention and working memory processes. Unlike written text, speech processing is carried out online in real time, with words coming in at a rapid rate of 120 to 180 words per minute, without opportunity for the listener to go back and review previous material. To comprehend speech, the listener must attend to the incoming speech signal in order to recognize phonemes and access lexical items, as well as carry out syntactic and semantic operations while holding previous information in memory. Ultimately, new information must be integrated with knowledge in long-term memory to create a coherent representation of the spoken message. Considering the complexity of this task, the level of

success that older adults achieve in everyday speech comprehension is impressive in light of a large body of research demonstrating age-related declines in attentional capacity and working memory or the ability to simultaneously hold information in a buffer while performing manipulations on it (Baddeley, 2002; Engle, 2002). In addition, declines in general cognitive processing speed have been considered virtually a hallmark of the aging process, beginning in young adulthood and continuing in a fairly linear fashion across the life span (Salthouse, 1996). Finally, to add to the complexity of processing speech in everyday environments, the older listener often must cope with background noise and distraction, or dividing attention between listening and other activities. There is evidence that these conditions may be especially challenging for the older listener, because of changes in the executive functions, such as dividing attention, switching attention, and inhibiting distraction (Baddeley, 2002; Hasher &Zacks, 1988; Logie, 2011; Miyake et al., 2000; Tun &Lachman, 2010). Neuroimaging research has confirmed age differences in brain activity during such activities, particularly in areas of prefrontal cortex (DiGirolamo et al., 2001), as well as hearing-related differences in patterns of brain activation (Peelle, Troiani, Wingfield, &Grossman, 2010). The precise links with behavior remain to be determined, but such structural and functional changes provide a mechanism for linking sensory and cognitive changes with age.

On the positive side, there is at the same time encouraging evidence from neuroscience for plasticity of the brain well into old age (e.g., Kramer &Erickson, 2007). Also, language skills such as vocabulary and speech comprehension are among those abilities that tend to be well preserved in old age (Tun, Benichov, &Wingfield, 2010). Thus, an important challenge for current researchers is to combine findings from research in audiology, cognitive aging, and cognitive neuroscience to better understand how these cognitive changes impact older listeners. Ultimately, the goal is to learn how to build on older adults' preserved abilities in order to optimize communication in their everyday listening environments.

To meet these challenges, researchers will need to move beyond the typical measures that have represented the gold standard for assessing abilities: for example, we will need to go beyond simply measuring accuracy of word recognition in order to examine comprehension of meaningful spoken language. This includes examining sentences and more extended discourse presented in the sort of "open-set" conditions that reflect listening in daily life. Tests of sentence or passage processing can provide qualitative information about how well younger and older listeners process information at different levels ranging from detail to gist. Also, measuring free recall (Tun, 1998; Tun &Wingfield, 1994) may provide a more sensitive index of differences in performance than comprehension questions (Schneider, Daneman, Murphy, &Kwong See, 2000). Including measures other than accuracy, which provides a dichotomized "success-failure" view of spoken language processing, will increase the sensitivity to detect nuances and qualitative changes in strategies and patterns of processing (cf. Stine-Morrow, Miller, Gagne, &Hertzog, 2008). For example, use of an auditory moving window technique that allows listeners to self-pace across the course of a sentence has revealed age differences in the pattern of how listeners allot processing time to different linguistic elements (Titone, Prentice, &Wingfield, 2000). Response latencies can be especially useful, as speed of processing is a critical dimension in speech understanding (Tun, 1998; Tun, Wingfield, Rosen, &Blanchard, 1998). This is especially true in the case of older listeners with slower central processing speeds, who may experience particular difficulties when speech rates are rapid (Gordon-Salant &Fitzgibbons, 1995; Wingfield, McCoy, Peelle, Tun, &Cox, 2006; Wingfield, Tun, &Rosen, 1995). Because the listener has little control over the rate of incoming speech information, it is important that he or she does not fall behind in comprehension, compounding difficulties with storing and retrieving information. Unfortunately, studies have shown that when speech is syntactically complex, older hearingimpaired adults may have particular difficulty maintaining comprehension speed, as reflected in latencies (Tun, Benichov, &Wingfield, 2010) as well as accuracy (Wingfield et al., 2006).

A critical issue for future work is the question of listening effort, as fatigue is a common complaint among those with hearing loss. Self-ratings can provide one index of perceived effort (Larsby, Hallgren, Lyxell, &Arlinger, 2005). However, there is increasing recognition that the increased perceptual effort associated with hearing loss

can have important consequences downstream on comprehension and memory processes, even when speech is intelligible (Heinrich, Schneider, &Craik, 2008; McCoy et al, 2005; Pichora-Fuller et al., 1995; Rabbitt, 1968; Wingfield, Tun, &McCoy, 2005). This may be compounded by background noise, which presents a special challenge to those with hearing loss (Gordon-Salant &Fitzgibbons, 1995; Schneider, Pichora-Fuller, &Daneman, 2010) as well as for older listeners, who may have particular difficulty inhibiting meaningful competing speech (Larsby et al., 2005; Tun,O'Kane,&Wingfield, 2002; Tun&Wingfield, 1999).

Finally, the field is becoming increasingly aware of people's need to listen while carrying out other activities in daily life, so an important consideration is how greater perceptual effort may impact other tasks. Recent studies have shown how hearing loss may be accompanied by larger costs in secondary task performance (Tun, McCoy, &Wingfield, 2009) and how signal processing in a hearing aid might affect performance on a secondary task (Sarampalis, Kalluri, Edwards, &Hafter, 2009). The latter study addressed a long and checkered history of active noise reduction (NR) in hearing aids, where there is little evidence of improved speech reception despite positive reports from listeners. Sarampalis et al. suggested that redundancy between NR and internal neural processes could produce both of those effects, with the idea being that by doing for a listener what he or she normally does for him or herself, the NR could free up cognitive effort for application to secondary tasks.

Lifestyle Engagement and Hearing-Related Cognitive Impairment

Although the results described above generally point to decrements in cognitive performance among older adults with hearing loss, it is important to note that much of this work has primarily examined group means, or average performance across cross-sectional samples. Increasingly, however, there is an awareness that "one size does not fit all" in many areas and certainly not in the area of spoken language processing in older adults. Although the declines cited previously have been found for groups, there is very large variability between individuals, as well as among different types of ability within a given individual (e.g., preservation of vocabulary and verbal abilities in spite of declines in episodic memory). This presents a challenge to researchers in characterizing a typical trajectory of performance, but it also allows great latitude in how individuals can compensate for declines in one area by optimizing strengths in another (Baltes, 1997). There are also a number of lifestyle and behavioral factors that may serve to offset age-related declines in cognitive abilities. These include education (e.g., Tun &Lachman, 2008; but see Zahodne et al., 2011), which may provide a cognitive reserve (Stern, 2009; Stern et al., 2005); physical exercise (Kramer &Erickson, 2007); and cognitively challenging activities (Hertzog, Kramer, Wilson, &Lindenberger, 2008; Schooler, 2007; Tun &Lachman, 2010). In this next section, we will consider in more detail the role of social engagement in the cognitive health of older adults. This influence is particularly relevant for older adults with hearing loss, who may be especially challenged in social situations as hearing loss compounds social isolation with age (Jerger, Chmiel, Wilson, &Luchi, 1995).

Several studies have suggested that older adults who are socially engaged exhibit superior cognitive performance (Bassuk, Glass, &Berkman, 1999; Hughes, Andel, Small, Borenstein, &Mortimer, 2008; Seeman et al., 2010) and are at a reduced risk of dementia (Fratiglioni, Paillard-Borg, &Winblad, 2004), as compared with their less engaged counterparts. For example, Hughes and colleagues (2008) found that satisfaction with social support and social network was consistently related to change in cognitive performance. Persons who indicated greater satisfaction with support had better overall cognitive functioning as well as fewer longitudinal declines in memory performance. However, one of the challenges of this area of research is the issue of determining whether declines in social activities precede declines in cognitive performance or whether persons who are declining cognitively relinquish social activities. Recently, Small and colleagues (Small, Dixon, McArdle, &Grimm, 2012) examined this issue by using latent-change-score models (McArdle, 2009). These allow comparisons between models that correspond to changes in social activities preceding changes in cognitive performance and the reverse. Unlike some other studies that have used these models (e.g., Lövdén, Ghisletta, &Lindenberger, 2005), the results indicated that changes in cognitive performance largely preceded changes in

social activities, such that persons who were declining on measures of verbal speed and memory were more likely to give up social activities.

Thus, hearing loss has the potential to negatively influence an older adult's cognitive performance both directly and indirectly. The evidence from experimental manipulations indicates that degrading speech can lead to poorer cognitive performance (e.g., Wingfield et al., 2005; Wingfield &Tun, 2007). Moreover, the negative impact can also be observed indirectly, through changes in the types of stimulating activities in which older adults participate and lower quality of life (Carabellese et al., 1993; Meadow-Orlans, 1985). As a result, the level of social complexity or engagement that has been associated with better cognitive performance may be reduced for older adults with hearing difficulties. In turn, these more impoverished environments may be associated with declines in cognitive functioning. Additional research that couples changes in auditory processing, environmental engagement, and cognitive functioning is necessary to tease out these associations.

Summary

In this brief review, we have summarized some of the perceptual, cognitive, and socioemotional changes associated with the aging process. Fortunately, there is increasing recognition of the opportunities afforded by compensating for age-related declines with lifestyle and activity changes, even in old age. An important challenge for researchers is to bridge the gaps that currently exist between audiology and cognitive science in order to optimize spoken communication in our rapidly aging population.

Recommendations

On the basis of the findings summarized here, we would make the following recommendations for researchers and clinicians:

1. Cognitive abilities, such as working memory, speed of processing, and executive function, should be considered, as well as sensory abilities that impact speech processing.
2. Data from large numbers of adults across the adult life span should be collected by using both cross-sectional and longitudinal research designs.
3. Among the same subjects, simple and complex stimuli should be used to obtain behavioral and nonbehavioral measures (e.g., electrophysiological, neuroimaging), to holistically evaluate the complexity of aging on speech processing.
4. Through the use of self-reported measures, factors such as listening effort, quality of life, and perceived handicap should be obtained.
5. As life is lived in complex and demanding environments, research studies need to extend testing conditions to include distraction by different kinds of noise and competing speech and to simulate situations in which there is a need to divide attention and carry out other concurrent secondary tasks.
6. Measures of speech processing should be extended beyond word recognition to include sentences and meaningful discourse, including open-set materials typically found in everyday listening. Also include measures of comprehension and memory and measures of processing speed (e.g., reaction times, latencies). All of these will improve the ecological validity of the data collected.
7. Individual differences in preserved abilities that can be used to compensate for declines (cognitive, social, personality or motivational, and so forth) should be built on.
8. Clinical interventions need to be tailored on the basis of patients' auditory processing and cognitive abilities along with their individual socioemotional demands. Such interventions might include specific parameters for assistive hearing technologies (e.g., NR in hearing aids), more intensive counseling, and auditory training or rehabilitation. The interventions would be designed to encourage maintenance of stimulating social interactions to offset any potential social isolation.

Abstract: In this study, the authors sought to determine whether reduced audible bandwidth associated with hearing loss contributes to difficulty benefiting from an onset asynchrony between sounds. Synthetic double-vowel identification was measured for normal-hearing listeners and listeners with hearing loss. One vowel (Target 2) was 250 ms in duration, and one (Target 1) varied in duration. The vowels had the same offset, and an onset asynchrony between the vowels ranged between 0 and 200 ms. Listeners identified both vowels in their perceived order. The scoring metrics used were as follows: Target 1 correctly identified in the correct position, Target 2 correctly identified in the correct position, ordered double-vowel identification, and unordered double-vowel identification. The same experiment was conducted with vowels low-pass filtered at 900 Hz simulating reduced audible bandwidth. For all scoring metrics, increases in onset asynchrony led to better vowel identification. Listeners with hearing loss benefited less from onset asynchrony than normal-hearing listeners only for Target 2 identification. Filtering the vowels reduced onset asynchrony benefit for all scoring categories and for both groups. Results implicate reduced audible bandwidth in difficulties of listeners when using onset asynchrony for sound segregation. Therefore, listeners with a reduced audible bandwidth may have communication difficulties in natural environments. [PUBLICATION ABSTRACT]

Purpose: In this study, the authors sought to determine whether reduced audible bandwidth associated with hearing loss contributes to difficulty benefiting from an onset asynchrony between sounds.
Method: Synthetic double-vowel identification was measured for normal-hearing listeners and listeners with hearing loss. One vowel (Target 2) was 250 ms in duration, and one (Target 1) varied in duration. The vowels had the same offset, and an onset asynchrony between the vowels ranged between 0 and 200 ms. Listeners identified both vowels in their perceived order. The scoring metrics used were as follows: Target 1 correctly identified in the correct position, Target 2 correctly identified in the correct position, ordered double-vowel identification, and unordered double-vowel identification. The same experiment was conducted with vowels low-pass filtered at 900 Hz simulating reduced audible bandwidth.
Results: For all scoring metrics, increases in onset asynchrony led to better vowel identification. Listeners with hearing loss benefited less from onset asynchrony than normal-hearing listeners only for Target 2 identification. Filtering the vowels reduced onset asynchrony benefit for all scoring categories and for both groups.
Conclusion: Results implicate reduced audible bandwidth in difficulties of listeners when using onset asynchrony for sound segregation. Therefore, listeners with a reduced audible bandwidth may have communication difficulties in natural environments.
Key Words: onset asynchrony, double-vowel, hearing loss, audibility
The auditory system accomplishes sound segregation through a sophisticated process in which the components of the combined stimulus that impinge upon the ear are analyzed and either grouped as belonging to the same source or segregated as parts of different sources. Speech perception in noise is likely to involve auditory grouping processes because the ear might separate noise from speech based, in part, on their acoustic differences (cf.Bregman, 1990;Darwin&Carlyon, 1995).Doublevowel experiments have demonstrated that listeners with sensorineural hearing loss often experience difficulty with this process, showing deficits in the

ability to segregate sounds based on onset asynchrony (e.g., Lentz &Marsh, 2006) and deficits in the ability to distinguish sounds from within themixture (e.g., Arehart, King, &McLean-Mudgett, 1997; Arehart, Rossi-Katz, &Swensson-Prutsman, 2005). The influence of sensorineural hearing loss on onset asynchrony as a sound-segregation cue has received only limited attention, and it is unclear what auditory mechanisms are responsible for the decreased onset asynchrony benefit in listeners with hearing loss. The goal of this study was to establish whether one factor that is often associated with hearing loss, reduced audible bandwidth, leads to deficits in sound-segregation abilities.

Double-vowel identification is a popular method of studying the sound-segregation process in normal-hearing listeners and listeners with hearing loss (e.g., Arehart et al., 1997; Assmann&Summerfield, 1989; Summerfield &Culling, 1992;Summers&Leek, 1998).During a doublevowel experiment, two synthetic vowels are presented concurrently to a listener, and the listener identifies one or both vowels. By using this paradigm the experimenter can study sound segregation using stimuli modeled after speech sounds yet also independently vary a number of stimulus parameters for each vowel (such as the duration, formant frequencies, and fundamental frequency). In this way, double-vowel experiments allow investigation of sound segregation through the manipulation of specific acoustic parameters. Inferences about sound segregation can be made based on changes in performance associated with the acoustic manipulations.

A compelling cue to sound segregation, onset asynchrony, has been demonstrated to facilitate sound segregation using double-vowel experiments. In particular, onset differences between two vowels lead to better vowel identification than when the vowels have synchronous onsets. Summerfield and Culling (1992) showed that the masked detection threshold of a target vowel decreasedmorewhen a masker vowel had a temporally asynchronous onset than when it was simultaneous with the target. Using double-vowel stimuli, Lentz and Marsh (2006) demonstrated improvements in identifying a constituent vowel of a double-vowel stimulus when the vowels had simultaneous offsets but increasingly asynchronous onsets. Hedrick and Madix (2009) also demonstrated benefits due to onset asynchrony for double vowels and implicated vowel identity in the benefits received, with specific vowel pairs leading to greater benefits than others. To date, Lentz and Marsh (2006) provide the only double-vowel experiment that has evaluated the impact of hearing loss on benefits received from onset asynchrony.Their results illustrated that although listeners with hearing loss receive benefits from onset asynchrony, the benefits are diminished compared to normal-hearing listeners.

Few nonspeech psychophysical studies have evaluated the effect of hearing loss on the ability to take advantage of onset asynchrony. Lentz, Leek, and Molis (2004) tested spectral-shape discrimination (i.e., profile analysis) using asynchronous pure-tone stimuli, and Grose and Hall (1996) tested comodulation-masking release using asynchronous narrow bands of noise. Both studies demonstrated little influence of hearing loss on the pattern of thresholds as a function of the onset asynchrony between the various stimulus components. These experiments suggest that hearing loss does not impair the ability to group or segregate nonspeech sounds based on onset asynchrony, a result that is in direct contrast with the findings of Lentz and Marsh (2006), who used speechlike stimuli. One major difference across the experiments is that the stimulus components were fully audible (though presented at different sensation levels) to listeners in both groups in the experiments of Lentz et al. (2004) and Grose and Hall (1996). In contrast, some of the stimulus components would have been attenuated by the subjects' hearing loss in the double-vowel experiment of Lentz andMarsh (2006), and so the stimuli in that study had narrower internal bandwidths for the listeners with hearing loss than for the listeners with normal hearing. This leaves open the possibility that the ability to fully represent onset asynchrony could be affected by an inability to hear all stimulus components. Although Lentz and Marsh (2006) ruled out the contribution of audibility on their results using an excitation-pattern analysis, the role of reducing the number of stimulus components was not explicitly tested. Further evaluation is needed to establish whether the ability to benefit from onset asynchrony is altered by a reduced audible bandwidth.

Psychophysical literature suggests that reduced audible bandwidth may detrimentally impact the ability to

benefit from onset asynchrony. First, listeners with hearing loss have more difficulty detecting amplitude modulation imposed on broadband noise (e.g., Bacon &Viemeister, 1985; Takahashi &Bacon, 1992) and detecting gaps in broadband noise stimuli (e.g., Fitzgibbons &Gordon-Salant, 1987; Grose, Eddins, &Hall, 1989). Second, when broadband stimuli are filtered, poorer temporal acuity is measured. Bacon and Viemeister (1985) measured temporal modulation transfer functions (TMTFs) using low-pass filtered stimuli. The TMTFs for the normal-hearing listeners with low-pass filtering were similar to TMTFs measured in listeners with hearing loss. Eddins, Hall, and Grose (1992) also measured elevated gap detection thresholds for narrower-bandwidth stimuli, particularly in higher frequency regions. Together, these studies suggest that reducing audible bandwidth limits the temporal information available to listeners.

Because such strong bandwidth effects are reported for temporal processing tasks, one might expect to see deficits in the ability to use onset asynchrony in listeners with sloping hearing loss, due to the limited bandwidth associated with the filtering characteristics imposed by the hearing loss. Although it is anticipated that listeners with hearing loss will experience deficits in their ability to benefit from onset asynchrony (see Lentz &Marsh, 2006), it is not clear whether these deficits are related explicitly to a loss of audible components, which would most greatly impact listeners with sloping hearing losses. To establish whether loss of audible components contributes to difficulties taking advantage of onset asynchrony, the current experiment measures asynchronous doublevowel identification in normal-hearing listeners and listeners with hearing loss using low-pass filtered and unfiltered synthetic vowels.

Method

Participants

Seven normal-hearing listeners, ranging in age from 23 to 64 years with a mean age of 45.0 years, and seven listeners with hearing loss, ranging in age from 22 to 65 years with a mean age of 47.7 years, participated. Normalhearing listeners had pure tone audiometric thresholds no greater than 20 dB HL between 250 and 3000 Hz and no greater than 25 dB HL between 4000 and 8000 Hz. Listeners with hearing loss were selected to have mildto- moderately severe sloping hearing losses with a pure tone average at 1, 2, and 4 kHz of 35 dB HL or greater and no greater than 75 dBHLat 3000 Hz. Hearing losses were bilateral and symmetric, with the site of lesion presumed to be cochlear in origin based on air- and boneconduction thresholds. The right ears were tested for the listeners with normal hearing, whereas the better ear was tested for listeners with hearing loss. Audiometric thresholds for all test ears together with the participants' ages are reported in Table 1. Listener NH7 was the first author of this study. All procedures were approved by the Institutional Review Board at Indiana University.

Stimuli

Stimuli used were steady-state synthesized vowels modeled after the Standard English vowels /æ , i, e, 3, a/. Table 2 lists the formant frequencies for each vowel, which matched those described by Arehart et al. (1997). For reference, spectra of the individual vowel sounds are plotted in Figure 1.

Vowels were synthesized using an implementation of theKlatt synthesis software (Klatt, 1980) by H. Timothy Bunnell at a sampling rate of 16000 Hz and then resampled in MATLAB at 24414 Hz for playback. The vowels were synthesized at two different fundamental frequencies, 126 Hz and 141 Hz, and were generated to be 550 ms in duration. When isolated single vowels were presented, they were shortened to 250 ms in duration and included 10-ms rise/fall times. Vowels were calibrated so that their unfiltered rms power was equivalent to 90 dB SPL. Vowels then were presented to listeners either in their original state (unfiltered), or after low-pass filtering. For the filtered conditions, each vowel was low-pass filtered at 900 Hz, using a 12th order Butterworth filter having a slope of 72 dB per octave. The cutofffrequency was chosen to be 900 Hz so that each individual vowel did not have energy above the first formant (see Table 2), giving each vowel similar formant information regardless of whether it was presented to a listener with hearing loss or not. Although the filtering reduced the total power of the vowels, the spectrum level of components below 900 Hz remained unchanged.

Once the individual vowels were synthesized, double vowels were made by adding two vowels of the same fundamental frequency (126/126 Hz or 141/141 Hz) together.1 One of the vowels, Target 1, was 250, 275, 350, or 450 ms in duration. The second vowel, Target 2, was always 250 ms in duration. To make the double vowel, the 550-ms single vowels were shortened to the appropriate duration and gated using 10-ms raised cosine on and offramps. Target 1 and Target 2 were added together such that both vowels had synchronous offsets. In those cases when the duration of Target 1 was longer than that of Target 2, an onset asynchrony between the two vowels was produced (25, 100, or 200 ms). For example, Figure 2 shows a waveform schematic of a double-vowel pair with Target 1 at 450 ms and Target 2 at 250 ms (an onset asynchrony of 200 ms).

A high-pass masking noise was presented with all vowel stimuli so that listeners with normal hearing could not use information related to upward spread of excitation (see Bacon &Viemester, 1985).2 This Gaussian noise was generated with a cutofffrequency of 4800 Hz for the unfiltered conditions and 1080 Hz for the filtered conditions. The spectrum level of the noise was approximately 26 dB. This noise did not limit the ability to hear any of the formants in the double vowel; it simply limited the ability of normal-hearing listeners to use additional high-frequency spread of excitation in the task. The noise began at the beginning of each experimental session and played continuously throughout the entire session. However, each time the listener switched from unfiltered vowel identification to filtered vowel identification, the appropriate noise was used.

The vowels were digitally generated off-line and were summed with the digitally generated high-pass noise before being played through one channel of a 24-bit digitalto- analog converter, TDTSystemIIIRP2.1 (Tucker Davis Technologies,Alachua, FL), at a sampling period of 4.096 ×10-5 s (sampling rate is about 24414 Hz). The output of the RP2.1 was fed into a programmable attenuator (TDT PA5), which was adjusted to appropriately calibrate the stimuli, and then to a headphone buffer (TDT HB6). The outputwas then fed into one earphone of a Sennheiser HD 250 II Linear headset.

Procedure

The experiment consisted of two separate phases: double-vowel and single-vowel identification. Although double-vowel identification provides the basis for establishing the benefits of onset asynchrony, single-vowel identification was measured for two reasons. First, singlevowel identification provided a familiarization phase to all listeners and allowed a determination of whether all vowelswere identifiable under unmasked, unfiltered conditions. Second, possible training effects that may have occurred throughout the duration of the experiment were assessed using single vowels.

Double-vowel identification. During the doublevowel phase of the experiment, 25 pairs of vowels were presented. Each vowel was paired with each other vowel once as Target 1 and once as Target 2, and each vowel also was paired with itself (5 vowels ×5 vowels = 25 vowel pairs). The order in which the vowel pairs were presented was randomly selected, with each possible pair heard only once in the 25-vowel sequence.

Double-vowel data were collected using a randomized blocked design in which the 25 vowel pairs were presented for a given filter cutofffrequency (900 Hz or unfiltered), fundamental frequency (126/126 Hz or 141/ 141 Hz), and onset asynchrony (0, 25, 100, or 200 ms). The filter cutofffrequency was first selected at random, and then the eight different experimental conditions were tested within each cutofffrequency with these eight different conditions referred to as a block. Within a block, the fundamental frequencywas chosen randomly, and then each onset asynchrony was tested in random order within a fundamental frequency. Data were collected by alternating between a block of unfiltered vowels and a block of filtered vowels, so that data were collected for a total of 16 conditions (2 filter conditions ×2 fundamental frequencies ×4 onset asynchronies). Listeners were tested on each of the 16 conditions a total of eight times. Within each condition, percent-correct scores were calculated based on 25 vowel pairs. The first three sets of 25 double vowels were treated as training (i.e., 6 blocks: 3 unfiltered and 3 filtered blocks), and the last five scores were averaged together and used as a final percent-correct estimate (125 trials per condition).

Listeners were seated in a sound-attenuating room during the experimental sessions. They were asked to

identify the two vowels in the order in which they occurred (unless the onset asynchrony was 0 ms and then no order judgment was possible). At the beginning of each set of 25 double vowels, subjects were given the opportunity (but were not required) to listen to the 250-ms single vowels for practice. On each trial, two sets of possibleword identifiers (top rowforTarget 1 and lower rowfor Target 2) were presented as button labels on the monitor in front of the subject. The identifiers (had, heed, head, herd, and hod) were used to represent the phonetic symbols (/æ , i, e, 3, a/). Following presentation of the stimulus, subjects used a mouse click to choose the buttons corresponding to the two vowels that were presented. Subjects were allowed to modify their initial responses and then were required to click a "confirm" button before continuing to the next trial. Each rowcontained all of the possible five identifiers; using two separate sets of identifiers for the first and second vowel encouraged independent judgments of the two vowels. No feedback was provided during the double-vowel presentations.

Because scores were obtained for identifying two asynchronous vowels, multiple different scoring scenarios were available. As such, percent-correct scores were obtained for the following vowel identification measurement scenarios: Target 1 identification (first vowel identified in the first position), Target 2 identification (second vowel identified in the second position), ordered double-vowel identification (Targets 1 and 2 identified in the appropriate positions), and unordered double-vowel identification (Targets 1 and 2 identified irrespective of position). For reference, Target 2 identification is the measurement that replicates the scoring convention of Lentz and Marsh (2006). Percent-correct scores are expressed in terms of rationalized arcsine units (RAU) to stabilize the error variance (Studebaker, 1985).

Single-vowel identification. During the training phase of the experiment (the first three replicates of double vowels) and at least five times throughout the experimental sessions, performance on single vowels was evaluated to ensure that subjects remained familiar with the vowel identities and that they maintained stable performance throughout the experiment.During the training sessions, unfiltered single-vowel identification was assessed prior to and after each block of unfiltered vowels. Filtered single-vowel identification was also assessed prior to and after each block of filtered vowels. In this way, listeners received training on the single vowels twice for each fundamental frequency for each training block. By the completion of the training phase subjects were required to achieve at least 88% on the unfiltered single vowels to continue participating in the study.One listenerwith hearing loss did not meet this criterion and so was excluded from further testing. Once the training sessions were completed, single-vowel identification was assessed only periodically (about four times throughout the experiment) to ensure stable performance.

Single vowels were tested by presenting each of the five vowel tokens a total of five times (25 vowels in isolation). Responses were collected in the samemanner as for the double-vowel paradigm, with the monitor screen presenting the responses in the context of key words (had, heed, head, herd, and hod) on the screen. However, rather than requiring two responses from the subject, only one response was required. Unfiltered single vowels were always tested following blocks of unfiltered double vowels, and filtered single vowels were always tested following blocks of filtered double vowels. For these single vowel conditions, listeners received feedback regarding the identity of the single vowel. Both groups of listeners had similar scores on the single vowels, but listeners with normal hearing did performslightly better. On average, listeners with normal hearing and hearing loss scored 110 RAU (98% correct) and 98 RAU (93% correct), respectively, on the unfiltered single vowels. Filtering decreased performance: Normal-hearing listeners achieved scores of 66 RAU (65% correct), whereas listeners with hearing loss scored 65 RAU (64% correct). Despite the severe form of filtering applied, listeners still achieved scores that were well above chance (20 RAU). A one-way t test for each listener was conducted on the final four percent-correct scores obtained during the initial training period and the final four percent-correct scores collected during the experimental sessions. These tests showed no significant improvement in unfiltered single-vowel identification.

Results

Figure 3 plots scores inRAUas a function of onset asynchrony collapsed across fundamental frequency for each vowelmeasurement scenario for normal-hearing listeners (filled symbols) and listeners with hearing loss (unfilled symbols). Data obtained from filtered and unfiltered conditions are also plotted as black circles and gray triangles, respectively. For reference, chance performance corresponds to 20 RAU (20% correct) for Target 1 and Target 2 identification, -4 RAU (4% correct) for ordered double-vowel identification, and 2 RAU (7% correct) for unordered double-identification. Average scores were at least 10 RAU above chance for all conditions tested, with scores increasing as onset asynchrony increased for both groups of listeners. This result demonstrates that onset asynchrony is an effective way of improving performance on a double-vowel task. In general, listeners with hearing loss have poorer scores than normal-hearing listeners when the vowels are unfiltered, but data of both groups tend to overlap in the filtered conditions. The patterns of benefit differ somewhat across the different vowel measurement scenarios and will be discussed in more detail below. For each of the four measurement scenarios, statistical effects were assessed using separate repeatedmeasures analyses of variance (ANOVAs), in which group membership was a between-subject factor and onset asynchrony (0 ms when tested, 25, 100, and 200 ms) and filtering (unfiltered or low-pass filtered) were treated as within-subject factors. These statistics were conducted by collapsing across fundamental frequency, which had only a small effect on scores (< 2 RAU).3 The statistical results are reported in Table 3. The statistical results that are consistent across all vowel measurement scenarios are discussed first, and the differences across the measurement scenarios are discussed in turn.

Across all vowel measurement scenarios, theANOVAs reveal that filtering and onset asynchrony are significant main effects. The main effect of onset asynchrony indicates that onset asynchrony leads to improvement in performance in double-vowel identification, as observed in Figure 3. The main effect of filtering is due to lower scores in the filtered conditions compared to the unfiltered conditions.Not surprisingly, filtering the vowels so that only F1 information is present leads to poorer performance.

Two of the three two-way interactions are also significant across all scenarios. The Filtering ×Group interaction reflects a greater effect of filtering on performance for the normal-hearing listeners than for the listeners with hearing loss. Looking back to Figure 3, one can see that the normal-hearing listeners outperformthe listeners with hearing loss when the vowels are unfiltered, but performance is similar for the twogroups in the filtered conditions. The filtering effectively removes the differences in performance that are typically observed between normal-hearing listeners and listeners with hearing loss.

The Filtering ×Asynchrony interaction indicates that the effect of onset asynchrony is greater for the unfiltered stimuli than for the filtered stimuli. This interaction is illustrated in Figure 4, with benefit (score in RAUat 25 ms subtracted from the score in RAU at 200 ms) collapsed across groups plotted versus vowel measurement scenario for the filtered and unfiltered conditions. As Figure 4 shows, filtering the double-vowel stimuli led to an overall reduced benefit received from onset asynchrony in all measurement scenarios (dark gray vs. light gray bars). Both groups of listeners received benefit fromonset asynchrony for both filtered and unfiltered vowels, although the benefits received for filtered vowels were smaller. Prior to filtering, normal-hearing listeners had an average benefit from onset asynchrony collapsed across all measurement scenarios of 26 RAU, and listeners with hearing loss had an average benefit of 23 RAU. After filtering, both normal-hearing listeners and listeners with hearing loss received smaller benefits, an average of 9 and 11 RAU, respectively. Consequently, we can conclude that a limited audible bandwidth can be expected to detrimentally impact sound segregation based on onset asynchrony.

Many of the significant factors involving group membership were significant for some but not all measurement scenarios. First, the main effect of group was significant for only two of the vowel measurement scenarios (ordered and unordered double-vowel identification). By examining Figure 3, we can see that there are differences in performance between groups for the unfiltered conditions (circles) but not the filtered conditions (triangles). The difference between the groups for the unfiltered conditions tended to be largest in ordered and

unordered double-vowel identification. The differences between the groups in the unfiltered conditions were too small in Target 1 and Target 2 identification to yield statistically significant effects.

Second, an interaction between onset asynchrony and group is revealed for unordered vowel identification. These measurement-specific benefits are illustrated in Figure 5,which plots the benefits due to onset asynchrony (200 ms scores - 25 ms scores) collapsed across filter conditions for each group of listeners. Figure 5 shows that for Target 1 identification and ordered double-vowel identification, the observed benefits are similar between normalhearing listeners and listeners with hearing loss. However, unordered vowel identification has a different magnitude of benefits for the two groups of listeners: 15 RAU for listeners with hearing loss versus only 8 RAU for normalhearing listeners.Here, listeners with hearing loss receive more benefit from onset asynchrony than the normalhearing listeners. Interestingly, this is the only measurement scenario in which some listeners with hearing loss approached chance performance for the filtered conditions (although average scores were about 14 RAUpoints above the floor of 2 RAU). Scores for HI1 and HI3 at the 0-ms onset asynchrony and under filtered conditions were 8 and 5 RAU points above the floor, respectively, but all other listeners had scores at least 12 RAU points above the floor. Even if floor effects were present at the 0-ms onset asynchrony, the interpretation would be that the onset asynchrony benefit is underestimated for the listeners with hearing loss, and in these conditions listeners with hearing loss had greater benefit than normalhearing listeners.

On the other hand, ceiling effects may have contributed to a reduced benefit from onset asynchrony for the normal-hearing listeners in ordered double-vowel identification. Figure 3 indicates that normal-hearing listeners had identification scores much higher than those of the listeners with hearing loss. The presence of Target 1 presented simultaneously with Target 2 could limit maximal performance, and it seems likely that listeners would not be able to achieve the same scores as in quiet, particularly so because the vowels have the same fundamental frequencies.

A decrease in benefit received by listeners with hearing loss for Target 2 identification is revealed in the three-way interaction involving group, filtering, and onset asynchrony. The three-way interaction reflects a result that listeners with hearing loss receive less benefit from onset asynchrony than normal-hearing listeners in the unfiltered conditions but not in the filtered conditions. This interaction is illustrated in Figure 6, which plots the benefits received by both groups of listeners in Target 2 identification. This pattern in unfiltered vowel identification replicates the results of Lentz andMarsh (2006),who only measured unfiltered vowel identification (for Target 2). Their results indicated a reduced benefit of onset asynchrony for listeners with hearing loss. However, it is notable that this effect of group is not evident in any of the other vowel measurement scenarios.

Generally, introducing an onset asynchrony between the two vowels leads to better vowel identification for both groups of listeners, but benefits also differ depending on the vowel measurement scenario. Figures 3-5 demonstrate that Target 1 identification is associated with the largest benefits due to onset asynchrony, whereas benefit for Target 2 identification and unordered double-vowel identification tend to be lower than in the other two vowel measurement scenarios. Large benefits for Target 1 identification are likely due to temporal unmasking effects, as increases in onset asynchrony lead to a portion of the vowel that does not overlap with a competing stimulus, making it much easier to identify than a vowel that is always presented simultaneously with a competing sound (e.g., Target 2). The smaller benefits for Target 2 identification probably occur because increases in onset asynchrony do not lead to an unmasking of Target 2-it is always presented under competition. Different amounts of benefit for unordered double vowel identification are likely to be related to different factors than for Target 2, possibly ceiling effects for unfiltered double-vowel identification. In general, however, onset asynchrony leads to an improvement in vowel identification scores for doublevowel stimuli. The amount of improvement depends on hearing status and vowel measurement scenario and is likely due to both masking and audibility.

Taken together, the effects of onset asynchrony can be summarized as follows:

1. Benefits due to onset asynchrony were observed for both groups of listeners and were present for both filtered and unfiltered vowels.
2. Filtering reduced the benefits due to onset asynchrony for both groups of listeners.
3. Listeners with hearing loss received similar benefits to normal-hearing listeners in Target 1 and ordered vowel identification. For unordered double-vowel identification, listeners with hearing loss received greater benefit from onset asynchrony. For Target 2 identification, the listeners with hearing loss experienced less benefit due to onset asynchrony in the unfiltered conditions but similar benefits to normalhearing listeners in the filtered conditions.
4. Benefits from onset asynchrony were greatest for Target 1 identification and smallest for bothTarget 2 identification and unordered double vowel identification.

Discussion

Benefit From Onset Asynchrony: Role of Bandwidth

For filtered and unfiltered vowels, the presence of an onset asynchrony leads to increases in performance for both groups of listeners. Filtering the vowels reduces the received benefit, which suggests that the ability to hear all stimulus components influences the ability to take advantage of onset asynchrony. However, filtering reduced the benefit in all vowel measurement scenarios, whereas listeners with hearing loss exhibited a reduced ability to take advantage of onset asynchrony only in Target 2 identification. As such, reduced audible bandwidth might play a role in reduced benefit from onset asynchrony, particularly for listeners with severe hearing loss, but other factors related to hearing loss also influence the pattern of data seen in the listeners tested here.

All vowel measurement scenarios exhibited large reductions in onset-asynchrony benefit with the size of the reduction varying across scenarios-ranging from 20 RAU for Target 1 identification and 7 RAU for Target 2 identification. The patterns of benefit across measurement scenarios for each specific vowel are generally similar to the patterns observed for the unfiltered vowels: Target 1 identification and ordered double-vowel identification scoring methods led to the greatest benefit due to onset asynchrony (see Figures 4 and 5). Because the filtered and unfiltered conditions reflect similar patterns of benefit across the different vowel measurement scenarios, the processes that underlie benefits due to onset asynchronymay be the samefor filtered and unfiltered vowels. The reduced benefits for the filtered vowels, however, imply that listeners must hear all stimulus components to receive the greatest benefit due to onset asynchrony. As Figure 4 illustrates, the reduced audible bandwidth impacts benefits across all measurement scenarios, in contrast to the milder form of reduced audibility experienced by listeners with hearing loss.

In general, the reduction in onset asynchrony benefit for both normal-hearing listeners and listeners with hearing loss under filtered conditions emphasizes the importance of hearing all stimulus components so that they may receive a large benefit from onset asynchrony. This result confirms our hypothesis based on psychophysical data revealing an influence of stimulus bandwidth on the measurements of temporal acuity (Bacon &Viemeister, 1985; Eddins et al., 1992). Further, we can conclude that a wide audible bandwidth leads to a large benefit from onset asynchrony. Decreases in this bandwidth (either due to hearing loss or environmental factors) are likely to reduce the benefit a person may receive from the onset asynchrony sound-segregation cue. Loss of the high-frequency components could be particularly problematic, as temporal resolution has been demonstrated to be better at high frequencies compared to low (e.g., Snell, Ison, &Frisina, 1994). Should this result generalize to other speech stimuli, one could argue that providing amplification across the widest frequency bandwidth possible would allow a listener with a sloping hearing loss to gain the most benefit from temporally based sound-segregation cues.

At this point, however, it is not clear whether it is the attenuation of all harmonics or only the formants that lead to this result. Note that low-pass filtering the vowels at 900 Hz eliminates both high-frequency harmonics and the high-frequency formants (F2-F5). It might be that attenuating the formants only (and not all of the

harmonics) leads to the reduced benefit from onset asynchrony, as the locations of the spectral or formant peaks play a significant role in vowel identification (e.g., Peterson &Barney, 1952). In the end, listeners with hearing loss experience attenuation of both formants and harmonics, and so we cannot differentiate between these two mechanisms using listeners with hearing loss or simple lowpass filtering.

One interesting aspect of these data is that filtering the vowel stimuli reduced the onset asynchrony benefit for all listeners in all vowel measurement scenarios, but listenerswith hearing loss showed reduced benefit only in Target 2 identification. If the limited audible bandwidth of the listeners with hearing loss was the only factor that diminished benefit from onset asynchrony, then it would have been expected that listeners with hearing loss would have exhibited this deficit in all vowel measurement scenarios. Although it appears that reduced audible bandwidth has a role to play in reduced sound-segregation abilities experienced by listeners with hearing loss, other suprathreshold factors are likely implicated; these are discussed in the next section.

Benefit From Onset Asynchrony: Role of Competition

The result that listeners with hearing loss experienced reduced benefit from onset asynchrony in Target 2 identification could be related to the greater susceptibility to masking by listeners with hearing loss. In Target 2 identification, the vowel being identified is always presented under competition, and so perhaps the greater susceptibility of masking experienced by listeners with hearing loss impacts the size of the benefits received for these stimuli. Notably, the studies of Lentz et al. (2004) and Grose and Hall (1996) did not measure onset asynchrony perception under competition, which might explain why listeners with hearing loss experienced similar effects of onset asynchrony as normal-hearing listeners in those experiments.

The role of competition can be observed by comparing the vowel identification benefits across the different vowel measurement scenarios (see Figures 4 and 5). As mentioned earlier, the largest benefit received is for Target 1 identification. These large benefits might be facilitated by an environmental release from masking of Target 1 concomitant with the increase in onset asynchrony. There is evidence that Target 2 does not fully mask Target 1 when they are synchronous (scores are not near chance for double-vowel identification at the 0-ms onset asynchrony); however, increases in onset asynchrony would lead to portions of Target 1 that are presented without a competing sound. These portions (even as short as 25 ms) could have provided a great deal of information to listeners regarding the identity of the first target, especially in cases where the two vowels are easily confusable. As onset asynchrony increases, the unmasked portion of Target 1 increases, and listeners could become more and more accurate in identifying that vowel. Thus, for Target 1 identification, the unmasking associated with onset asynchrony is likely to have contributed to the large benefits seen for thismeasurement scenario.

With regard to Target 2 identification, benefits are likely smaller because of masking of Target 1 on Target 2. In contrast to Target 1, Target 2 was always presented under simultaneously (but not necessarily fully) masked conditions. Increases in onset asynchrony would not have led to unmasked portions of the vowel. Thus, benefits received for longer onset asynchronies in the Target 2 identification are not related to a temporal unmasking. Here, Target 2 is partially masked because a conflicting representation of formant peaks in that excitation pattern associated with the Target 1 vowelmakes itmore difficult to identify. In this case, onset asynchrony benefits could be related to "higher-level" factors, such as reduced uncertainty regarding the identity of the two vowels, reduced uncertainty regarding the order of the two vowels, or improvements in sound-segregation abilities at the greater onset asynchronies.

To begin to establish whether masking may have a role to play in performance and the benefits due to onset asynchrony for Target 2 identification, we looked more closely at the patterns of vowel identification at two onset asynchronies and qualitatively compared those patterns to excitation patterns based on the simultaneous presentation of two vowel sounds. Because this result was observed only for unfiltered vowels, this is the only condition explored here.

Figure 7 plots the identification score of each individual vowel for Target 2 identification in the unfiltered

conditions and shows that the patterns of individual vowel identification vary substantially between the normalhearing listeners and the listeners with hearing loss. For example, at the 25-ms and the 200-ms onset asynchronies, the /i/ was easily identifiable for the normalhearing listeners butwas themost difficult for the listeners with hearing loss to identify. As Figure 1 illustrates, F2 and F3 of the /i/ are both above 2000 Hz, and they may have been be rendered inaudible by the losses of some of the listeners used here. Onset asynchrony provided relatively moderate benefits for /i/ within both groups, but there was a larger improvement in scores for the normalhearing listeners than for the listeners with hearing loss. On the other hand, the /e/ was relatively difficult for the listeners with normal hearing but relatively easy for the listeners with hearing loss to identify. Here, listeners with hearing loss received greater onset asynchrony benefits compared to normal-hearing listeners.

To establishwhethermasking effects might have contributed to the group differences in performance and onset asynchrony benefit, Figure 8 plots the difference between the excitation pattern of the competing vowel and excitation pattern of the double vowel.4 This calculation allows an estimate of how much of the vowel of interest is represented in the double vowel. In a sense, these excitation pattern differences represent the amount of spectral contrast available to the listener when one vowel is masked by another.

Using this type of analysis, two particular patterns are expected for vowels that are easily identified. First, the formant peaks of the vowel of interest should be prominent once the competing vowel is subtracted from the sum. As listeners typically use the formant peaks for vowel identification, a representation with strong formant peaks would be associated with high scores. Second, we would also expect that the same formant peaks would be present across the different competing sounds. Listeners would be expected to perform better on tasks that have consistent cues across experimental trials. So, if F1 is present only for two competing vowels and F2 is present for the other two competing vowels, then identification performance might be difficult for listeners, as listeners may not know a priori whether to listen for F1 or F2. Further, the formant information should not be redundant across the various vowels. For example, if F1 is only available for one vowel, it could be easily confused with another vowel having similarly limited formant information. Hedrick and Madix (2009) suggested that vowels that are less confusable from others are more likely to receive large benefits due to onset asynchrony. Consequently, we expect that consistent, unambiguous, formant information would be associated with large benefits due to onset asynchrony.

Excitation pattern differences are plotted in Figure 8 for a normal-hearing simulation (leftpanels) and a hearing-loss simulation (right panel). For reference, the frequencies of the first three formants are indicated on the panels as filled circles.The leftpanels ofFigure 8 illustrate that across the different vowels, most vowels have a fairly robust representation even in the summed representation for the normal-hearing listeners.Take /i/, for example (second panel on left): Both F1 and F3 have robust peaks that are prominent in the presence of all competing sounds. Itmay not be surprising then, that the /i/ is easily identified by the normal-hearing listeners when presented under competition (see Figure 7). This robust representation might also allow listeners to receive strong benefits from onset asynchrony when identifying this vowel. In contrast, the /e/, which is more difficult to identify, has robust formant peaks, but the location of those formant peaks are not as consistent across the competing sounds (see middle panel, left). When presented with /i/, F1 and F2 are available, but when presented with /3/, only F3 is robust. Further, some of the /e/ representations may be confused with the representations of other vowels (e.g., /æ / when paired with /i/, /3/, and /a/). Consequently, the onset asynchrony may not always disambiguate the vowels, possibly leading to a reduced benefit.

On the other hand, the right panels of Figure 8 illustrate that listeners with hearing loss are at a distinct disadvantage compared to normal-hearing listeners due to their reduced frequency selectivity. The general amount of spectral contrast available to them is greatly reduced, at times being less than half that available to normalhearing listeners. The scale of the y-axis has been kept the same as for the normal-hearing listeners to illustrate the magnitude of this effect. The most notable effect of hearing loss is that many of the vowel sounds

do not have robust representations of all formants in the double vowel. The /a/ is an exception (bottom right panel), as the F1/F2 region is robust across the various competing vowels, but when compared with the /a/ as presented to normal-hearing listeners, the strength of the F1 peak is reduced for all double-vowel combinations. It is notable that listeners with hearing loss had the greatest ease in identifying the /a/ at the 25- and 200-ms onset asynchronies (see Figure 7). Onset asynchrony also improved identification of this vowel to a greater degree for normalhearing listeners than for listeners with hearing loss, perhaps because the F1/F2 region is not confusable with the spectral representation of other vowels for the listeners with hearing loss. On the other hand, the /æ / does not have a consistent representation across the competing vowels. When the /æ / is paired with /i/, F1 and F2 are robustly available (though not as robustly as for normalhearing listeners). However, when /æ / is paired with /a/ and /3/, only F3 is well available and consistent across the two competing vowels. It is not surprising, then, that the /æ / has relatively poor performance in the Target 2 identification measurement scenario and also leads to a relatively small benefit of onset asynchrony. The pattern present for /e/ is quite similar, as the peaks associated with the greatest spectral contrast are quite varied across the competing sounds. The /i/ is also likely difficult for these listeners because only F1 is robustly available to them (due to their reduced audibility and frequency selectivity, the F2 and F3 spectral information is diminished). The /i/ can therefore be easily confused with other vowels in certain combinations (e.g., the /e/ when presented with /a/ or /æ / and the /3/ when presented with /a/).

Hedrick andMadix (2009) suggested that vowels that are less confusable from others are more likely to receive large benefits due to onset asynchrony. For normal-hearing listeners, the /i/ and /3/ are the most distinct from the other vowels and therefore benefit more from onset asynchrony. For listeners with hearing loss, the /i/ and /3/ are not nearly as distinct: Figure 8 indicates that both vowels have similar spectral contrast in a low-frequency region, and even though F2 and F3 are quite different for these two vowels, there may not be sufficient spectral contrast available to listeners in these frequency regions. Because these twovowels have poorer representations, they do not lead to large benefits due to onset asynchrony. The reduced frequency selectivity of listeners with hearing loss, then, impacts the patterns of vowel-specific identification and the amount of benefit that listeners are able to receive from the onset asynchrony.

Summary and Conclusions

In summary, low-pass filtering of double vowels leads to a reduced benefit from onset asynchrony differences in double-vowel identification. This result indicates that limiting the bandwidth of the double vowel impairs the ability to use onset asynchrony as a sound-segregation cue for listeners with normal hearing and those with cochlear hearing loss. Listeners with hearing loss received less onset asynchrony benefit than the normal-hearing listeners for Target 2 identification when the vowels were unfiltered, but they received similar benefits due to onset asynchrony in the other three vowel measurement scenarios. The fact that onset asynchrony benefit was similar between the two groups in three of the four vowel measurement scenarios suggests that masking of Target 1 on Target 2 could contribute to the reduced benefit received for identifying the second target.

Once the vowels were filtered, the benefits received from onset asynchrony were similar for normal-hearing listeners and listeners with hearing loss in all vowel measurement scenarios, including Target 2 identification. The filtering provided similar amounts of information to both listener types. Taken together, these results implicate reduced audible bandwidth for the group differences observed for Target 2 identification, and excitation pattern analyses support the idea that reduced frequency selectivity impacts the ability to benefit fromonset asynchrony differences.

Footnote

1Although fundamental frequency differences between the two vowels were not evaluated in this study, the vowels were synthesized at two fundamental frequencies for potential comparison with future data.

2The high-pass noise was included for two major reasons. First, upward spread of excitation occurs for both normal-hearing listeners and listeners with hearing loss, but listeners with hearing loss are limited due to poor auditory thresholds at high frequencies. Listeners with normal hearing have the potential to use the spread of excitation generated by highfrequency formants to assist with identification of individual vowels, but listeners with hearing loss, especially those with sloping losses, frequently do not have this opportunity. The high-pass noise limits the chance that normal-hearing listeners could use these frequency regions to provide any additional information to accomplish the task. Second, because we are specifically testing whether bandwidth impacts onset asynchrony benefits, presenting a high-pass noise ensures that listeners are presented with similar bandwidth information.

3On average, vowels synthesized at the 126-Hz fundamental frequency yielded scores that were 1.5 RAU better than vowels synthesized at the 141-Hz fundamental frequency. These differences were the same magnitude for both groups of listeners.

4Excitation patterns were constructed using the auditory filters reported by Glasberg and Moore (1990) and MATLAB code provided by Jens Appell. Excitation patterns for each individual vowel and each double vowel were generated (excluding double vowels in which the constituent vowels were the same). To simulate the reduced frequency selectivity for the listeners with hearing loss, the bandwidths of the filters (in equivalent rectangular bandwidth) were doubled. Average audiometric thresholds were also included, as the excitation values were limited to those that exceeded audiometric thresholds (as obtained via interpolation). These excitation patterns also included the high-pass noise to more faithfully represent the spectral contrast available to the listener in the experiment.

Perceptual Acclimatization Post Nonlinear Frequency Compression Hearing Aid Fitting in Older Children

Author: Glista, Danielle; Scollie, Susan; Sulkers, Jacob.

Publication info: Journal of Speech, Language and Hearing Research (Online) 55.6 (Dec 2012): 1765-1787.
ProQuest document link

Abstract: In this study, the authors evaluated the effect of frequency compression hearing aids on speech perception ability and the time course and magnitude of acclimatization-related changes. Participants included children ages 11-18 years. Speech perception ability was evaluated over well-controlled baseline, treatment, and withdrawal study phases. Study-worn hearing aids were individually fitted to all participants. The authors evaluated speech perception ability using outcomes of speech detection (/s/ and /S/ sounds), /s-S/ discrimination, and plural and consonant recognition. Indices of change were discussed on a case-by-case basis across all study phases. Significant treatment effects were measured for all cases, on at least one measure, with some listeners displaying significant acclimatization trends following a trial of frequency compression. Findings suggest that frequency compression provided varying outcomes, both in benefit and acclimatization, across listeners. For some, a period of acclimatization was necessary before change could be measured. For others, performance remained stable over the time course under evaluation, suggesting that some but not all children will experience improved speech recognition ability after a period of frequency compression hearing aid use.

Rehabilitation for listeners with hearing impairment (HI) often includes the provision of amplification via hearing aids.When conventional hearing aids are not able to provide audibility of high-frequency speech sounds, frequency-lowering signal processing is a clinically available treatment option. In this study, we evaluated the time course of acclimatization to a frequency-lowered signal over several months of realworld use.
For adult listeners with severe-to-profound highfrequency hearing loss, the gain needed to provide audibility of high-frequency speech sounds does not always translate into better speech perception performance. Several studies suggest that amplification at frequencies where hearing impairment is severe provides little to no speech perception benefit (Ching, Dillon, &Byrne, 1998; Ching, Dillon, Katsch, &Byrne, 2001; Hogan &Turner, 1998). Others have suggested that providing high-frequency information to listeners with highfrequency hearing loss can significantly improve speech perception, especially in noisy listening environments (Plyler &Fleck, 2006; Turner &Henry, 2002). However, individual variability in these studies suggests that some listeners receive speech perception benefit from amplified high-frequency sound, whereas others do not. For the pediatric

population, both age and hearing loss have been shown as significant predictors of speech recognition measured in both quiet and noise (Scollie, 2008; Stelmachowicz, Hoover, Lewis, Kortekaas, &Pittman, 2000). Listeners with high-frequency cochlear dead regions may experience a lack of benefit with high-frequency audibility (see review in Moore, 2004); this may vary across listeners and has largely been studied in the adult population (Cox, Alexander, Johnson, &Rivera, 2011). Studies including both adults and children have suggested that hearing aids with frequency-lowering technology could be considered for listeners with significant dead regions (Vickers, Moore, &Baer, 2001) and/or for listeners with severe high-frequency hearing loss (Glista, Scollie, Bagatto, et al., 2009; Robinson, Stainsby, Baer, &Moore, 2009).

Some clinically available types of frequency-lowering hearing aid technology include nonlinear frequency compression and frequency transposition. Studies suggest that these frequency-lowering technologies may benefit adults and children with high-frequency hearing loss, and that benefit varies across individuals (see review by Simpson, 2009). In general, frequency compression splits the incoming hearing aid signal into two channels. The high-frequency channel is compressed into a narrower bandwidth. This results in sound being lowered in frequency within the high-frequency channel (Simpson, Hersbach, &McDermott, 2005). Research suggests that frequency compression provides speech perception benefit for someadults and children with high-frequency hearing loss (Bohnert, Nyffeler, &Keilmann, 2010; Glista, Scollie, Bagatto, et al., 2009; Simpson et al., 2005; Simpson, Hersbach, &McDermott, 2006; Wolfe et al., 2010). In previous studies of frequency compression, researchers have examined varying degrees/configurations of highfrequency hearing impairment, fitting approaches, and listening environments. Research suggests that candidacy may be affected by both audiometric configuration and age group, with both children (versus adults) and listeners who have greater high-frequency hearing loss being more likely to receive benefit (Glista, Scollie, Bagatto, et al., 2009).

Auditory Acclimatization Post Hearing Aid Fitting

For listeners with longstanding severe-to-profound high-frequency hearing losses, frequency-lowering hearing aids may provide access to new high-frequency cues, albeit presented at lower frequencies. When the auditory system receives this new acoustic information, some time for learning-induced reorganization may be required to accommodate novel sounds. This adjustment period has been defined as auditory acclimatization (Arlinger et al., 1996), as reported in the Eriksholm Workshop on Auditory Deprivation and Acclimatization (1996): "Auditory acclimatization is a systematic change in auditory performance with time, linked to a change in the acoustic information available to the listener. It involves an improvement in performance that cannot be attributed purely to task, procedural or training effects" (p. 87S).

The role of auditory acclimatization post hearing aid fittings has been a topic of interest in the literature for many years. The evidence presented in the older research is mixed. In several studies, researchers concluded that the acclimatization effect is minimal and may vary according to measurement technique, practice effects, and/or changes made to hearing aid gain within a study (Bentler, Niebuhr, Getta,&Anderson, 1993; Flynn, Davis, &Pogash, 2004; Humes, Halling, &Coughlin, 1996; Saunders &Cienkowski, 1997; Surr, Cord, &Walden, 1998; Turner, Humes, Bentler, &Cox, 1996). Alternatively, several studies have reported change in benefit over time in the range of 0% to 10%, with some individuals demonstrating larger improvement (Arlinger et al., 1996; Cox, Alexander, Taylor, &Gray, 1996; Gatehouse, 1992, 1993; Horwitz &Turner, 1997; Kuk, Potts, Lee,Valente,&Picirrillo, 2003; Silman, Silverman, Emmer, &Gelfand, 1993; Yund, Roup, Simon, &Bowman, 2006). In all of the studies noted above, experimenters tested adult subjects, with one exception-the study by Flynn and colleagues, in which the authors concluded that that the trend in improved speech perception over time likely related to fine-tuningmodificationsmade over the course of the study rather than an acclimatization effect. Overall, individual variability in acclimatization post hearing aid use may relate to factors including hearing loss severity/configuration, age, cognitive ability, hearing aid experience, hearing aid style, and the complexity of the hearing aid signal-processing scheme (Bentler et al., 1993; Cox et al., 1996; Gatehouse, 1992; Horwitz &Turner, 1997; Saunders &Cienkowski, 1997; Yund et al., 2006).

Data regarding adult-child differences in post hearing aid acclimatization patterns are not readily available, although auditory learning studies in listeners with normal hearing indicate that maturation of auditory learning continues to develop through adolescence (Huyck &Wright, 2011). These studies are consistent with maturation of auditory evoked potentials, in which maturation may occur by age 6 years or continue to approximately age 12, depending on the methodology (Pang&Taylor, 2000; Ponton, Eggermont,Kwong, &Don, 2000;Wunderlinch&Cone-Wesson, 2006). Overall, research suggests that maturation related to auditory processing skills, such as speech recognition, may continue into adolescence. This evidence is consistent with the idea that children may not show the same acclimatization patterns as adults. In addition to maturation effects, generalization of auditory learning may be both task and stimulus dependent (Wright &Zhang, 2009). In general, frequency resolution abilities tend to mature earlier (Hartley,Wright, Hogan, &Moore, 2000) and generalize outside of trained tasks (Wright&Zhang, 2009), compared with temporal abilities.

Auditory Acclimatization and Frequency Lowering

Current research suggests that acclimatization may play a role in speech perception performance with frequency-lowering technologies. Wolfe and colleagues (2010, 2011) formally evaluated the long-term effects of frequency compression in children ages 5-13 with moderate to moderately severe hearing loss at 6 weeks and 6 months post fitting. Results varied across the different speech measures used in the study. Aided detection results improvedwith frequency compression and remained stable over the 6-month time course. Recognition of wordfinal plurality improved with frequency compression; however, high performance levels limited measurement of long-term acclimatization effects. Nonsense syllable recognition was significantly better at the 6-month period when compared with conventional processing and after 6 weeks of frequency compression use. Last, frequency compression offered improved speech recognition in noise after several weeks to several months of use. Because there was no control group, Wolfe and colleagues could not determine whether the improvement in recognition of speech sounds over time should be attributed to a learning effect, acclimatization, or both. The authors pointed out the possibility that improvements measured over time may have been, in part, due to linguistic and/or cognitive maturation, on the basis of the study length and the children's ages (Wolfe et al., 2011). Additional studies on the effects of frequency lowering with children have suggested that benefit may vary with acclimatization time (Auriemmo et al., 2009; Glista, Scollie, Bagatto, et al., 2009; Glista, Scollie, Polonenko, &Sulkers, 2009; Wolfe et al., 2010). Further research is needed to examine the time course of acclimatization effects on perceptual benefits of frequency-lowering technology.

The Current Study

This study was designed to examine the time course of acclimatization to frequency-lowering hearing aids. We recruited a group of older HI children and followed them for 6 months of hearing aid use. We selected this age range of children to minimize expected maturational confounds.We chose this age range on the basis of studies related to the maturation of auditory evoked potentials (described above) in the absence of direct evidence related to adult-child differences in post-hearing-aid acclimatization patterns. Speech perception measures were administered on 10 different testing appointments spanning baseline, treatment, and withdrawal phases. We used a single-subject design; each participant acted as his or her own control. In this study, we evaluated the effect of nonlinear frequency compression hearing aids on speech perception ability and the time course and magnitude of acclimatization-related changes following a real-world trial.

Method

Participants

Recruitment of six participants ages 11-18 years took place at the University of Western Ontario (UWO) H. A. Leeper Speech and Hearing Clinic, local audiology clinics, and through an educational audiologist. Participants who met the inclusion criteria for the study were enrolled in a sequential manner; recruitment efforts were limited to a smaller number of participants, facilitating a single-subject design. The feasibility of collecting data from a larger number of participants was limited due to challenges encountered when conducting repeated

outcome measurement over an extended time course. No participant was excluded on the basis of task performance or degree of benefit. For binaurally aided participants, audiometric inclusion criterion were as follows: a bilateral sensorineural hearing impairment, sloping to at least a moderately severe high-frequency pure-tone average (HF-PTA) hearing level averaged across 2000 Hz, 3000 Hz, and 4000 Hz.

Participants were required to be full-time users of digital behind-the-ear (BTE) hearing aids prior to entering the study. Five of the participants wore binaural hearing aids and had high-frequency losses that were symmetrical within 10 dB on the basis of HF-PTA. One participant with an asymmetrical hearing loss was monaurally aided in the better ear (Case 6). On average, the participants beganwearing hearing aids at age 3.75 years, as per parental report. Details pertaining to previously worn hearing aid type, fit-to-targets, and FM usage are reported in Table 1. A data-logging feature tracked hearing aid usage over the course of the study on all studyworn hearing aids. All participants were assessed as full-time hearing aid users (i.e., achieving continuous usage during school hours) prior to beginning data collection. TheUWOResearchEthicsBoard approved this study for health sciences research involving human subjects.

Pure-tone air conduction thresholds were measured bilaterally at all octave and interoctave frequencies between 250 Hz and 8000 Hz for each participant using a Grason-Stadler 61 audiometer. Air conduction threshold testing was completed in a double-walled soundtreated booth using Etymotic Research ER-3A insert earphones coupled to each participant's personal earmolds. We measured hearing thresholds at the beginning and end of the study; all participants demonstrated hearing levels within 10 dB of baseline over the course of the study. Participants were evaluated for cochlear dead regions (DRs) through use of the threshold equalizing noise (TEN-HL) test; results were interpreted through use of published criteria (Malicka, Munro, &Baker, 2010; Moore, 2004; Moore, Glasberg, &Stone, 2004). Refer to Table 1 for demographic and TEN test results. This test supports measurements up to 4000 Hz. Suspected DRs are reported according to TENtest results; in some cases, no DRs were measured (denoted with "none") or hearing threshold levels were beyond the range of the TEN-HL test (denoted with "INC"). Participants are listed from least to greatest HF-PTA.

Hearing Aid Fitting

Device fitting followed protocols from the Desired Sensation Level (DSL) method Version 5.0 (Bagatto et al., 2005; Scollie et al., 2005) as implemented within the Audioscan Verifit VF1. Each participant was fitted with study-worn hearing aids: Phonak Naida IX SP BTE hearing aids coupled to integrated FM receiver boots (MicroLink ML10i); these devices were worn for the entire duration of the study with the gain/advanced features of the devices held constant throughout.We disabled the volume control (VC), digital noise reduction (DNR), and automatic program selector features in the main listening program. Prescriptive targets were matched using simulated real-ear measures incorporating individual real ear to coupler difference (RECD) values.We selected a coupler-based verification strategy to reduce room noise/reverberation effects and concerns with feedback during real-ear procedures; this promoted test environment consistency and replicable measures across the repeated fitting appointments. Aided measurements of speech at 55 dB SPL, 65 dB SPL, 70 dB SPL, and 75 dB SPL, and for a 90 dB SPL puretone signal were completed during fitting appointments. Hearing aids were adjusted so that the best possible match to targets would be provided. When required, participant-driven gain adjustments took place, and only prior to beginning the baseline condition. Reported fit-to-targets data reflected measurement made at the settings worn for this study including any participantrequested gain adjustments. Table 1 includes a summary of the fit-to-targets per child, indexed as the highest frequency at which prescriptive targets could be met within 5 dB for a 70 dB SPL input level. The baseline condition began once this fitting process was completed.

Following the baseline condition, frequency compression parameters were individually adjusted according to a previously established protocol (Glista&Scollie, 2009; Glista, Scollie, Bagatto, et al., 2009), described briefly here. Gain and amplitude compression were held constant to match those of the baseline fitting. Better-ear hearing thresholdswere used in the selection of frequency compression settings. The settings were then applied

binaurally; in this study, we did not investigate the use of asymmetrical settings. Verification of frequency compression used filtered speech passages available in the Audioscan Verifit VF-1. These passages are shaped to include low-frequency energy, a notched mid-frequency area, and a 1/3 octave band of high-frequency speech energy. This high-frequency band is clinician-selectable, and it centered on frequencies at 3150 Hz, 4000 Hz, 5000 Hz, or 6300 Hz. When tested with frequency compression offversus on, the clinician can observe the frequency location and audibility of the speech band (Bentler, 2010; Glista &Scollie, 2009). We measured the bands centered on 4000 Hz and 6300 Hz at an input level of 70 dB SPL and assessed whether they were audible. We enabled and adjusted frequency compression until they were audible or until the limits of adjustment were reached (refer to Table 1 for case-specific results). This type of measurement does not take into account the bandwidth of frication sounds. For this reason, fittervocalized sustained fricatives (/s/ and /S/) were used in aided response measurements through the Verifit "livespeech" mode. This allowed an evaluation of the frequency overlap of the frication bands. Fitting adjustments were made to minimize /s-S/ overlap, if possible, in an attempt to provide a fitting that minimized the risk of /s-S/ confusion.

Outcome Measures

We administered four aided behavioral outcome measures: (a) speech sound detection, (b) plural recognition, (c) /s-S/ discrimination, and (d) consonant recognition. The first three measures assessed detection or discrimination of high-frequency speech sound (for sensitivity in the frequency range of the processor), and the fourth assessed recognition of a broad range of speech sounds (to provide a more generalizable assessment of speech sound recognition). Test stimuli were presented monaurally to the better-hearing ear according to preference and HF-PTAvalues. For discrimination and consonant recognition tasks, we varied presentation levels between 55 dB SPL and 70 dB SPL re: the 2cc coupler across cases to ensure testing above chance performance in the baseline condition, but presentation levels were held constant thereafter. The plural recognition task was presented at 55 dB SPL on the basis of procedures from previous studies (Glista, Scollie, Bagatto, et al., 2009; Wolfe et al., 2010). The speech sound detection task was adaptive by level. Counterbalancing was used during outcome measure presentation, per test session. Calibration was performed in the coupler using a hearing aid programmed to have no gain.

Outcome measures were implemented in custommade experimental software, executed from a personal computer. A computer monitor, positioned in front of each participant, displayed response choices that the participant selected via the use of a mouse. Signals, in the form of .wav files, were routed from the computer to a custom-made programmable attenuator (CM108AH audio chip and LM1973 audio attenuator) and a clinical audiometer (GSI-61). Signals from the audiometer were presented through a modified direct-audio-input (DAI) connector cord connected to the hearing aid.

Speech sound detection. We measured aided detection thresholds for speech sounds using an adaptive, computer-controlled version of the Ling Test (Ling, 1988; Tenhaaf &Scollie, 2005). Stimuli, spoken by a female talker, were presented in isolation through the use of a starting presentation level of 70 dB SPL. Threshold values were estimated as the average level of four reversals to a 50% detection criterion. A 10-dB step size was used in the first reversal, followed by a 4-dB step size for all subsequent reversals. These parameters of the adaptive testing procedure remained constant throughout testing. The detection procedure was administered twice for each phoneme across all testing phases. Phonemes were tested in a random order per administration.

Traditionally, the Ling Test is composed of six sounds: /m/, /a/, /i /, /u/, /S/, and /s/. To facilitate measurements of aided detection, sensitive to changes in highfrequency audibility, two mid/high-frequency sounds were included: /S/ and /s/. A 1/3 octave band spectral analysis of the stimuli is provided in Figure 1a. Spectral peaks reside at approximately 6000 Hz for /s/ and 2500 Hz for /S/. Aided thresholds measured with these two sounds have been used in previous studies of frequency lowering (Glista, Scollie, Bagatto, et al., 2009). In general, this test measures the lowest level at which isolated speech sounds can be heard. When presented in a repeated

measures paradigm, this test can provide information concerning a change in hearing level across different hearing aid conditions (i.e., with and without frequency compression). Depending on the hearing level of the listener and/or activation of frequency compression, it is possible that a listener could hear the phonemes in a distorted and/or alternate form. In the case of steeply sloping, severe-to-profound high-frequency hearing loss, audibility of /s/ or /S/ may be limited to only the lower shoulder of the frication band; this means that resulting measured detection thresholds would likely reflect partial audibility of the sound(s) tested.

Plural recognition. The UWO Plurals Test (Glista &Scollie, 2012) assesses participants' ability to use the fricatives /s/ and /z/ as bound morphemes. For this task, we chose stimuli similar to those used in previous research to test sensitivity to high-frequency audibility in children who use hearing aids (Stelmachowicz, Pittman, Hoover, &Lewis, 2002). Stimuli include the singular and plural forms of 15words: ant, balloon, book, butterfly, crab, crayon, cup, dog, fly, flower, frog, pig, skunk, sock, and shoe. The testing paradigm included the use of computer-controlled software to automate stimulus presentation, presentation of a closed set of responses, and scoring. A 1/3 octave band analysis of the concatenated words and the extracted fricative portion at the end of each word is displayed in Figure 1b. The mean spectral peak of the fricative portion resides at approximately 5000 Hz. Stimulus files were automatically generated via a computer in random order and including two repetitions, generating a score out of 60 items per measurement. Stimuli were mixed with a speech-shaped noise at a +20-dB signal-to-noise ratio (SNR). The noise was included to mask low-level stimulus offset cues that could have served as a surrogate cue for plural identification. Participants were instructed to pay attention to the stimuli rather than to the noise. Tester observation inferred that the inclusion of low-level noise did not appear to influence the ability of the children to focus on the stimuli of interest. A closed response set was presented on a computer monitor using pictures (from articulation cards; Super Duper Publications [Webber, 1998a, 1998b, 1999, 2000, 2003]) and a corresponding orthographic display. Each response set included the singular and plural form of each target word. Participants were instructed to choose which picture best described what he or she heard.

The UWO Plurals Test has been included in other studies designed to assess the effects of frequency compression hearing aid technology (Glista, Scollie, Bagatto, et al., 2009; Wolfe et al., 2010). Literature on the development and evaluation of this test proposes its use in evaluating the detection of high-frequency fricative sounds in a word-final position. Results obtained in listeners with normal hearing and in listeners with hearing impairment (aided conditions) indicated reliable repeated outcome measurement (Glista &Scollie, 2012).

/s-S / discrimination. An aided discrimination task, developed at UWO, was included in the test battery to facilitate the measurement of /s-S/ discrimination. This consisted of six consonant-vowel (CV) syllables including high-frequency fricatives coupled to three vowels ranging in articulator dimension (i.e., front-back, high- low). The stimulus set included nonsense CV pairs /si-Si/, /sa-Sa/, and /su-Su/, spoken by three adult female talkers. Stimuli were presented in a three-alternative forcedchoice paradigm, and participants were instructed to choose the "oddball" item. Each discrimination score included 54 items (18 items ×3 repetitions). Items were randomized and run in a single block at each testing session. Due to the nature of frequency compression hearing aid processing, frequency compression can result in sounds being presented at lower frequencies and/or with an altered spectral shape (when compared with conventional processing). These effects are of particular interest when considering discrimination of /s-S/ with frequency compression because it can modify the spectral shape of /s/, making it appear closer to that of /S/. Results measured with the /s-S/ discrimination may be influenced by factors including degree of hearing loss, previous exposure to partial or full cues of /s/ and /S/ sounds with conventional amplification, and strength of frequency compression settings.

In the development of this task, we chose the /s/ and /S/ sounds to form recordings made in a double-walled sound booth using a studio-grade AKG condenser microphone (C 4000 B). The microphone was connected to a preamplifier and analog-to-digital converter (USBPre) and desktop computer. Recorded files were digitized at a sampling rate of 44100 Hz, using 16-bit resolution. We used the SpectraPLUS FFT Spectral Analysis System to

store the resulting file. All stimuli were recorded several times, and final test items were chosen for similarity and neutrality of intonation for each /s-S/ pair.We introduced stimulus-specific variability to minimize the ability to use idiosyncrasies of a specific stimulus for recognition rather than spectral cues, per se. Variation in the spectral energy of the fricatives was achieved through the pairing of consonants with three different vowels (Boothroyd &Medwetsky, 1992). In addition, multiple talkers and repetitions of each utterance were included.
We analyzed the CV spectra to determine differences in the spectral energy of /s/ versus /S/ (using Praat software). Specifically, we measured the centroid frequency, or center of gravity of the frication noise (Forrest,Weismer, Milenkovic, &Dougall, 1988), by extracting the fricative portion of the CV stimuli using 1/3 octave bands analysis (SpectraPLUS; see Figure 2). Centroid values range from 8.03 kHz to 10.37 kHz for CVs beginning with /s/, and from 3.81 kHz to 5.98 kHz for CVs beginning with /S/. The spectral peak is estimated at approximately 10 kHz for CVs beginning with /s/ and at approximately 3 kHz for CVs beginning with /S/. These findings are consistent with those reported in the literature describing the spectral peak frequency of female speech: The spectral energy of an /s/ sound peaks at approximately 6- 9 kHz for female speech, whereas the spectral energy of /S/ peaks over a range of approximately 3-6 kHz (Boothroyd& Medwetsky, 1992; Pittman, Stelmachowicz, Lewis, &Hoover, 2003).
Consonant recognition. To measure consonant recognition, we used the University of Western Ontario Distinctive Features Differences Test (UWO-DFD; Cheesman &Jamieson, 1996), developed with four talkers and 21 nonsense disyllables, including / b, tS, d, f, g, h, dZ, k, l,m, n, p, r, s, S, t, 8, v, w, j, and z/.We presented all items in a fixed, word-medial context (i.e., LCIl). Participants were instructed to select the target nonsense word from an orthographic display on a computer monitor. Presentation of stimuli, recording of responses, scoring, and presentation of results were all under computer control. The final task included 84 items, comprised of tokens spoken by two female talkers and two male talkers. Each phoneme was therefore presented four times in a random order across speakers. We included the UWO-DFD in this study to provide both a general measure of the participant's abilities to identify consonant sounds and an indication of the types of confusion errors made across the different testing conditions. Previous studies found consonant identification tasks to be sensitive to changes in the patterns of consonant confusions introduced by frequency-lowering technologies (Robinson, Baer, &Moore, 2007; Robinson et al., 2009). This test was included in previous research evaluating aided speech sound recognition in child and adult listeners (Glista, Scollie, Bagatto, et al., 2009; Jenstad, Seewald,Cornelisse,&Shantz, 1999; Scollie, 2008; Scollie et al., 2010).
Study Design and Data Collection Sequence
Case series evaluation was conducted as a withdrawal design, including outcome measures administered repeatedly for two test conditions: evaluation of conventional processing and evaluation of frequency compression. The experiment was sectioned into three phases: (a) Baseline (with conventional processing), (b) Treatment (with frequency compression), and (c) Withdrawal (with conventional processing). Across all conditions, study participants were blind to the status of hearing aid processing. Experimenter bias was minimized through the use of fully automated, computer-controlled testing.
We employed a single-subject design to evaluate change at the level of the individual; this approach was used in prior research on acclimatization effects post hearing aid use (Gatehouse, 1992). This type of research design requires experimental control and rigor, as does group-level design, although the specific experimental parameters differ and are specific to singlesubject design (Logan, Hickman, Harris, &Heriza, 2008). In single-subject design, each participant serves as his or her own control, thus allowing researchers the opportunity to measure significant changes in performance at the individual level (Gast, 2010). Achieving this level of control was of particular interest in this study because each participant presented with different hearing loss degrees/configurations, thus requiring different frequency compression settings. In addition, previous studies (Simpson, 2009) have reported large between-subject variability in results obtained with frequency-lowering hearing aids. The use of change indices within singlesubject design can facilitate measurement of small,

consistent variations in performance level within a testing condition. Such findings may not be as apparent at the group level. Although this type of design offers a way of evaluating clinical significance, the extent to which findings can be applied to HI listeners beyond this study is limited.

Baseline phase. The volume control was disabled during this phase (and all other phases of the study). A minimum of two testing sessions were scheduled for all tasks during the baseline phase. A stopping criterion enabled evaluation of stable performance without frequency compression prior to introducing treatment. Confidence intervals (CIs) were used briefly to judge whether performance across adjacent testing sessions was significantly different; lack of change across adjacent sessions was interpreted as stable performance. The goal of this design was to allow practice and acclimatization time without frequency compression and start the treatment phase once stable baseline performance was achieved.

Treatment phase. This phase included six test sessions-four sessions of outcome measurement completed every 2 weeks, followed by two sessions at monthly intervals. Frequency compression processing was enabled for the first test session and remained enabled without modification across the entire treatment phase. Strict adherence to the intended biweekly/monthly timeline could not be achieved for all participants due to illness and/or scheduling factors. On average, we allotted a 16-week treatment phase to all participants (range = 14.1-17.0 weeks). This time period is consistent with that reported in the literature (i.e., 12-18 weeks) investigating acclimatization effects in aided speech perception (Gatehouse, 1992, 1993; Horwitz &Turner, 1997).

Withdrawal phase. We included a final test session to evaluate performance without frequency compression following acclimatization to frequency compression. We achieved this by disabling the frequency compressor on the final day of testing. All participants wore the study aids with frequency compression enabled until the time of this withdrawal appointment. On average, withdrawal testing was completed 3.5 weeks (range = 1.0-7.4 weeks) after finishing the treatment condition of the study. Details pertaining to the study design and individual results were disclosed to the participants upon completion of the withdrawal phase. The study-worn aids were then offered to all participants free of charge, with the option of reenabling frequency compression and/or incorporating other fitting alterations. All participants chose to keep the study-worn aids with frequency compression enabled; the sole change requested was enabling of the VC.

Results

Analysis Strategies

Analyses focused on significant change, both positive and negative, in speech perception performance at the individual level within and across study conditions. Analyses included the use of CIs calculated across change indices (Morgan &Morgan, 2009; Portney &Watkins, 2000) and a within-condition approach (Gast, 2010), as described below. Within-condition analyses are traditionally found in single-subject research to analyze the direction of change within a testing condition. All analysis strategies were chosen to facilitate measurement of small, consistent change at the individual level. Indices of change included (a) increased or decreased performance within the baseline condition, (b) overall difference in performance between baseline and treatment, (c) increased or decreased performance during the treatment condition (denoting acclimatization trends), and (d) differences between adjacent scores at the boundaries of the baseline and treatment or treatment and withdrawal conditions. Error pattern analyses were performed for three of the four indices of changes, according to results obtained on the UWO-DFD test. Case-specific results are presented in the order in which they appear in Table 1.

Change within the baseline condition. For each child, CIs were calculated around scores corresponding to each testing session within the baseline condition. This facilitated an evaluation of change across adjacent testing sessions and the use of a stopping criterion. Intervals were computed from the mean baseline score, which is ±1.96 ×the SD of test-retest scores for repeated measures including plural recognition, /s-S/ discrimination, and detection measures (Portney &Watkins, 2000). For the consonant recognition measure, the SD was calculated from the binomial theorem (Thornton &Raffin, 1978). The length of the baseline condition was determined on a

case-by-case basis and according to the following stopping criterion: demonstration that (a) the mean score of the adjacent testing session fell within this CI or (b) the mean score for the adjacent testing session fell below the CI. These simplified CIs (related to test-retest) assisted the tester in deciding when a participant should advance to the treatment phase; this strategy differed from those described below.

We used a CI, derived around the entire baseline phase, to evaluate change attributable to treatment. This interval was calculated as the upper limit of a CI around the mean scores across the baseline phase. CIs were calculated around mean scores according to the binomial theorem for all recognition- or discrimination-based tasks and using a CI of ±5 dB for detection tasks. This yielded a CI around detection scores larger than the mean baseline test-retest error for this task. Significant change attributable to frequency compression use was observed when two ormore consecutive treatment scores fell outside these CIs; this is consistent with established procedures and takes into account that treatment effects are not always stable over a prolonged period of testing (Morgan &Morgan, 2009).

Change within the treatment condition. Additional analyses were performed on scores within the treatment condition in a two-step process for each measure and child; this second step was completed only when the first step yielded a significant result. First, we evaluated the relative change in performance level by subtracting the median value of the last three testing sessions from that of the first three testing sessions; we used median values, rather than mean values, to limit degree of influence from outliers (Gast, 2010). Second, we performed linear and nonlinear regression analyses to further evaluate the acclimatization trend. Data sets displaying a gradual change over time were fitted linearly; results were deemed significant when the slope of the line was significantly different from zero. Data sets displaying improvement after a specific period of time (i.e., S-shaped curves) were fitted with a sigmoidal function using XLfit curve-fitting software (ID Business Solutions, 2009):

... (1)

whereDdescribes the bottom plateau of the curve, Vmax describes the range of performance values the curve takes, n describes the slope factor, and Km describes the x value at which the middle y value is attained. Nonlinear analyses were deemed significant when raw data points were strongly correlated to those predicted ($p < .05$). Trends are plotted for significant cases only (see Figures 3 through 8) and are summarized in Table 2.

Change between adjacent scores: Baseline to treatment or treatment to withdrawal. To evaluate an initial treatment effect, we derived CIs around the final baseline scores; these extended into the treatment phase to include the initial treatment score. We calculated CIs around mean scores according to the binomial theorem for all recognition/discrimination-based tasks and using a CI of ±5 dB for detection tasks. A significant treatment effect (benefit/decrement) was reported when the initial treatment score fell outside the interval. To evaluate the withdrawal effect, we derived CIs around the final treatment score; these extended to include the withdrawal score. Intervals were calculated through use of the binomial theorem for all recognition- or discrimination-based tasks and using a fixed CI of ±5 dB for detection tasks. A significant withdrawal effect (benefit or decrement) was reported when the final score with frequency compression disabled fell outside this treatment CI.

Error pattern analysis.We used raw scores obtained on the UWO-DFD test to generate tables of "difference" confusion matrices, across participants and for the latter three of the changes indices (see the Appendix). The first column of matrices display change in consonant confusions due to initial activation of frequency compression; scores are a result of subtracting final baseline scores from initial treatment scores. The second column displays change within the treatment condition (i.e., acclimatization effects); scores are a result of subtracting initial treatment scores from final treatment scores. The final column displays change due to withdrawal of treatment; scores reflect subtraction of the withdrawal scores from the final treatment scores. Stimuli appear in alphabetic order according to the response options presented to the participants. Interpretation of results falling along the diagonal are as follows: Positive numbers indicate less errors with frequency compression enabled (first and last columns), or an improvement with frequency compression over time (second column only), and negative numbers indicate frequency compression decrement. The opposite can be

interpreted for results falling offthe diagonal: Positive numbers indicate more errors with frequency compression enabled, and negative numbers indicate fewer errors without frequency compression (compared with either frequency compression or across time). Because of the small sample of results displayed for each participant, this discussion focuses on changes in confusion identification greater than 50% (i.e., a difference value of three or four).

Case Study 1

Case Study 1 is an example of a child who received little benefit from frequency compression and who performed at ceiling on most tests regardless of hearing aid condition. Figure 3 shows the results for the first case, displayed for each measure as a function of time. The vertical lines within each panel delineate the baseline, treatment, and withdrawal phases. Shaded areas represent the CIs. Results without and with frequency compression are plotted as open and filled symbols, respectively. Note that the ordinates for the upper panels (measured in percent correct) and lower panels (measured in dB SPL) indicate performance and threshold measures, respectively. An asterisk and/or a trend line indicates significant effects. Also included in this figure is an audiogram showing the child's hearing thresholds.

Overall, Case Study 1 had high performance scores for the recognition and discrimination tasks across test sessions. Significant initial frequency compression benefit was measured on the /s/ detection task only, which is an adaptive task with the highest frequency stimulus in this battery. Electroacoustically, there was little room for improvement with frequency compression because the conventional processing condition was able to match targets to 4000 Hz. Participant comments made during the treatment phase included that of new audibility of warning signals at school and during use of personal listening devices; the participant viewed these new sounds in a positive manner.Asignificant withdrawal effect was measured for consonant recognition and detection of /s/ relative to the final score for the treatment condition. No significant trends were observed within the treatment condition, suggesting limited acclimatization (see Table 2), although ceiling performance limited our ability to measure further change on many measures. Error pattern analyses (see the Appendix) revealed that this participant had initial difficulty identifying /8/ and /v/ sounds with frequency compression; /8-v/ recognition improved with acclimatization.

Case Study 2

Case Study 2 is an example of a child who received significant benefit from frequency compression in addition to nonlinear acclimatization trends but had initial decrement on some measures. Figure 4 displays all results for Case Study 2. Significant initial benefit with frequency compression was measured for the plural recognition task, whereas significant initial decrement was measured for /s-S/ discrimination and /S/ detection. Significant overall treatment benefit was found on the plural and consonant recognition tasks, whereas significant overall treatment decrement was found for the /S/ detection task. Significant changes occurred when frequency compression was withdrawn, with poorer performance on /s-S/ discrimination and better performance on /S/ detection. Acclimatization trends were observed for consonant recognition, /s-S/ discrimination- and detectionbased tasks with significant nonlinear acclimatization trends for consonant recognition, and /s-S/ discrimination (see Table 2). Error pattern analyses (see the Appendix) suggest consonant confusions between affricate and fricative sounds; however, no clear patterns of error change can be observed across study conditions. Approximately 10 weeks with treatment was required to demonstrate significant consonant recognition improvement. One interesting aspect of this acclimatization pattern is the initial decrement observed with /s-S/ discrimination, which resolved with increased experience with frequency compression.

Interpretation of this case is difficult given the mixed pattern of results. Electroacoustically, the 6300-Hz region of speech was audible with frequency compression but not without. Therefore, sounds with energy in this region (e.g., /s/) may have become audible, which would explain the improved performance in detection word-final plurality and in detection of /s/. However, for detection of an /S/ sound and /s-S/ discrimination, verification evidence suggests that audibility of the 4000-Hz region was present both with and without frequency

compression. Therefore, the participant was required to change her discrimination of /s/ and /S/ froma sound versus silence cue to those of newly audible cues. It appears that she did so following 8-10 weeks of experience with the new processor, but this came at the cost of poorer detection thresholds for /S/. Looking at consonant recognition from a broader perspective, these various beneficial and unfavorable effects combined to provide an overall benefit to consonant recognition after 8-10 weeks of acclimatization to the new processor. The participant did not report any difficulty understanding speech over the course of the study. Overall, the results presented for Case 2 suggest more benefit than detriment with frequency compression.

Case Study 3

This case study describes a child who showed significant acclimatization post hearing aid fitting with frequency compression; however, a withdrawal effect was not measured for this participant. Figure 5 displays all results for Case 3. Significant initial benefit was measured for detection of /s/. Significant overall treatment benefit was measured for plural recognition and /s/ detection. When frequency compression was removed, no significant changes were measured. This may have been due to results approaching the significance level on the plurals task and to fairly small changes on /s/ detection overall. As well, performance on the discrimination task was at ceiling across all phases of the experiment. Error pattern analyses (see the Appendix) suggest that this participant experienced many different consonant identification errors over the course of the study; errors are not confined to specific distinctive features. However, acclimatization effects are noted for /r-v/ and /r-w/ confusions (i.e., identification improved over time) and on /z- dZ/ confusions (i.e., more errors were made over time).

Within the treatment condition, significant acclimatization-related changes were measured for plural and consonant recognition and for detection tasks. A significant nonlinear trend was observed for plural recognition along with a linear trend for consonant recognition (see Table 2). Therefore, two different acclimatization trends are present in the data sets for Case Study 3: gradual improvement over time on the consonant recognition task and improvement after 6 weeks of acclimatization on the plural recognition task.

Case Study 4

The child in Case Study 4 had the largest degree of benefit from frequency compression in the study, along with prominent patterns of acclimatization. Prior to beginning testing, this child requested a significant amount of adjustments to the initial fitting due to loudness, which contributed to gain reduction at approximately 2000Hz and above, consistent with reported fit-to-targets (see Table 1). TEN test results suggested the presence of cochlear dead regions at 2000 Hz and above; therefore, gain adjustments may have been driven by perceived distortion in sound quality and excessive loudness for sounds in the dead region (complaints related to average and loud conversational speech, spoken by school peers). These reports are consistent with those in the literature of listener-perceived sound quality at frequencies where dead regions are present (Moore, 2004). In addition to participant-driven gain reductions, we also created a noise management program (second to the main study worn listening program) to assist with hearing aid use in noisy environments; this program had the same frequency response as that of the testing program but included noise reduction digital signal processing. Figure 6 displays all results for Case Study 4. Significant initial frequency compression benefit was measured for plural recognition. Significant overall frequency compression benefit was found on the plural recognition, /s-S/ discrimination, and detection of /s/ and /S/. Significant decrements occurred when frequency compression was withdrawn-on all measures except the consonant recognition task; therefore, withdrawal effects were measured for tasks where frequency compression benefit was also noted and for tasks measuring the effects of speech perception related to /s/ and /S/ sounds. In addition, significant acclimatization trends were observed. A linear increase in performance with time was measured for plural recognition and detection based-tasks along with a nonlinear trend for /s-S/ discrimination (see Table 2). Error pattern analyses (see the Appendix) suggest improved consonant identification with frequency compression for some of the affricate, fricative, and other consonant sounds. Specifically, identification of /d/ improved with initial activation of frequency compression,

/tS-k/ confusion improved over time, and identification of /S/ and /8/ sounds improved with acclimatization time. Two unique acclimatization trends are present in the data presented for Case Study 4: gradual improvement over time for plural recognition and detection-based tasks and improvement after a specific period of acclimatization (i.e., approximately 6 weeks) for the discrimination task. Given this participant's history and extensive dead regions, enabling frequency compression likely would have provided novel sounds. For this reason, an acclimatization periodmay have allowed this listener to associate these novel cueswith specific phonemes (to be able to recognize and discriminate sounds). The significant withdrawal effect reported across four out of the five tasks suggests that benefit change over time can be attributed to novel speech cues introduced with frequency compression as opposed to practice effects.

Case Study 5

Case Study 5 is an example of a child who received significant benefit after acclimatizing to frequency compression. Across measures, this child's within-session variability was larger than that of other children, resulting in larger CIs. Figure 7 displays all results for Case 5. Significant initial and overall frequency compression benefit was measured for the discrimination task; a significant acclimatization effect occurred at approximately 8 weeks. Overall frequency compression decrement was measured for both detection tasks. When frequency compression was withdrawn, /s/ detection was significantly poorer. This participant did not comment on differences in sound quality or perceived speech perception ability over the course of the project. It is unclear why this participant experienced a performance decrement with frequency compression on the detection tasks. Hearing threshold levels, screened on more than one occasion, ruled out the presence of threshold shift.

Significant acclimatization-related improvement was measured in plural and consonant recognition as well as for /s-S/ discrimination (see Table 2). A large improvement in /s-S/ discrimination ability was observed after approximately 8weeks. Error pattern analyses (see theAppendix) suggest an initial decrement in identifying /tS/ and /f/ sounds, with /f/ largely being confused with /s/. Initial improvement in /z-v/ identification with frequency compression is also noted. Over time, /tS/, /dZ/, /s/, and /8/ identification improved with frequency compression. Improvement in /s/ identification was largely due to less /s-S/ confusions over time.Withdrawing frequency compression resolved /s-f / confusion but introduced greater difficulty identifying /d /.

Case Study 6

The child in Case Study 6 received little benefit from frequency compression and performed relatively poorly on all speech perceptionmeasures. Recall that this adolescent had the most hearing loss of all cases and was a longstanding wearer of monaural amplification due to lack of benefit amplification in her poorer ear. Although the study aidprovided greater range of sounds thanwas audible with her previous aid, speech audibility was very limited in the high frequencies. The chosen frequency compression setting was among the strongest available in the clinical software, yet neither the 4000-Hz bands nor the 6300-Hz bands were made audible (see Table 1). Aided measurements of /S/ indicated that the lower shoulder of the /S/ frication band was above threshold only when frequency compression was applied, whereas the /s/ frication band was well below threshold regardless of frequency compression activation/deactivation. Therefore, this case illustrates outcomes associated with a less-than-optimal fitting, even with frequency compression, due to limitations in fitting arising from profound hearing loss and device limitations.

Figure 8 displays all results for Case Study 6. Significant initial and postacclimatization frequency compression benefit was measured on the discrimination task. On the basis of the measurements of aided speech bands and aided live /S/ and /s/, this may relate to hearing a partial cue for /S/ and differentiating it from an inaudible or very soft/s/ when using frequency compression, versus hearing neither sound when frequency compression was not active. This type of discrimination was previously observed in studies of childrenwithmoderately severe to profound hearing losses (Kosky &Boothroyd, 2003). Within the first half versus last half of the treatment condition, we observed small but significant acclimatization-related improvements for plural identification,

consonant recognition, and /s-S/ discrimination (see Table 2). However, the acclimatization trend across the treatment period did not reveal a significant linear or nonlinear pattern and was not accompanied by a significant withdrawal effect (this result pattern is detailed below in the Discussion section). Error pattern analyses (see the Appendix) are difficult to interpret for this participant, as they are scattered across many different consonants and are nonuniform; this is thought to be due, in part, to the degree of hearing loss presented in Case Study 6. Initial improvement in identification of /b/ is noted with frequency compression, and greater /r-w/ confusions are noted over the treatment condition. Overall, this adolescent experienced significant frequency compression benefit in /s-S/ discrimination. The small but significant acclimatization-related improvements experienced during a trial with frequency compressionwere not large enough to result in significant benefits when compared to baseline or posttrial testing without frequency compression.

Discussion

In this experiment, we evaluated treatment effectiveness and auditory acclimatization effects attributable to frequency compression hearing aid signal processing. Performance with frequency compression varied across speech perception measures and participants. In general, a unique pattern of results was measured for each participant, with some participants demonstrating large changes in speech perception ability with frequency compression hearing aids and others demonstrating little change. Significant frequency compression benefit following an acclimatization period was observed for five of the six participants on any one measure. This pattern of results was more often observed when speech perception effects were measured through the use of high-frequency fricative sounds (i.e., using /s/ and /S/ stimuli). One participant (Case Study 3) did not demonstrate posttrial changes on anymeasure, and his performance was generally at ceiling acrossmeasures and processors. Frequency compression benefit, when it occurred, had a magnitude of up to 20% for tasks scored in percentage and up to 10 dB for aided thresholds. A frequency compression decrement of 12 dB was measured for one participant, even when the same participant derived benefit in other measures. We investigated acclimatization effects over 4 months in older children and adolescents in an effort to minimize maturational effects; however, improvements measured over time could have been due, in part, to maturation.

Treatment Effectiveness

Treatment effects described by outcome measure can be summarized as follows. For the plural recognition task, frequency compression benefit was measured for three participants: For one participant, benefit was measured right away, another demonstrated benefit only after an acclimatization period, and the third demonstrated an initial improvement in plural recognition that further improved with acclimatization time. For the consonant recognition task, none of the participants demonstrated initial benefit with frequency compression hearing aids; overall or posttrial benefit was measured for two of the participants. Benefit was measured on the /s-S/ discrimination task for three of the participants, with all three demonstrating overall benefit and two demonstrating initial and/or posttrial benefit; initial/posttrial performance decrement was measured for one participant on this task. Finally, on the detection tasks, benefit on either the /s/ or /S/ task was measured initially and/or posttrial for five of the six participants, with slightly more participants demonstrating improved /s/ detection ability when compared with /S/ detection; an initial performance decrement, resulting in posttrial benefit, was measured for one participant on the /S/ detection task. Overall, these results may indicate that detection measures appear to require less acclimatization time to show treatment effectiveness compared with discrimination or recognition measures. Further research would be required to evaluate this speculation.

Auditory Acclimatization

For two participants (Case Studies 2 and 4), postacclimatization benefit from frequency compression was accompanied by significant improvements over the treatment interval, suggesting that a period of acclimatization was needed for these listeners to benefit from the processor. These same participants did not show improvements during their baseline trial without frequency compression, suggesting that benefit observed over time was specific to audibility changes from frequency compression rather than from new sound from the

study aids versus their previous fittings.

Frequency compression-related decrement was most apparent for the child with the flattest audiometric configuration (Case Study 2). Results suggest that the child in Case Study 2 had more difficulty detecting /S/ and discriminating /S/ from /s/ when frequency compression was activated. Although this participant learned to differentiate between /s/ and /S/ and demonstrated improved consonant discrimination and error patterns, her ability to identify /S/ was best without frequency compression. We cannot fully explain this pattern of results, which speaks to the fact that frequency compression may introduce adverse speech perception effects for some listeners. A different setting may have resulted in different outcomes, but investigation of performance with an alternative frequency compression setting was beyond the scope of this study.

Two unique acclimatization patterns were measured in this study: gradual improvement over time (i.e., a linear trend) and improvement after a specific period of acclimatization (i.e., a nonlinear trend). The latter pattern, resembling an S-shaped curve, mainly occurred for the /s-S/ discrimination task (Case Studies 2, 4, and 5). An S-shaped pattern may be associated with the nature of the discrimination task and/or the novel cues presented with frequency compression. Specifically, this task requires the participant to be able to not only detect novel sounds but also differentiate between them. In some cases, only one sound may have been novel to the participant (e.g., new audibility of /s/ only), and the amount of frequency shifting may have differed for /s/ versus /S/. Differentiating between /s/ and /S/ in the presence of highfrequency hearing loss may be more difficult when the previously learned cues (e.g., the frequency location of a frication band) have been frequency lowered. This type of change likely requires the listener to relearn cues associated with a specific phoneme. The literature suggests brain plasticity as a possible underlyingmechanism for auditory acclimatization (Palmer, Nelson, &Lindley, 1998;Willott, 1996); the literature also suggests that frequency discrimination tasks are highlyamenable to auditory learning effects that generalize across tasks (Wright &Zhang, 2009). Because the peak frequency is an important cue for fricative recognition (Dubno &Levitt, 1981), we may speculate that learning the new frequency locations of /s/ and /S/ may be required for some users of frequency-lowering strategies. Brain plasticity may be required to excel on such a task, requiring the listener to learn to represent and integrate new acoustic information. Furthermore, some participants with S-shaped data patterns for the discrimination task required 6-10 weeks of acclimatization time prior to measurement of significant frequency compression benefit. In other cases (e.g., Case Study 6), participants demonstrated significant initial benefit, which remained stable over the treatment phase.

We also noted other interesting acclimatization results. In some cases, participants scored more poorly on some measures with conventional processing following the frequency compression trial (even though they did not benefit from frequency compression) versus the baseline trial. A possible explanation includes perceptual adjustment to speech cues, to the point that listening without frequency compression was disadvantageous. In other cases, significant improvements measured during treatment with frequency compression were followed by equally good scores with frequency compression withdrawn. A possible explanation for absent withdrawal effectsmay be a carryover effect in which the participants learned to use cues during the treatment phase of the study and were able to apply this learning even without the frequency-compressed signal (i.e., in the withdrawal phase). One possible mechanism for a carryover effect could be neural reorganization. Alternatively, it could be that the increased bandwidth of the study aids (versus their own aids) caused an acclimatization effect that was not specific to frequency compression. Although we took multiple measures during the baseline trial to guard against this confound, it is not possible to entirely rule out the potential for further acclimatization to conventional processing beyond the baseline phase in all cases.

Test Battery and Trial Length

The test battery used in this study was chosen to be sensitive to the effects of frequency-lowering hearing aids, both for high-frequency sounds and across a wide range of consonants. Stimuli containing fricative sounds such as /s/ and /S/ were of particular interest in this study because both contain high-frequency energy and because

the nonlinear nature of the frequency compressor used here provides more lowering for /s/ than for /S/, leading to the possibility of overlap of the two fricatives. The test battery contains stimuli spoken by different speakers, which resulted in minor spectral differences across tasks (see Figures 1 and 2), and spectral stimuli that are consistent with those reported in the literature (Boothroyd &Medwetsky, 1992; Pittman et al., 2003). The use of frequency compression processing alters the spectral shape of individual fricatives by lowering and narrowing the frication band. This depends on how the frequency compression was set; stronger settings provided more lowering effects. It is possible that frequency compression can alter the nature of fricatives substantially, resulting in their being perceived as a different phoneme or perhaps as a nonrecognizable sound. Certainly, some such effects were noticed in the consonant confusion matrices. These effects arose from a task in which listeners used a closedset response and were, therefore, forced to designate a phonemic response. Results from the consonant recognition test suggest that the participants experienced many different speech sound confusions in addition to the hypothesized /s-S/ confusion. Other types of confusions noted in this study include, but were not limited to, /8-v/, /r-w/, /s-f/, and /tS-k/. Some consonant confusion errors were present in the baseline fitting, some were a result of the introduction of frequency compression, and some resolved over time.We did not evaluate whether listeners would misidentify some phonemes if they had been given an open-set task, although this would be an interesting question for further research. Other factors to consider in test battery construction include the use of adaptive measures. One participant in this study performed at ceiling on all measures but /s/ detection, which was not only an adaptive task but also the highest frequency stimulus and was, therefore, highly sensitive to the effects of frequency lowering. These ceiling effects were not anticipated. The tasks themselves are difficult either due to the high-frequency content of the stimuli in combination with participants' hearing losses (detection and discrimination measures), low presentation level (plurals task), or low context (consonant recognition). Factors explaining the higher-than-anticipated scores may include the older ages of these adolescent participants- although many adolescents were tested on similar tasks by Glista et al. (2009)-or more recently developed hearing technologies that include broader bandwidth in both processing and output than the aids used by Glista et al. Ceiling performance with frequency compression hearing aids was reported previously (Wolfe et al., 2011).

Comparison With Other Studies of Frequency Lowering

Certain findings reported in the present study differ from those previously reported. Simpson and colleagues (2006) investigated frequency compression outcomes in seven adult participants with steeply sloping losses. The participants in the Simpson et al. study did not receive frequency compression benefit after a brief or absent acclimatization period. The authors of that study concluded that frequency compression for steep losses may use a strong degree of frequency lowering and that, perhaps, this may require additional adaptation time and/or training efforts (Simpson et al., 2006). In the present study, we found evidence to support this speculation in some (but not all) listeners; however, due to the small number of participants included in this study, further research is needed to investigate this correlation. A longer acclimatization period was needed to achieve significant frequency-lowered benefit for recognition tasks when compared withdetection tasks; these findings are consistent with those reported in studies of children by Auriemmo et al. (2009) andWolfe et al. (2011). Similarly, in a study including adult listeners, Kuk, Keenan, Korhonen, and Lau (2009) discussed the need for an adaptation period with frequency-lowering hearing aid technology, given the possibility that some wearers may not immediately accept the sound quality of such devices. Factors that may explain differences between the results reported in this study and those reported by Simpson et al. include the use of pediatric participants, more recently developed hearing instruments, and the use of a different fitting method. Further research would be required to determine the individual role of each of these factors.

In a previous study on frequency transposition, error pattern analyses revealed improved identification for some consonants, in addition to the introduction of different confusions (Robinson et al., 2007, 2009). Specifically, errors confusing /s/ with /S/ increased with the introduction of frequency lowering; New confusions remained

despite a 5-week period of experiencewith the study hearing aids. Robinson and colleagues (2009) speculated that the lack of overall benefit measured with frequency loweringmay have related, in part, to the relatively short trial period. Alternatively, findings from the current study suggest that speech sound confusions introduced with frequency lowering may resolve over time, for some listeners, and with a prolonged acclimatization period. It is difficult to compare these two studies directly, given the difference in fittings methods, participant ages, and processing schemes evaluated. Further research is needed to directly compare outcomes with different forms of frequency-lowering technologies.

In summary, this experiment provided case-specific evidence of auditory acclimatization to newly audible high-frequency sounds for some of the child listeners (ages 11-18 years) and in the presence of a well-controlled adaptation period. A unique pattern of results was measured across cases, suggesting that treatment and/or acclimatization effects measured within this study cannot be generalized outside of case-specific findings. Given the low incidence of permanent childhood hearing loss and the lower incidence of precipitous hearing losses within this group, the study of acclimatization effects through the use of strategies such as single-subject design allowed a systematic exploration of outcome in this group. Because the exact limits of candidacy for frequency lowering are not yet known, we sampled across a range of high-frequency hearing losses. In this sample, we had some participants who received little or no benefit from this technology and others who received significant benefit that sometimes required a period of acclimatization in order to take effect. These results are consistent with those of Glista et al. (2009), who reported a significant association between the degree and configuration of highfrequency hearing loss and candidacy for frequency compression, as well as those of Wolfe et al. (2011), who reported improvement of frequency compression benefit over time. In the present study, we measured the time course of acclimatization (when it did occur) by sampling outcomes at frequent intervals. From this design, we observe that acclimatization trends (when they occur) take two forms: (a) gradual linear changes and (b) sudden nonlinear changes that occur after a period of 6-10 weeks. Presence or absence of speech perception change varied not only across people but also across outcome measures. On the basis of this, we concluded (a) that individual determination of candidacy, fitted settings, and outcomes of frequency compression are warranted in clinical practice and (b) that further research is required to determine limits of candidacy and an optimal test battery for use in evaluation of outcome. Furthermore, research is needed with new frequency-lowering strategies to determine optimalmethods for fitting, particularly in cases of asymmetrical hearing losses, the construction of optimal outcome batteries, and evaluations of whether participant variables such as developmental status and hearing-loss profile affect benefit and/or acclimatization.

Abstract: Auditory perception of vowels in background noise is enhanced when combined with visually perceived speech features. The objective of this study was to investigate whether the influence of visual cues on vowel perception extends to incongruent vowels, in a manner similar to the McGurk effect observed with consonants. Identification of Dutch front vowels /i, y, e, Y/ that share all features other than height and lip-rounding was measured for congruent and incongruent audiovisual conditions. The audio channel was systematically degraded by adding noise, increasing the reliance on visual cues. The height feature was more robustly carried over through the auditory channel and the lip-rounding feature through the visual channel. Hence, congruent audiovisual presentation enhanced identification, while incongruent presentation led to perceptual fusions and thus decreased identification. Visual cues influence the identification of congruent as well as incongruent audiovisual vowels. Incongruent visual information results in perceptual fusions, demonstrating that the McGurk effect can be instigated by long phonemes such as vowels. This result extends to the incongruent presentation of the visually less reliably perceived height. The findings stress the importance of audiovisual congruency in communication devices, such as cochlear implants and videoconferencing tools,

where the auditory signal could be degraded.

Purpose: Auditory perception of vowels in background noise is enhanced when combined with visually perceived speech features. The objective of this study was to investigate whether the influence of visual cues on vowel perception extends to incongruent vowels, in a manner similar to the McGurk effect observed with consonants.

Method: Identification of Dutch front vowels /i, y, e, Y/ that share all features other than height and lip-rounding was measured for congruent and incongruent audiovisual conditions. The audio channel was systematically degraded by adding noise, increasing the reliance on visual cues.

Results: The height feature was more robustly carried over through the auditory channel and the lip-rounding feature through the visual channel. Hence, congruent audiovisual presentation enhanced identification, while incongruent presentation led to perceptual fusions and thus decreased identification.

Conclusions: Visual cues influence the identification of congruent as well as incongruent audiovisual vowels. Incongruent visual information results in perceptual fusions, demonstrating that the McGurk effect can be instigated by long phonemes such as vowels. This result extends to the incongruent presentation of the visually less reliably perceived height. The findings stress the importance of audiovisual congruency in communication devices, such as cochlear implants and videoconferencing tools, where the auditory signal could be degraded.

Key Words: audiovisual speech perception, vowels, McGurk effect

(ProQuest: ... denotes formulae omitted.)

Perception of spoken language is not an auditory phenomenon only; it is also heavily influenced by visually perceived pronunciation information. The influence of visual cues on speech perception has been shown for a variety of speech tokens such as consonants (see, e.g., Massaro, 1987; for an overview, see Massaro, 1989; Massaro &Cohen, 1990) and vowels (Robert-Ribes, Schwartz, Lallouache &Escudier, 1998; Traunmüller &Öhrström, 2007) and for conditions such as hearing impairment (Baskent&Bazo, 2011; Grant,Walden,&Seitz, 1998; Miller &D'Esposito, 2005). This interaction is so strong that when the auditory and visual components are incongruent, they may fuse into a single percept that is different from both the original auditory stimuli and the original visual stimuli-also known as the McGurk effect (McGurk &MacDonald, 1976). For spoken man- machine interaction devices and video applications, such knowledge of audiovisual integration is crucial. For example, the precision with which the auditory and visual information are aligned in videoconferencing tools follows directly from research on audiovisual integration of temporally mismatching stimuli (McGrath &Summerfield, 1985; Miller &D'Esposito, 2005). Also, appropriate audiovisual alignment is especially important for users of rehabilitative communication devices such as cochlear implants and hearing aids. Because the auditory signals are less well transmitted, listeners with hearing impairment rely heavily on the visual cues (Baskent &Bazo, 2011; Champoux, Lepore, Gagneú, &Théoret, 2009; Rouger,Fraysse, Deguine&Barone, 2008).When auditory information is correctly aligned with visual information, listeners-especially those with hearing impairment- profit significantly from the visual information for understanding speech (Baskent &Bazo, 2011). However, when audiovisual information is not correctly aligned, disruptive interactions may be observed in addition to the loss of positive interaction. Disruptive interactions of audiovisual information have been shownwiththeMcGurkeffect for consonants but are not as extensively investigated for the case of vowels. However, it was recently shown that the contribution of vowels to the auditory intelligibility of speech is significant and could, in some listening situations, be even higher than the contribution of consonants (Cole,Yan, Mak, Fanty,&Bailey, 1996; Kewley-Port, Burkle, &Lee, 2007). Kewley-Port et al. (2007) argued that listeners with hearing impairment are evenmore dependent on the correct perception of vowels because, in most cases of hearing impairment, high frequencies (which are associated with consonants) are lost more readily than are lowfrequencies (which are associated

with vowels). Thus, correct alignment is shown to be important for audiovisual interaction devices, and although vowels are shown to be important for speech intelligibility, research has focused on audiovisual incongruence with consonants. As vowels are of higher intensity and have longer duration than consonants, the effect of visually incongruent information-for example, as in cochlear implant or hearing aid users-might be different for vowels than for consonants. In the present study, therefore, we investigated the perceptual processes that play a role in the audiovisual perception of vowels- more specifically, the Dutch high- and mid-high-front vowels ([i, y, e, Y], as in the Dutch words biet, fuut, beet, and hut, respectively)-with congruent and incongruent audiovisual features.

Onthe basis of acoustic information, the first formant (F1) and second formant (F2) of a particular vowel are most crucial for its recognition (for an overview, see Rosner &Pickering, 1994). Regarding the vowels of interest of the present study, the F1 is generally associated with the height feature, and the F2 is generally associated with the backness feature (Ladefoged, 1982; Rosner &Pickering, 1994). Furthermore, the literature suggests that F2 is also related to the lip-rounding feature for some vowels (Lisker&Rossi, 1992;Valkenier&Gilbers, 2008).Masking one of the formants by noise leads to perceptual confusions. By establishing confusion matrices for different levels of white noise, Pickett (1957) showed that the shared features of the vowels explain the relatively structured confusions that were observed. In short, height-by virtue of the perception of F1-is the most robust acoustic feature, followed by backness (F2).

In addition to the acoustic cues, visual cues also influence the perception of high-front vowels. Robert-Ribes et al. (1998) quantified the facilitatory influence of visual cues on the French high- and mid-high-front vowels [i, y] and [e, L] by using congruent audiovisual stimuli presented with white noise at different levels. In most cases, the visual and auditory cues are complementary (Massaro &Stork, 1995); for instance, lip rounding is a strong visual cue, whereas height is a strong auditory cue. Similarly, Miller and Nicely (1955) showed that most features of consonants that were easy to identify from a talker's face were hard to identify from hearing them, and vice versa. Summerfield (1987) labeled and described those findings as complementarity in audiovisual processing. Complementarity of the two modalities improves the perception of congruent audiovisual stimuli, especially when the auditory input is deteriorated (e.g., in background noise). However, if the audiovisual stimuli are incongruent, fusions may occur, such as in the McGurk effect (McGurk&MacDonald, 1976). In short, when a visual [ga] stimulus1 was concurrently presented with an auditory [ba] stimulus, the resulting perception was that of /da/.2 The McGurk effect is extensively investigated on different pairs of consonants. However, research has not yet established the limits and themagnitude of the fusion effect in the vowels that are acoustically more stable. One reason for this could be that such an investigation is relatively difficult to do in English, where the most visually distinctive feature-lip rounding-is not an independent distinctive feature of vowels. In other languages with an independent lip-rounding feature, however, an experiment can be conceived that uses vowels that share all perceptual features but rounding. In Swedish, for example, Traunmüller and Öhrström (2007) found a shiftin the auditory response from theSwedish high unrounded front vowel /e/ to the high rounded front vowel /L/, when an auditory [e] stimulus was shown concurrently with a visual [y] stimulus. However, this effectwasnot generalizable, as it was observed only with a subgroup of participants who were more prone toward using visual speech cues.

The aim of the present study was to establish the extent to which the acoustic and visual domains influence audiovisual vowel perception, both in quiet and in background noise. In addition to congruent audiovisual vowel perception, taking advantage of the lip-rounding feature of Dutch vowels, we investigated the perceptual fusion using incongruent audiovisual stimuli. If the visual and acoustic features are complementary, as argued by Robert- Ribes et al. (1998), the visually more salient (i.e., prominent) feature (i.e., lip rounding) leads to a stronger McGurk effect than the visually less salient one (i.e., height). For this purpose,wemeasured confusions (similar to the measurements done in Traunmüller &Öhrström, 2007, and Robert-Ribes et al., 1998) with the Dutch high- and mid-high-front vowels of [i, y, e, Y]. These vowels allowed vowel pairs thatwould differ only in

height or lip rounding. Hence, in the incongruent stimuli, conditions of audio and video input that differed in height only and/or rounding only could be tested.Contrary to the findings of Traunmüller and Öhrström (2007)-who analyzed the data for the subset of participants who were more prone toward using visual cues-we included all participants without a pre-selection.We induced a visual bias-that is, an increased reliance on visual information in audiovisual perception-for all participants by systematically adding noise to the auditory channel. The advantage in doing so is that the results can now be generalized to not only the subgroup of perceivers who are more prone toward visual cues but also to the entire group of normalhearing listeners and their audiovisual speech perception in suboptimal listening conditions.

Method

Subjects

Sixteen native speakers of Standard Dutch (11 men [Mage = 24.8 years, SD = 1.9]; 4 women [Mage = 23.8 years, SD = 0.5]) participated in the experiment. The data of one participant were not reliable because some data points were missing; therefore, we excluded all data of this participant from analysis. All participants reported normal hearing and normal-to-corrected vision. Participation was voluntary, with the possibility of withdrawing at any time during the study. Participants were fully informed about the study, and their written consent was obtained prior to data collection.

Stimuli

Selection of speech material and speech context. In order to give an impression of the Dutch vowel system, Figure 1 shows the vowel triangle of the Dutch vowels. The vowel triangle was created with the formants as determined with Praat (Boersma, 2001) from vowels produced in isolation by a 31-year-old female speaker of Standard Dutch. In the present study, we investigated the audiovisual perception of the Dutch high- and mid-high-front vowels [i, y, e, Y], which are represented as shaded circles in Figure 1. These vowels were selected because (a) lip-rounding and height features of these vowels cross in the acoustic as well as the visual domain and (b) there are no other confounding features. (For a more extensive analysis and justification of the selected vowels, see the Appendix.)

The vowels [i, y, e, Y] were recorded in the context of [c V c], where [c] represents a voiceless velar fricative (such as in the Dutch word acht). This choice was based on the argument by Traunmüller and Öhrström (2007) that velar consonants hardly affect the visibility of vowel features because the lips and the jaw do not need to be in a particular position. The voiced velar plosive [g], as was used in the Traunmüller and Öhrström study, does not exist in the Dutch language. Also, the use of the voiceless velar plosive [k] would lead to (semantically) meaningful Dutch words. As the context of the voiceless velar fricative c produces phonologically allowed nonsense words for all Dutch vowels, this seemed to be the most appropriate context structure.

Recording and editing of speech material. The stimuli were recorded in a quiet room with bright natural daylight against a white background. The speaker was a 22-year-old female native speaker of the standard variety of Dutch.The stimuliwere recordedwith a Samsung HMX-H106-SP video recorder placed approximately 3 m from the speaker, who was standing against the white background with audio sampled at a rate of 48000 Hz. Recordings were made from the front of the speaker's face, including the entire face and neck and with the mouth at one third from the bottom of the display screen on the computermonitor. The total frame size on the computermonitor was 513 cm2, and the size of themouth was approximately 3 cm2. The front portion of the tongue was visible for the high vowels (see Table 1).

For each vowel, two utterances were selected where the head movement was minimal, and the experimenters agreed on successful pronunciation of the target vowel. The duration of the video files of the selected stimuli were cut to equal duration of 1 s, with approximately 0.3 s neutral face at the start and end of the video. The long-term root-mean-square (RMS) levels of the audiorecordings were normalized with Praat. Steady low-pass filtered noise of varying intensities (SLN) was produced by low-pass filtering white noise (filter order = 1, resulting in a slope of -6 dB/oct in filter response). SLN was added to the stimuli (which were kept at constant

intensity), resulting in stimuli with signal-to-noise ratios (SNRs; calculated on RMS levels) of 30 dB (almost quiet), 0 dB, -6 dB, -12 dB, and -18 dB. Audio presentation level of processed stimuli was calibrated to a comfortable level of approximately 70 dBA (varying with variations in stimulus intensity).

Those prepared recordings were used as control conditions and served as a starting point for the creation of the stimuli of the experimental conditions. In the experimental conditions, the audio tracks with added noise were recombined with differing video tracks to create incongruent audiovisual stimuli in three conditions: (a) fully crossed, (b) incongruent lip rounding, and (c) incongruent height. In the fully crossed condition, vowel pairs differed in both height and rounding. In the incongruent lip-rounding and incongruent height conditions, vowel pairs differed in rounding only or in height only, respectively. This resulted in 328 stimuli of 1 s each (8 video vowel tokens + 8 audio vowel tokens ×5 noise levels + 16 incongruent audiovisual vowel stimuli ×5 noise levels ×3 conditions + 8 congruent audiovisual vowel stimuli ×5 noise levels). Thus, two different stimuli of each type were presented per condition in the control conditions (video, audio, and congruent audiovisual), and four different stimuli of each type were presented per condition in the incongruent experimental conditions.

Experimental procedure. An identification task was carried out in a sound-attenuated booth over headphones. Each participant was tested on the full set of control and experimental stimuli. Stimuli were presented and responseswere collected usingE-PrimeVersion 2.0 software (Psychology Software Tools) via a MacBook (aluminum unibody, Spring 2008 edition) running Windows XP SP2 via Boot Camp. The participants were seated facing (and about 70 cm away from) a 13.3-in. flat-panel LED display (resolution 1280 pixels ×800 pixels, vertical angle of view 18°, horizontal angle of view 26°). Participants wore Sennheiser HD 600 headphones that were directly connected to the MacBook sound card output.

The actual data collection was preceded by a short introduction with task instruction and symbol explanation (we did this to familiarize the participants with the possible responses and accompanying keys). The participants were informed that auditory, visual, and audiovisual stimuli were to be presented. The test instruction was to continuously look at the screen and to indicate by keypress what was perceived.

The test consisted of two blocks of approximately 15 min, with a short break in between. The stimuli were presented with all conditions and all stimuli randomized over both blocks. For each trial, the participant could start the presentation of the target stimulus by keypress. Afixation-cross appeared in themiddle of the screen for 1 s, after which the stimulus was presented. In the audio-only condition, the screen was black. After presentation of the stimulus, the response alternatives were shown on the monitor. The possible answers consisted of all rounded and unrounded Dutch high- and mid-high-front vowels: /y, Y, L, i, I, e/ plus the vowels /u, o, a/. These vowels were indicated on the screen with the grapheme that is normally written in Dutch with a common Dutch word to clarify the intended vowel sound. No limitation was imposed on response time.

Methodology of analysis. Perceptual confusions were measured, and confusion matrices were formed to depict patterns of perceptual change.However, in order to determine the significance of perceptual change, the experimenter must quantify the data differently, which we did by using error rates, as described below. Error rates were calculated for each experimental condition (c) by subtracting the accuracy (acc; the mean correct responses) from the highest possible error score of 1 (multiplied by 100 to obtain percentages), where acc was calculated as

... (1)

whereNTRIALS (c) was the number of trials for condition c andNCORRECT (pp,c) was the number of correct responses for participant pp in condition c.We used either the visual or the auditory stimulus as a truth reference in order to determine NCORRECT. As a means to determine the interaction effects in the audiovisually congruent conditions, we predicted error rates for multisensory responses (ep) from the accuracy scores for the auditory-only and visualonly conditions as

... (2)

where acc(A) was the accuracy score for the audio-only condition and acc(V) was the accuracy score for the

visualonly condition, and acc(A) ×acc(V) was the probability that both were correct. This way, we omitted effects of statistical facilitation and only determined the possible effects of multisensory interaction.

We used a second measure, relative transmitted information score (TREL), to analyze the availability of speech features in different noise conditions (for an overview and explanation, see van Son, 1994). TREL was the ratio between the transmitted information, T, and the maximum rate of transmission, TMAX, in percentages, such as

... (3)

where

... (4)

and

... (5)

HSTIM and HRESP were mean logarithmic products (entropies) for stimulus and response, respectively, and HCM was the entropy of the confusion matrix, calculated by

... (6)

where p(i, j) was the probability of observing response j for stimulus i in a two-dimensional vector or confusion matrix (HCM) and was replaced by either p(i) (HSTIM) or p(j) (HRESP) for a one-dimensional vector.

TREL was calculated per feature; the analysis was performed on matrices representing either rounded and unrounded stimuli and responses, or high and mid-high stimuli and responses. The relative rate of transmission represented the ratio of the responses that can be predicted from the stimuli (Miller &Nicely, 1955).

Results

Complementarity in Congruent Audiovisual Vowels

Table 2 shows the confusion matrices aggregated over all noise levels for the congruent conditions. Note that the visual-only [Y] was more likely to be perceived as /y/ than as / Y/. All other single-channel stimuli were perceived as mostly correct. Error rates (see Figure 2) and transmitted information scores (see Figure 3) were calculated for every noise condition separately. Also, the multisensory error rates as predicted from the auditory and visual error rates are presented. Figure 2 shows the error rates for the audio-only (filled triangles), video-only (filled squares), audiovisual congruent (filled circles), and audiovisual as predicted (ep; open circles) conditions as a function of noise level. Vowel discrimination benefited from combined audiovisual input, which is reflected in slightly lower error rates in the congruent audiovisual condition than ep, the multisensory error rates as predicted from the auditory and visual error rates (Friedman's test, c2 = 2.67, pone-sided = .051).A post hoc comparison showed that the difference was significant for the SNR levels -6 dB, -12 dB, and -18 dB (pairwise Wilcoxon, pone-sided <.05, adjusted for Bonferroni correction).

Visual Influence in Incongruent Audiovisual Vowels

Because the responses to incongruent stimuli can be evaluated with respect to the audio as well as the video input, we calculated two error rates for each incongruent condition. The leftand right panels of Figure 4 show the error rates with regard to the auditory and visual parts of the input, respectively. The error rates for the audiovisual congruent condition are the same in both panels because the visual and auditory stimuli were the same in this condition. The figure shows that both the auditory and the visual error rates are higher in the three incongruent conditions (open symbols) than in the congruent condition (filled symbols). In all conditions, the auditory perception deteriorates with increasing noise level, which is reflected by upward slopes. In contrast, the visual perception improves with increasing noise, reflected by a similar, but inverse and less profound, pattern with regard to the visual error rates.

Table 3 shows the results of Friedman's test (a)when the visual error rate of an incongruent condition was compared with the congruent condition or the visual-only condition and (b)when the auditory error rate of an incongruent condition was compared with the congruent condition or the audio-only condition. Table 3 also shows the levels for which the post hoc Wilcoxon test is significant (after correction for Bonferroni).

For all incongruent conditions, the overall auditory and the overall visual error rates are significantly different

from the four reference levels (Friedman, p <.001, post hocWilcoxon's test, adjusted p <.05 for all comparisons except for visual error rate for incongruent liprounding compared with visual-only for -6 dB, -12 dB, and -18 dB). For all but one of the conditions, the error rates in the experimental condition are significantly higher than the reference levels; namely, the overall auditory error rate in the incongruent height (and, thus, congruent lip-rounding) condition is significantly lower than the audio-only error rate.

The auditory error rates in the incongruent liprounding condition and the incongruent lip-rounding and height condition are significantly different from the auditory error rates in both the audiovisual congruent and the audio-only conditions for the 0 dB, -6 dB, -12 dB, and -18 dBSNRlevels (p <.01). The auditory error rates in the incongruent height condition are significantly higher than the audiovisual congruent error rates for the SNR of -18 dB (p <.05) and are significantly lower than the audio-only error rates for the SNR of -18 dB (p <.05).

Transmitted Information Scores

The transmitted information scores provide more detailed insight into the error rates, as they show what part of the information was or was not available when analyzed for different features. Figure 3 shows the transmitted information scores for lip-rounding (leftpanel) and height (right panel) for the audio-only, video-only, and audiovisual congruent conditions. Highest profit from visual inputwas in noise; the audiovisually transmitted information for lip-rounding is significantly higher than the auditorily or visually transmitted lip-rounding information for SNRs of -6 dB, -12 dB, and -18 dB (Friedman c2 = 42 and 23, respectively, p <.001;Wilcoxon, adjusted p <.05). Furthermore the lip-rounding is better transmitted visually than auditorily at SNRs of -12 dB and -18 dB (Friedman c2 = 7, p <.01;Wilcoxon, adjusted p <.001). The height information is better transmitted auditorily and audiovisually than visually for all SNR levels (Friedman c2 = 59 and 66, respectively, p <.001; Wilcoxon, adjusted p <.05).

McGurk Effect in Incongruent Audiovisual Vowels

In incongruent conditions, fusions of features were expected to occur-namely, features from the visual and auditory input are recombined into a perceived vowel that was not presented in either one of the channels. We originally expected fused percepts that combine the auditorily salient height feature and the visually salient rounding feature. In the present study, apart from these expected fusions, unexpected ones were also found, as seen in the confusion matrices aggregated over all noise levels (see Table 4), where the shaded numbers represent the expected fusions. All fusions that seemto be a trend in the data are reported in this section, and the unexpected findings (that are a trend) are explained in theDiscussion section. Furthermore, the effect of noise on the number of fusions is analyzed. An increased reliance on visual information in audiovisual perception was induced by adding noise to the auditory channel. In order to quantify this effect, we present the major fusions; these are the fusions that occur most often per category, whether they were predicted or not. Namely, if reliance on visual cues as a result of noise in the auditory domain leads to increased audiovisual integration, a significant increase in number of fusions is expected. The major fusions are plotted in Figure 5 as a function of noise. Later in the text of this article, test results for the increase (or decrease) of these fused responses is reported (see end of this section).

Table 4A shows the responses in the fully crossed condition. In this condition, fusions occurred when the vowels [iA, eA, yA, YA] were presented with the vowels [YV, yV, eV, iV] (where superscript "A" or "V" denotes that the phoneme was presented through the auditory {A} or visual {V} channel). Although we expected to find the fused responses /y, Y, i, e/, respectively, the observed fusions led predominantly to perceived /y, L, i, I/ instead. The peak of the observed fusions was found at a SNR of -18 dB for [iA] with [YV] and at SNR of -12 dB for the other three stimulus pairs.

Next, Table 4B shows the responses for the liprounding incongruent condition. We expected increased visual responses because the auditory and visual height information are combined with the visually salient liprounding feature. Next to this expected result, we found that [YA] presented with [eV] was sometimes perceived as /I / (ranging from 9% at 30 dB SNR to 40% at -6 dB SNR). Also, [eA] presented with [YV] was sometimes perceived

as /L/ (ranging from 34% at 30 dB SNR to 70% at -12 dB SNR).
Finally, Table 4C shows the responses for the incongruent height condition. We expected increased auditory responses because the auditory and visual rounding information are combined with the auditorily salient height feature. Next to this expected result, we found an increase in /I/ responseswhen [iA]was presented with [eV] (ranging from 0% at 30 dB SNR to 56% at -18 dB SNR).
The major fusions are shown in Figure 5 as a function of noise. For each crossed condition, a separate bar gives the percentage of fusions ranging from 1.5% fused responses for [yA] with [eV] in clean speech to 86% fused responses for [eA] with [yv] in -12dB. For all pairs, the percentage of fused responses increases with increasing noise up to SNR of -12 dB. For all pairs but [iA] with [YV], the increased percentage of fused responses is turned around with SNR of -18 dB. A Friedman test with noise level as factor revealed that the amount of fused responses is significantly different for different noise levels: Friedman c2(4) = 202, p <.001.Apost hocWilcoxon analysis revealed that the amount of fusions significantly changed for each increase in noise. The amount of fusions increased for SNRs of 0 dB, -6 dB, and -12 dB and decreased for SNR of -18 dB (adjusted p <.01 for all comparisons).

Discussion

In the present study, we used congruent and incongruent Dutch front vowels as audiovisual stimuli, presented in steady low-pass filtered noise, to investigate to what extent visual cues influence the perception of vowels. The noise, by degrading the auditory input and forcing the participants to relymore on the visual input, served the purpose of producing robust perceptual interactions between the audio and visual cues.
Robert-Ribes et al. (1998) showed, for the case of vowels, that visual and auditory features are complementary (see also Summerfield, 1987)-namely, the feature whose auditory discrimination is hardest can be perceived better through vision, and vice versa. When the information is incongruent, the auditory and visual features were expected to interact in a way that can be explained by the ease of perception in either of the two channels. For incongruent stimuli, this would yield perceived vowels that combined the most salient auditory cue with the most salient visual cue. This would, in turn, lead to fusions of vowel features, similar to the McGurk effect previously observed with consonants.

Complementarity in Congruent Audiovisual Vowels

We reproduced the findings of Robert-Ribes et al. (1998) for Dutch vowels. Our results showed complementarity of the features in the auditory and visual channels; the transmitted information for lip-rounding, for example, was higher in the congruent audiovisual condition than the transmitted information for lip-rounding in the audio-only or video-only condition (see Figure 3). Also, for low SNR, the perception of congruently presented audiovisual vowels was better than the score that was predicted on the basis of vowels perceived through either of the single channels (see Figure 2).

Visual Influence in Incongruent Audiovisual Vowels

Themain interest of the present study was the perception of audiovisually incongruent vowels. Because vowels are shown to contribute significantly to intelligibility of speech (Kewley-Port et al., 2007), correct perception of vowels can be decisive for speech understanding. Yet, this can be disrupted as a result of misalignment of the auditory and visual signals-for example, in modern audiovisual communication devices. Until now, research on audiovisual incongruency has focused on consonants; this research needs to be extended to vowels.
In this study,we showed that the auditory processing of vowels was influenced by incongruent visual information that was reflected by an increase in auditory error rates in comparison to the audiovisual congruent condition (see Figure 4). The increased auditory error rate was highest for both conditions when the auditory stimulus was presented with incongruent lip-rounding; however, incongruently presented height also led to a change in the response distributions. Thus, apart from the beneficial influence that congruent visual information has on the perception of speech (Baskent &Bazo, 2011)-and, more specifically, vowels (in addition to this study, see also Robert-Ribes et al., 1998)-incongruent visual vowel information is disadvantageous for the correct perception of

vowels. Even when the visual input is not very salient (i.e., height), incongruent presentation can disrupt the perceptual process, especially when the auditory signal is less well transmitted. If processing speed in audiovisual devices can be improved by passing half the auditory information, one can think of special conditions where ignoring the visually salient lip-rounding information in the audio channel of technical devices would improve the alignment by improving the processing speed. This could aid the correct perception of vowels and, hence, speech, as the information is transmitted through the channel through which it is saliently perceived.

McGurk Effect in Vowels With Incongruent Lip-Rounding

For the incongruent conditions where both visual and auditory error rates were higher than the audiovisual congruent error rates, the perceived vowel was neither the auditorily presented one nor the visually presented one. This was the case in both conditions with incongruent lip-rounding. The confusion matrices for those conditions showed fusions of vowel features (known as the McGurk effect). As was hypothesized, the fusions consisted mainly of vowels in which the height of the auditory vowel was combined with the rounding of the visual vowel (see shaded cells in Table 4). Exceptions to this were the following: In the incongruent lip-rounding and height condition, [YA] that was presented with [iV]was perceived as /I/, and [eA] that was presented with [yV]was perceived as /L/. Similarly, the incongruent lip-rounding condition showed a recombination of [YA] that was presented with [eV] into / I / percepts and [eA] that was presented with [YV] into /L/ percepts. Although wepresent themas exceptions, the responses can be interpreted as natural fusions. As explained in the Appendix, the vowel [Y] was used instead of [L] because [Y] belongs to the same viseme category as [y]. Although both [L] and [Y] are called "mid-high vowels," their first formant frequencies (F1s) are not identical (Adank, Hout, &Smits, 2004). F1 of [Y] ismore similar to the F1 of [I] than to the F1 of [i] or [e]. Also, the F1 of [e] is more similar to the F1 of [L] than to the F1 of [Y] or [y]. Therefore, the results are not intrinsically different from McGurk-like fusions, especially considering the fact that height is most salient in the auditory channel. Namely, an audiovisual vowel is perceived with the rounding of the visually presented vowel and with the F1 closest to the auditorily presented vowel.

McGurk Effect in Vowels With Incongruent Height

Contrary to our expectations, we also found significant visual influence when height was presented incongruently in the auditory and visual channels. Height is not a very visible feature because tongue placement is hidden behind lip articulation. Therefore, we expected results similar to those of the congruent stimuli-that is, [YA] presented with [yV] would then lead to the auditory height perception of /Y/ and the visual rounding perception of /y/, resulting in a perceived / Y/. Indeed, the visual influence of congruent lip-rounding was additive or complementary; auditory identification improved with regard to the audio-only condition. However, next to this positive influence, we also found a detrimental influence; both auditory and visual identification degraded (i.e., resulted in higher error rates) with regard to the audiovisual congruent condition, which implies that neither the visual nor the auditory input was effectively perceived.

The confusion matrices show that the detrimental effect in both modalities was due to two effects of nonnormal perception /fusions (see Table 4C). First, [yA] that was presented with [YV] led to the perception of either /y/ or / Y/, where we expected a congruency effect leading to predominantly /y/ responses. The perception of /Y/ combined the auditory and visual perception of liprounding with the visual height despite the fact that the visual height was less well transmitted visually than auditorily at all SNR levels (see Figure 3). Second, an increase in the number of /I/ perceptions was found when [iA] was presented with [eV]. This was not a purely auditory effect, as auditory [i] that was presented on its own did not often result in /I / percepts (see Table 2A). It must be noted, however, that also in the three control conditions, / I / responses were given to both [i] and [e] stimuli. The effect can partly be explained as follows: [I, i, e] belong to the same viseme category of short unrounded vowels (van Son, Huiskamp, Bosman, &Smoorenburg, 1994). Adank et al. (2004) showed that the mean F1 values for those vowels (pronounced by 10 female speakers) are 442 Hz, 399 Hz, and 294 Hz for [e], [I], [i],

respectively. Therefore, the perceived /I/ combines the audiovisual lip-rounding with a vowel having the height (F1) in between the height of the presented vowels [e] and [i] despite the fact that height is best transmitted auditorily at all SNR levels. It turns out that the incongruent visual inputwas sometimes preferred over themore reliably transmitted auditory information (see confusions in Table 4C).

It can be concluded that in special cases,where perceptual features are crossed, fusions occur in incongruently presented vowels, similar to the McGurk effect commonly observed in consonants. Vowels are longer in duration and higher in energy than consonants, and the results show evidence that these intrinsic differences do not prevent the cognitive system from binding information from the different modalities, especially when the auditory signal is less reliable. Further research could reveal audiovisual interactions between vowels and consonants. Audiovisual interactions of long vowels and short consonants could lead to partial incongruence, the effect of which is unknown. Also, the interaction of auditory and visual streams of information for peoplewho are hard of hearing might differ from the results found in this study and, thus, needs further investigation. Namely, longstanding hearing loss might lead to a different phonological system (e.g., a few of the participants with cochlear implants in the study conducted by Schorr, Fox, Wassenhove, and Knudsen [2005] gave [ta] responses to the three different stimuli /ka, pa, ta/, indicating that the phonological system is broadened for these participants with regard to these phonemes), which could result in interactions different from the ones found here. Insight into the interaction of auditory and visual information streams in different conditions may help provide a better understanding of the problems that people experience with misalignment of the auditory and visual channels and where the focus should be with regard to alignment.

The Influence of Saliency on the McGurk Effect

The influence of saliency on the amount of fused responses can be related to the transmitted information scores. It was shown that the amount of fused responses increases significantly for increasing noise levels up to SNR of -12 dB. The auditory transmitted information scores for height decrease gradually, with noise increasing to SNR of -12 dB, and, hence, the reliance on visual information increases; transmitted information for liprounding is better through the visual than through the auditory channel for SNR of -6 dB and below. Furthermore, it was shown that the amount of fused responses significantly decreases for -18 dB SNR with respect to -12 dB SNR. This can similarly be related to the steep drop in transmitted information for height-and, hence, the identifiability of the height feature. Thus, when noise increases, the reliance on visual information increases accordingly, which leads to fused responses provided that the auditory height is perceived correctly.

Conclusions

In summary, we have demonstrated that the audiovisual information leads to complementarity in congruent vowels. Furthermore, we have shownthat incongruent visual input influences the perception of stimuli, although visual information alone may not be sufficient to disambiguate between vowels. Finally, we have shown that this knowledge is not always used optimally, as listeners sometimes used less salient information from one modality even when more salient information was available fromthe other modality.The finding that even the visually less salient height feature influences auditory identification stresses the importance of appropriate audiovisual alignment in communication devices, such as cochlear implants and/or videoconferencing tools, especially when the auditory signals are degraded and listeners rely heavily on visual cues (Champoux et al., 2009; Rouger et al., 2008). For those types of applications, the addition of visual information is of great help; however, if misaligned with auditory information, it may distort the perception of speech.

Appendix

Appendix. Detailed analysis and justification of the selected vowels.

The high and mid-high front vowels [i, y, e, Y] were selected because lip-rounding and height features of these vowels cross in the acoustic as well as the visual domain with no other confounding features, as explained

below in detail:
1. With regard to the acoustic features, height and diphthongization were aimed to be matched in pairs of vowels. The Dutch vowels [i, y] are high vowels and [e, I, Y, L] are mid-high vowels (Adank et al., 2004; Pols, Tromp, &Plomp, 1973; van Hout, Adank, &van Heuven, 2000). Van Hout et al. (2000) found that expert listeners judged the vowels [e] and [L] in standard Dutch as relatively monophthongal, although they are conventionally described as diphthongs (Gussenhoven, 1999) or near-diphthongs (Rietveld &van Heuven, 2009). Therefore the vowels [i, y] and [e, I, Y, L] make appropriate candidates for the forming of vowel pairs that are either different from or equal to one another in height.
2. With regard to the visual features, the rounded vowels [y] and [Y] belong to the viseme category of "short rounded front vowels," whereas [L] belongs to "long rounded front vowels" (Van Son et al., 1994). The vowels [e, I, i] belong to the viseme category of "unrounded front vowels." Therefore, the vowels [y, Y] and [I, i, e] make appropriate candidates for the forming of vowel pairs that are either different from or equal to one another in rounding.
3. The crossing of features in the acoustic and visual domains was necessary for analyzing the responses to the incongruent vowel stimuli-that is, where a feature can conflict in the auditory and visual domains without other conflicting features. Using crossing of features as a criterion, it was most appropriate to use [e] and [i] as monophthongal and unrounded vowels (mid-high and high, respectively) and [Y] and [y] as monophthongal and rounded vowels (mid-high and high, respectively; see Table 1). As an example, complete crossing can now be achieved by combining the auditory vowel [e] with the visual vowel [y] (crossed on both the rounding and height features, whereas all other features are kept equal).

The Consonant-Weighted Envelope Difference Index (cEDI): A Proposed Technique for Quantifying Envelope Distortion

Abstract: The benefits of amplitude compression in hearing aids may be limited by distortion resulting from rapid gain adjustment. To evaluate this, it is convenient to quantify distortion by using a metric that is sensitive to the changes in the processed signal that decrease consonant recognition, such as the Envelope Difference Index (EDI; Fortune, Woodruff, &Preves, 1994). However, the EDI relies on the entire duration of the signal, including portions irrelevant to consonant recognition. This note describes a computationally efficient method of automatically segmenting speech in time according to the syllable structure. Our technique uses the 1st derivative of the envelope as a basis. Peaks located in the derivative were used to generate a weighting function for the computation of a metric of signal distortion. The weighting function significantly improved the variance explained in consonant recognition scores over previous methods. However, only 3.2% of the variance was explained in the revised model. This technique was effective in focusing the analysis of distortion on specific segments of the signal. Use of the technique has implications for speech analysis. The difference in the amplitude envelope of consonants is not a robust model of the effect of hearing aid compression on consonant recognition.

Purpose: The benefits of amplitude compression in hearing aids may be limited by distortion resulting from rapid

gain adjustment. To evaluate this, it is convenient to quantify distortion by using a metric that is sensitive to the changes in the processed signal that decrease consonant recognition, such as the Envelope Difference Index (EDI; Fortune, Woodruff, &Preves, 1994). However, the EDI relies on the entire duration of the signal, including portions irrelevant to consonant recognition.
Method: This note describes a computationally efficient method of automatically segmenting speech in time according to the syllable structure. Our technique uses the 1st derivative of the envelope as a basis. Peaks located in the derivative were used to generate a weighting function for the computation of a metric of signal distortion.
Results: The weighting function significantly improved the variance explained in consonant recognition scores over previous methods. However, only 3.2% of the variance was explained in the revised model.
Conclusion: This technique was effective in focusing the analysis of distortion on specific segments of the signal. Use of the technique has implications for speech analysis. The difference in the amplitude envelope of consonants is not a robust model of the effect of hearing aid compression on consonant recognition.
Key Words: envelope, consonant, speech, distortion, syllable
(ProQuest: ... denotes formula omitted.)
Amplitude compression is widely used in hearing aids to provide audibility without making loud sounds uncomfortable. A negative consequence of amplitude compression is distortion of the temporal envelope (e.g., Jenstad &Souza, 2005), which consists of slow changes in level over time useful for speech understanding. In previous work (Jenstad &Souza, 2005, 2007; Souza, Hoover, &Gallun, 2012), envelope distortion was measured using theEnvelope Difference Index (EDI; Fortune, Woodruff,&Preves, 1994). The EDI is the mean absolute difference in envelope between two signals. For amplitude compression, there is an approximate threshold of EDI = 0.2, above which consonant recognition, in both nonsense syllables and sentences, decreases (Jenstad &Souza, 2007). This information can be used in the design and prescription of hearing aid compression parameters as an upper limit of acceptable envelope distortion.
A limitation to the conventional EDI when used with vowel-consonant-vowel (VCV) stimuli is that the calculation included portions of the vowels that were unlikely to contribute to consonant recognition.We hypothesize that calculating the EDI from the entire duration of the speech token included envelope distortions irrelevant to consonant recognition. By restricting the analysis to the portion of the token that is thought to contribute to information transmission, we expect to improve the predictive power of the EDI for levels of signal distortion typical of hearing aid compression.
In order to focus our analysis on the consonant, we must make choices about what portions of the signal contribute to consonant recognition. In running speech, this issue is complex (see, e.g., Drullman, Festen, &Plomp, 1994). In more strictly controlled stimuli, such as VCVs, we can reasonably assume that the signal amplitudes at the onset of the initial vowel and the offset of the final vowel contribute minimally-or not at all-to the recognition of themedial consonant.These onsets and offsets can be greatly affected by compression (e.g., overshoot at a vowel onset). We would like to reduce the influence of these regions to our measure of consonant distortion by decreasing the weighting of amplitude changes in regions far from the medial consonant.
Current techniques for automatically parsing syllables attempt to identify vowels at syllable nuclei using peaks in the temporal envelope (de Jong &Wempe, 2009; Wang &Narayanan, 2007). Although this is a robust approach, it is not suitable for our purposes because it is temporally imprecise and is susceptible to amplitude compression. Temporal imprecision results from the use of very low envelope filter cutoffs and correlations over time to improve the accuracy of syllable identification in spontaneous speech. Our restricted set of VCV stimuli allows for the use of a less complex method. However, our test stimuli are subjected to amplitude compression, which flattens the temporal envelope and can introduce artificial peaks when gain is reduced (reviewed in Souza, 2002). Because we need to parse speech stimuli that may be heavily compressed, existing techniques

relying on locating peaks in the temporal envelope are not appropriate.

Instead of relying on peaks in the temporal envelope, we propose relying on peaks in the first derivative of the temporal envelope. These peaks, both positive and negative, correspond to transitions into and out of pauses in speech, and to the opening and closure of articulators during transitions between consonants and vowels. This is a modification of existing techniques, resulting in a representation of syllables that is temporally precise, informative of both syllable onsets and offsets, and robust to the temporal envelope distortions introduced by amplitude compression.

Algorithm for Syllable Segmentation

The proposed algorithm, the consonant-weighted Envelope Difference Index (cEDI), identifies syllables in a speech signal by selecting consecutive positive and negative peaks from the first derivative of the temporal envelope. Figure 1 (Panel A) demonstrates the algorithm output at various stages for an input signal with two syllables. The waveform for the syllable [ama] is shown by the light etching. The envelope (dark solid line) is extracted by using rectification and low-pass filtering. The result is down-sampled, and the first derivative (medium-dark line) is computed. Peaks in the derivative (vertical dashed lines) are identified that occur at magnitudes greater than a threshold parameter. The highest magnitude peak is selected in alternating directions. These peaks represent the transitions in the envelope from low to high or high to low amplitude, corresponding to the onset and offset of vowels in each syllable. Panel B in Figure 1 is discussed in the Analysis of Consonant Distortion section below.

Method

The cEDI was evaluated by retrospectively applying it to a subset of previously collected data. Details are available in Souza, Hoover, and Gallun (2012). Briefly, 10 listeners (Mage = 25.1 years) with normal hearing (thresholds <25 dB HL)were presentedwithVCVstimuli, whichwereprocessed to reduce spectral cues so that recognition relied primarily on the low-frequency temporal envelope. The stimuli included the consonants /b, d, g, p, t, k, f, q, s, X, v, 8, z, Z,m, n/ spoken with the vowel /a/ by four American English talkers (Turner, Souza, &Forget, 1995). Each stimulus waveform was band limited to 176-7168 Hz and was converted into signal correlated noise (SCN; Schroeder, 1968) by filtering into four bands (crossover frequencies 440, 1130, and 2800 Hz), multiplying each sample of the four time-domain waveforms randomly by either +1 or -1, and filtering the four resulting signals into their respective input bandwidths. Amplitude compression was applied to the stimuli using a hearing aid simulator (GennEM v1.0; Armstrong, 1997) in four conditions determined in a preliminary analysis to produce a range of EDI. The compression ratio and release time for each condition are listed in Table 1, as well as the mean EDI for each condition. Listeners were seated in a sound-treated booth, and data were collected with a touch-screen monitor. Sounds were presented at 65 dB SPL using Etymotic Reseach ER-2 insert earphones. Listeners were instructed to select, from a grid of consonants, the one most similar to the sound presented in a 16-alternative, forced-choice paradigm.

Analysis of Consonant Distortion

In order to measure only the envelope changes that could affect consonant recognition, we first identified the segment of each token surrounding the consonant, as follows (see Figure 1, Panel A). TheVCVwas rectified using half-wave rectification and was low-pass filtered using a fifth-order Butterworth filter with a 50-Hz cutofffrequency. The resulting envelope signal was down-sampled to a sampling rate of 450 Hz. The first derivative of the envelope was computed by the difference between consecutive samples. Peaks greater than a threshold slope parameter of m = ±0.41 were labeled. From this set, four peaks were selected as the onset and offsets of the nuclei in each syllable. The peaks were selected using the following logic: For each syllable, the greatest positive peak is the onset until a negative peak is reached, then the most negative peak is the offset until a positive peak is reached, indicating the next syllable. The identified locations were inspected manually to ensure that the algorithm was successful in all cases.

A window function was computed from the selected peaks, and this window was applied as a scaling function in

theEDI computation, resulting in a consonant-weighted metric: cEDI. The window was formed independently for each consonant and talker, based on the syllable landmarks identified from peaks in the derivative of the envelope. The window was a cosine-squared ramp from 0 before the first peak to 1 at the midpoint in time between the first and the second peak, then back to 0 from the midpoint between the third and the fourth peak to the fourth peak. An example window is shown by the thin line in the upper panel of Figure 1.

The computation of the cEDI is as follows:

... (1)

The absolute value of the difference between the compressed and uncompressed envelopes (Env1 and Env2, normalized) is averaged over each sample (N) and divided by two (Fortune et al., 1994).The computation of the cEDI multiplies each envelope by the window computed above, w(n), prior to normalization. A window of 1 for all ns was used when calculating the EDI by the conventional method.

The bottom panel of Figure 1 shows the uncompressed (solid line) and compressed (dotted line) envelopes for /ama/. The gray vertical bars in the lower panel of Figure 1 showthe difference values included in the conventional EDI, and the darker vertical bars in the lower panel of Figure 1 show the difference values included in the cEDI,which result fromthe application of the window function. The window reduced the contribution of the initial vowel onset and final vowel offset, which are regions distorted by compression, yet unlikely to contribute to consonant recognition, and not likely to affect the EDI proximal to the consonant transition regions.

Results

The effect of distortion on temporal envelope cues was quantified by using the conventional EDI, as reported previously, and by using the cEDI. Figure 2 shows the correlation between the EDI and cEDI for each stimulus waveform in the study. Results from normal hearing listeners recognizing the spectrally reduced and compressed consonants are shown in Figure 3. Mean consonant recognition was reduced in Condition 3, $t(9) = 2.6$, $p = .028$, and Condition 4, $t(9) = 4.0$, $p = .003$, in which envelope distortion from compression was the greatest. To evaluate our prediction that focusing the analysis of distortion on the consonant portion of the signal would improve its correlation to behavioral performance, we used both the EDI and cEDI in a linear model of consonant recognition. A stepwise linear regression was used with three factors: (a) a metric of distortion (EDI or cEDI), (b) the consonant, and (c) an interaction between consonant and distortion metric. Both the EDI and cEDI accounted for a small but significant portion of the variance in consonant recognition (EDI, $r2 = .019$, $p = .028$; cEDI, $r2 = .032$, $p = .004$), and the cEDI accounted for more of the variance. The consonant and consonant interaction factors were not significant for either model.

Discussion

Comparison of EDI and cEDI

The results confirm our hypothesis that focusing the analysis of distortion in a signal on the consonant would improve the relationship between distortion and consonant recognition. As demonstrated in Figure 2, the cEDI gives a broader range of values for the same compressed signals comparedwith the conventional EDI. This indicates that the cEDI is more sensitive to the effects of compression on consonant cues in the temporal envelope than the conventional EDI. As a result, more of the variance in consonant recognition is accounted for with the cEDI. However, the total amount of variance explained remains an unremarkable 3.2%. While it is an improvement over the EDI, the cEDI fails to capture the changes to the temporal envelope that are perceptually salient to the listener. A model based on a frequency analysis of the temporal envelope, such as the Spectral Correlation Index (SCI), may be a better approach to quantify the effect of envelope distortion (Gallun &Souza, 2008). Future work will apply the syllable parsing presented here to a model of signal distortion based on the spectrum of the envelope.

Syllable Analysis

The algorithm for automatically parsing syllables presented in this article was highly successful when applied to VCV stimuli. The technique located the peaks corresponding to every VC and CV transition in the set of 16

consonants for all 4 talkers. A single threshold value was needed for the entire set of signals when uncompressed.The techniquewas also successful in parsing the compressed signals, but high levels of compression required the selection of a lower threshold value for some consonants. The central two points identified by the algorithm, which indicate the location of the consonant, were not affected by compression. Because of the success of the algorithm under heavy compression, we are confident that itwill be useful in a broad range of applications.

Future Directions

The technique for syllable segmentation developed for this article has applications beyond segmenting the two-syllable speech signals analyzed here. Future work will apply the technique to longer utterances, so that a comparison can be made between short-time, phonemic metrics, such as SCI (Gallun& Souza, 2008), and metrics that require a long duration input, such as the Speech Intelligibility Index (SII; American National Standards Institute, 1997). Such comparisons can be made regardless of the source of envelope distortion (e.g., reverberation, noise reduction). Preliminary data indicate that the algorithmsuccessfully locates syllable boundaries in continuous speech.We plan to use these boundaries as a guide to performing short-time signal analyses on continuous signals for comparison to longer durationmetrics. The use of the first derivative of the envelope also may provide an advantage over existing techniques for syllable analysis in speech signal processing, or in such applications as automatic speech recognition (Bartels &Bilmes, 2007).

Abstract: This study investigated how different instructions for eliciting clear speech affected selected acoustic measures of speech. Twelve speakers were audio-recorded reading 18 different sentences from the Assessment of Intelligibility of Dysarthric Speech (Yorkston &Beukelman, 1984). Sentences were produced in habitual, clear, hearing impaired, and overenunciate conditions. A variety of acoustic measures were obtained. Relative to habitual, the clear, hearing impaired, and overenunciate conditions were associated with different magnitudes of acoustic change for measures of vowel production, speech timing, and vocal intensity. The overenunciate condition tended to yield the greatest magnitude of change in vowel spectral measures and speech timing, followed by the hearing impaired and clear conditions. SPL tended to be the greatest in the hearing impaired condition for half of the speakers studied. Different instructions for eliciting clear speech yielded acoustic adjustments of varying magnitude. Results have implications for direct comparison of studies using different instructions for eliciting clear speech. Results also have implications for optimizing clear speech training programs.

Purpose: This study investigated how different instructions for eliciting clear speech affected selected acoustic measures of speech.
Method: Twelve speakers were audio-recorded reading 18 different sentences from the Assessment of Intelligibility of Dysarthric Speech (Yorkston &Beukelman, 1984). Sentences were produced in habitual, clear, hearing impaired, and overenunciate conditions. A variety of acoustic measures were obtained.

Results: Relative to habitual, the clear, hearing impaired, and overenunciate conditions were associated with different magnitudes of acoustic change for measures of vowel production, speech timing, and vocal intensity. The overenunciate condition tended to yield the greatest magnitude of change in vowel spectral measures and speech timing, followed by the hearing impaired and clear conditions. SPL tended to be the greatest in the hearing impaired condition for half of the speakers studied.
Conclusions: Different instructions for eliciting clear speech yielded acoustic adjustments of varying magnitude. Results have implications for direct comparison of studies using different instructions for eliciting clear speech. Results also have implications for optimizing clear speech training programs.
Key Words: clear speech, instructions, acoustics
Speech clarity has been a topic of significant research interest over the past few decades. Following Smiljanic and Bradlow (2009), the term clear speech refers to a speaking style wherein talkers voluntarily adjust their conversational or habitual speech to maximize intelligibility for a communication partner. Talkers may use clear speech in a variety of situations, such as when conversing in a noisy environment or when talking to someone who has a hearing impairment. Clear speech is further recommended for use as a therapy technique for speakers with dysarthria (Beukelman, Fager, Ullman, Hanson, &Logemann, 2002; Dromey, 2000; Hustad &Weismer, 2007), for use in military aviation training programs (Huttunen, Keränen, Väyrynen, Pääkkönen, &Leino, 2011), and for use in aural rehabilitation training programs (Schum, 1997). Identifying variables responsible for the improved intelligibility typically associated with clear speech also may help to improve signal processing technologies for auditory prostheses (i.e., Krause &Braida, 2009; Picheny, Durlach, &Braida, 1985, 1986; Uchanski, Choi, Braida, &Reed, 1996; Zeng &Liu, 2006). Thus, clear speech research has real-world implications for optimizing clear speech training programs and for developing technologies for use with populations who have difficulty understanding speech. In addition, the construct of clear speech figures prominently in certain speech production theories (Lindblom, 1990; Perkell, Zandipour, Matthies, &Lane, 2002). The increase in intelligibility from conversational to clear speech has been termed the clear speech benefit, and the magnitude of this effect is known to vary widely across studies. That is, with the exception of a few investigations that used listeners with particular kinds of hearing impairment or simulated hearing impairment, the average clear speech benefit in a given study reportedly ranges from 3% to 34% (Smiljanic &Bradlow, 2009; Uchanski, 2005). Variables contributing to cross-study variation in the overall clear speech benefit are not well understood. As noted in a following section, differences in instruction or cues for eliciting clear speech may be a contributing factor.

In a variety of studies, researchers have sought to determine the acoustic basis of the improved intelligibility typical of clear speech.The following reviewhighlights findings from studies reporting acoustic measures that were of interest to the present investigation, including vowel formant frequency characteristics, speech durations, and vocal intensity. More comprehensive reviews may be found in Smiljanic and Bradlow (2009) as well as Uchanski (2005).

Vowel space area, calculated from midpoint or steady-state values of F1 and F2, indexes the size of an individual's vowel articulatory-acoustic working space (Turner, Tjaden, &Weismer, 1995). The relationship between vowel space and intelligibility for neurologically normal talkers is suggested by studies reporting larger vowel space areas for talkers who are inherently more intelligible in conversational speech (Bradlow, Torretta, &Pisoni, 1996; Hazan &Markham, 2004). Some dysarthria studies have also suggested a relationship between vowel space area and intelligibility (e.g., Hustad &Lee, 2008; H. Liu, Tsao, &Kuhl, 2005; Tjaden &Wilding, 2004). An expanded vowel space area for clear versus conversational speech has been widely reported (Bradlow, Krause, &Hayes, 2003; Ferguson &Kewley-Port, 2002, 2007; Johnson, Flemming, &Wright, 1993; Moon &Lindblom, 1994; Picheny, Durlach, &Braida, 1986). There are exceptions, however. Goberman and Elmer (2005) did not find significant vowel space expansion for clear speech produced by speakers with dysarthria secondary to Parkinson's disease. Krause and Braida (2004) also reported minimal vowel space area

expansion when neurologically normal talkers were trained to produce clear speech at normal or conversational speech rates. Picheny et al. (1986) further suggested a tendency for midpoint formant frequencies for lax vowels, and the derived lax vowel space area, to change more dramatically for clear speech as compared with tense vowels, although this trend has not been strongly supported in more recent studies (Krause &Braida, 2004).

Ferguson and Kewley-Port (2007) used a novel approach to investigate acoustic changes likely responsible for improved intelligibility of clearly produced /bVd/ words. Static and dynamic spectral measures of vowel production for speakers exhibiting a large clear speech benefit (big-benefit talkers) were contrasted with measures for speakers exhibiting no clear speech benefit (no-benefit talkers). Clear speech for big-benefit talkers was characterized by greater vowel space area expansion, a greater overall increase in F1, and higher F2 values for front vowels when compared with clear speech produced by the no-benefit talkers. Vowel formant dynamics did not differ for the big-benefit and no-benefit talkers, nor did Tasko and Greilick (2010) find clarityrelated differences in F1 or F2 diphthong transitions. However, other studies have reported that vowel formants are more dynamic in clear speech as compared with conversational speech (Ferguson &Kewley-Port, 2002; Moon &Lindblom, 1994; Wouters &Macon, 2002). Perceptual studies using speech resynthesis have also suggested the importance of dynamic spectral cues for accurate vowel identification (e.g., Assmann &Katz, 2005; Hillenbrand &Nearey, 1999).

Slowed speaking rate is probably the most widely reported characteristics of clear speech (Bradlow, Krause, &Hayes, 2003; Picheny et al., 1986; Smiljanic&Bradlow, 2008). The slower than normal speaking rate typical of clear speech further tends to be associated with a reduced articulation rate, increased segment durations, and longer, more frequent pauses (Bradlow et al., 2003; Picheny et al., 1986; Uchanski et al., 1996). Although many studies have reported a slowed speech rate for clear speech, speakers can be trained to produce clear speech at a normal or conversational speech rate (Krause &Braida, 2004). This observation might be taken to suggest that a reduced rate, lengthened segment durations, and longer, more frequent pauses do not contribute to the improved intelligibility typically associated with clear speech. However, the fact that Krause and Braida (2004) found that the increase in intelligibility for clear speech produced at a normal speech rate was not as great as the increase in intelligibility for clear speech produced at a typically slower than normal rate suggests the contribution of temporal adjustments to the clear speech benefit. Other studies have also suggested that an increased number of pauses accompanying clear speech benefits intelligibility (S. Liu &Zeng, 2006).

Finally, clear speech studies reporting vocal intensity measures have found that clear speech is generally accompanied by at least some increase in vocal intensity (e.g., Dromey, 2000; Goberman &Elmer, 2005; Picheny et al., 1986). As noted by Uchanski (2005), the contribution of increased vocal intensity to the clear speech benefit is not attributable to improved audibility, as the relevant perceptual studies have equated clear and conversational speech for overall SPL. Rather, other speech production changes accompanying an increased vocal intensity, such as the use of more canonical vocal tract shapes, may help to explain improvements in intelligibility.

Although research conducted over the past few decades has made a great deal of progress in advancing our knowledge of clear speech,many important questions still need to be addressed. One is the extent to which the instruction or cue for eliciting clear speech impacts both production and perception (Smiljanic &Bradlow, 2009). To date, clear speech has been elicited using a variety of instructions or cues, including "speak clearly" (Ferguson, 2004; Ferguson &Kewley-Port, 2007), "hyperarticulate" or "overenunciate" (Dromey, 2000; Moon &Lindblom, 1994), or "speak to someone with a hearing impairment or non-native speaker" (Bradlow et al., 2003; Smiljanic &Bradlow, 2008). Other studies have used a combination of these instructions (e.g., Picheny et al., 1985; Rogers, DeMasi, &Krause, 2010; Tasko &Greilick, 2010). Studies comparing different cues for increasing vocal loudness (e.g., Darling &Huber, 2011; Huber &Darling, 2011; Sadagopan &Huber, 2007) and studies investigating different cues or instructions for slowing speech rate (VanNuffelen,De Bodt,Vanderwegen,

&Wuyts, 2010) have suggested that speech output differs depending on the nature of the instruction or cueing provided to talkers. It seems reasonable to hypothesize that clear speech output also may differ depending on the cue or instruction used to elicit this speech style.

The question of whether different instructions or cues for eliciting clear speech result in equivalent articulatory-acoustic and perceptual changes is nontrivial. Differences in clear speech instruction could help to explain cross-study variation in production characteristics as well as cross-study differences in the magnitude of the clear speech benefit. Knowing the speech production adjustments associated with a particular clear speech instruction further has the potential to assist in optimizing clear speech training programs for dysarthria or aural rehabilitation. As an initial step in addressing this multifaceted issue, the current study examined the impact of three clear speech instructions on selected acoustic measures of speech for a group of healthy adult talkers. Instructions included "speak clearly" (clear condition), "overenunciate" (overenunciate condition), and "talk to someone with a hearing impairment" (hearing impaired condition). These cues or instructions were selected for several reasons. First, all instructions have been used in separate, previously published studies and are reasonably distinct from one another (Bradlow et al., 2003; Dromey, 2000; Ferguson, 2004; Johnson et al., 1993; Moon &Lindblom, 1994). In addition, these cues are probable candidates for use in clear speech training programs, and it was of interest to determinewhether instructions likely to be used therapeutically would elicit similar types or magnitudes of acoustic change.

Method

Participants

A total of 12 neurologically healthy speakers (six men and six women) ranging from 18 to 36 years of age (M = 24, SD = 6 years) were recruited from the student population at the University at Buffalo to serve as participants. Participants were judged to speak Standard American English as a first language and reported no history of hearing, speech, or language pathology. All speakers passed a pure tone hearing screening, administered bilaterally at 20 dB HL at 500, 1000, 2000, 4000, and 8000 Hz (American National Standards Institute [ANSI], 1969). In addition, no speaker had received university training in linguistics or communicative disorders and sciences.

Speech Sample

For each of the 12 speakers, 18 different sentences, varying in length from five to 11 words, were selected from the Assessment of Intelligibility of Dysarthric Speech (AIDS; Yorkston&Beukelman, 1984). Sentences were audio-recorded as part of a larger speech sample, which also included /hVd/ words. Each sentence set was selected to include three to five occurrences of the tense vowels /A, i, æ, u/ and the lax vowels /I, e, u, Ã/. Vowels also were selected to occur in content words and in syllables receiving primary stress. In addition to measures of duration and intensity discussed below, spectral characteristics of vowels were of primary interest, following Ferguson and Kewley-Port (2007).

Speakers read the sentences in four conditions, including, habitual, clear, hearing impaired, and overenunciate. These conditions were selected for several reasons. First, other clear speech studies have elicited adjustments in clarity by instructing speakers to "overenunciate/ hyperarticulate" (overenunciate condition), "talk to someone with a hearing loss" (hearing impaired condition) or "speak clearly" (clear condition) (e.g., Bradlow et al., 2003; Ferguson, 2004; Johnson et al., 1993; Moon &Lindblom, 1994; Smiljanic &Bradlow, 2008). When selecting instructions from among those utilized in previous studies, care also was taken to choose distinctive instructions. Thus, only "talk to someone with a hearing impairment" but not "talk to a non-native speaker" was included for study. In addition, these cues were deemed to be reasonable candidates for use in clear speech training programs, especially "overenunciate" and "speak clearly," and it would seem important to know whether training program instructions would elicit similar types or magnitudes of acoustic change.

For the habitual condition, speakers were simply instructed to read the sentences. Thus, the habitual condition is similar to "conversational" or "citation" speech in other clear speech studies. Speakers subsequently were

asked to read the sentences "while speaking clearly" (clear), allowing each participant to determine what this phrase meant (see Ferguson, 2004). Speakers also were instructed to "speak as if speaking to someone who has a hearing impairment" (hearing impaired condition) and to "overenunciate each word" (overenunciate condition). The order of these latter two conditions was alternated among participants such that the order of conditions for six participants was habitual, clear, hearing impaired, and overenunciate, and the order of conditions for the remaining six participants was habitual, clear, overenunciate, and hearing impaired. Participants were engaged in casual conversation for a few minutes between recordings for each condition to minimize carry-over effects. The clear condition was always recorded immediately following the habitual condition. This order of conditions was followed so that speakers could interpret the instructions to "speak clearly" without the prior influence of hearing the instructions to "overenunciate" or "talk to someone with a hearing impairment."

Procedure

Data collection took place in a sound-attenuated booth. A head-mounted CountryMan E6IOP5L2 Isomax condenser microphone was used to record the acoustic signal. A mouth-to-microphone distance of 6 cm was maintained throughout the recording for each speaker. The microphone signal was preamplified using a Professional Tube MIC Preamp, low-pass filtered at 9.8 kHz and digitized to a computer at a sampling rate of 22 kHz using TF32 (Milenkovic, 2002). Prior to recording each participant, a calibration tone of known intensity was also recorded. The calibration tone was later used to calculate vocal intensity from the acoustic speech signal (see Tjaden &Wilding, 2004). Stimuli were presented using MicrosoftPowerPoint and were read from a computer screen.Written instructions for each condition were presented both visually on the computer screen and verbally at the beginning of recording, as well as a quarter, half, and three quarters of the way throughout each condition. For each speaker, four random orderings of sentences were created such that sentences were produced in a different order for the four speaking conditions.

Prior to performing the acoustic analysis, audio files were recoded by a research assistant not involved in the study so that the investigators performing the acoustic measures were blinded to the identity of each speaking condition. The purpose of this procedure was to help control for possible experimenter bias when performing the acoustic analysis.

Table 1 summarizes acoustic measures of interest. These measures were selected from among those reported in previous clear speech studies (Bradlow et al., 2003; Ferguson &Kewley-Port, 2002, 2007; Moon &Lindblom, 1994; Picheny et al., 1986). Because it was expected that the various clear speech instructions would elicit articulatory adjustments, as inferred from the acoustic signal, and possibly different magnitudes of adjustment, ameasure of segmental articulation was included. The current focus on vowels is consistent with that of Ferguson and Kewley-Port (2007). Similarly, a measure of vocal intensity was obtained because it was speculated that the instruction to "speak to someone with a hearing impairment" might elicit a relatively greater adjustment in vocal intensity than other instructions. Finally, global speech timing was included for study because a reduced speaking rate has been so widely reported in clear speech research. Given that the instructions selected for study might be used in clear speech training programs for dysarthria, and that speaking rate reduction is often desirable in the treatment of dysarthria, it was of interest to determine whether the various clear speech instructions would elicit different magnitudes of speaking rate adjustment. Each of the acoustic measures is discussed in more detail below. All acoustic analyses were performed using TF32 (Milenkovic, 2002).

Segmental acoustic measures. Vowel segment durations were obtained using a combination of the waveform and wideband (300-400 Hz) digital spectrographic displays. Vowel durationwas computed from the first glottal pulse of the vocalic nucleus to the last glottal pulse as indicated by energy in both F1 and F2 (Tjaden, Rivera, Wilding, &Turner, 2005; Turner et al., 1995). For each speaker and condition, vowel segment durations were averaged for tense (A, i, æ, u) and lax (I, e, u, Ã) vowel categories. These averages were subsequently used in

the statistical analyses for segment durations.

Linear predictive coding generated formant trajectories for F1 and F2 also were computed over the entire duration of each vowel of interest. Computer-generated tracking errors were inspected for errors and manually corrected as needed. Using MicrosoftExcel, F1 and F2 values were extracted at three time points corresponding to 20%, 50%, and 80% of vowel duration (Hillenbrand, Getty, Clark, &Wheeler, 1995). Average midpoint formant frequencies (50% point) for each speaker and condition were used to calculate a variety of static measures of vowel production, including vowel space area, F1 range, F2 range, intravowel distance, and tense-lax spectral distance.

Using Heron's formula (see Goberman &Elmer, 2005; Turner et al., 1995), a separate vowel space area was calculated for tense vowels /A, i, æ, u/ and lax vowels /I, e, u, Ã/, yielding a tense vowel space area and lax vowel space area for each speaker and condition for use in the statistical analysis. Because tongue height and tongue advancement broadly correspond to adjustments in F1 and F2, respectively (Kent &Read, 2002), F1 range and F2 range also were calculated to supplement measures of vowel space area. Following procedures used by Ferguson and Kewley-Port (2007), F1 and F2 ranges were computed using midpoint formant frequencies from the four tense vowels that form the extremes or border of the articulatory-acoustic working space /A, i,æ , u/. F1 range was determined by calculating the absolute difference between average F1 values for /i / and /u/, and average F1 values for /æ / and /A/. Similarly, F2 range was determined by calculating the absolute difference between average F2 values for /i / and /æ /, and average F2 values for /A/ and /u /. Separate F1 and F2 ranges were calculated for each speaker and condition for use in the statistical analysis.

As illustrated in Figure 1, a measure termed intravowel distance (ID) was calculated to index the amount of change in F1 ×F2 space for a given vowel in the clear, hearing impaired, and overenunciate conditions relative to the habitual condition. Relatively greater IDs suggest that a given vowel is more amenable to condition effects. Thus, the ID measure is not unlike the Euclidean distance fromhabitual centroid measure reported by Turner et al. (1995). As shown schematically in Figure 1, ID was determined by calculating the length of the line between a vowel's habitual F1 ×F2 coordinate and the corresponding F1 ×F2 coordinate for that vowel in the clear, hearing impaired, and overenunciate conditions. In Figure 1, the habitual F1 ×F2 coordinates for /u / and /u/ are indicated with open circles labeled with the appropriate phonetic symbol. Squares in Figure 1 correspond to F1 ×F2 coordinates for each vowel in the clear, hearing impaired, and overenunciate conditions. Solid lines represent IDs. Thus, for each speaker and vowel, three ID measures were obtained. IDs were calculated to describe vowels contributing to adjustments in vowel space area and were not included in the parametric statistical analysis.

Previous studies have suggested that clear speech impacts dynamic characteristics of vowel production (Ferguson &Kewley-Port, 2002; Moon &Lindblom, 1994; Wouters &Macon, 2002). Thus, following procedures established by Ferguson and Kewley-Port (2007), formant frequency values at the 20% and 80% points were used to calculate the dynamic measure, lambda (l), using the formula |F180 - F120| + |F280 - F220|. For each speaker and condition, lambda measures were calculated for each vowel and then averaged across tense and lax vowel categories, yielding a mean lambda measure for tense vowels and a mean lambda measure for lax vowels for use in the statistical analysis.

The measure tense-lax spectral distance between the four vowel pairs, /æ -e/, /i-I /, /u-u/ and /A-Λ/, was calculated to provide an index of the relative spectral distinctiveness of tense-lax vowel pairs. This measure is illustrated in Figure 1 by the dashed line, which indicates the Euclidean distance in F1 ×F2 space for the tense-lax vowel pair /u/ and /u/. Several additional measures also were derived to further characterize the degree of acoustic contrast for the four tense-lax vowel pairs. These measures included duration ratios and lambda ratios. These ratios were calculated separately for each of the four tense-lax vowel pairs for use in the statistical analysis. Thus, average lax durations were divided by average tense durations, yielding four duration ratios per speaker and condition. Similarly, average lax lambda values were divided by average tense lambda values,

yielding four lambda ratios per speaker and condition.

Global timing. Measures of total utterance duration, run duration, and syllable counts were obtained for use in calculating speaking rate and articulation rate in syllables per second. Pause durations and pause frequencies were also measured. A pause was defined as a silent period of 200 ms or greater between words (Turner &Weismer, 1993).

Standard acoustic criteria were used to identify onsets and offsets for total utterance durations and run durations. A run was defined as a stretch of speech separated by interword pauses (Turner &Weismer, 1993). Total utterance durations were calculated by summing all run durations and pauses within a sentence. Sentence or run onsets beginning with obstruents were defined as the leftedge of the release burst or fricative noise (Klatt, 1975). The onset of a nasal was indicated by a reduction in intensity in the higher frequencies (Kent &Read, 2002). Onsets for vowels, liquid, and glides were defined as the leftedge of the first glottal pulse, as indicated by energy in both F1 and F2. Similar criteria were applied when determining offsets.

Speaking rate for each sentence in syllables per second was calculated by dividing the number of syllables produced by total utterance duration (in milliseconds) and then multiplying by 1,000. For each sentence, articulatory rate (syllables per second) was calculated by dividing the number of syllables produced by the total duration of all runs (in milliseconds) composing a sentence and multiplying by 1,000 (Turner &Weismer, 1993). For each speaker and condition, measures of speaking rate, articulation rate, pause duration, and pause frequency were averaged across sentences for use in the statistical analysis.

Vocal intensity. Following procedures from previous studies, the average root-mean-square (RMS) voltage of each run was converted to dB SPL in reference to each speaker's calibration tone (Tjaden &Wilding, 2004). For each speaker and condition, a measure of average intensity was determined by averaging SPL across all runs. These averages were used in the statistical analysis.

Measurement Reliability

Acoustic measures were performed by the first author, with measurement questions resolved by conferral with the second author. The second author also performed ongoing accuracy checks for a randomly selected sample of approximately 10% of stimuli (i.e., n = 2 sentences) for each speaker and condition at the initial time of measurement. One set of sentences from each speaking condition (i.e., approximately 10% of stimuli) was selected from four different speakers for use in determining measurement reliability following the same procedures utilized for performing the initial measures. Absolute measurement errors and Pearson product-moment correlations were used to index reliability. The correlation between the first and second set of segment duration and run duration measures was 0.96 (M absolute difference measure = 0.008 s, SD = 0.016 s) and 0.99 (Mabsolute difference measure = 0.02 s, SD = 0.08 s), respectively. The correlation between the first and second set of spectral measures was 0.99 (Mabsolute difference measure = 20.0 Hz, SD = 60.0 Hz), and the correlation between the first and second set of SPLs was 0.95 (Mabsolute difference measure = 0.23 dB, SD = 0.69 dB).

Data Analysis

Descriptive statistics in the form of means and standard deviations were calculated for all acoustic measures. Parametric statistical analyses (i.e., analysis of variance) were performed for tense vowel space area, lax vowel space area, tense segment duration, lax segment duration, F1 range, F2 range, tense-lax spectral distance, SPL, lambda (l), duration ratios, lambda ratios, speaking rate, and articulation rate. Pause frequency and pause duration data were characterized using descriptive statistics because pauses occurred fairly infrequently. Using SAS Version 9.1.3 statistical software, a multivariate linear model was fit to each dependent variable in this repeated measures design. For all dependent variables, models included the main effect of condition (habitual, clear, hearing impaired, overenunciate). The analyses for tense-lax spectral distances, lambda ratios, and duration ratios also included a vowel main effect as well as a Condition ×Vowel interaction, as potential differences among the four tense-lax vowel pairs were of interest. To control for gender differences in

dependent measures, a variable representing gender also was included in each analysis. To account for the within-subject dependence structure, each multivariate linear model assumed that the distribution of the error terms for each subject was multivariate normal with zero mean and an unstructured covariance structure (Brown &Prescott, 1999). Post hoc pairwise comparisons were performed using a Bonferroni correction for multiple comparisons. All tests were two-sided, and a significance level of $p < .05$ was used in all hypothesis testing. Finally, for convenience, the clear, hearing impaired, and overenunciate conditions are collectively referred to as the nonhabitual conditions throughout the Results and Discussion.

Results

Vowel Space Area

Figures 2 and 3 report average F1 ×F2 coordinates and the associated vowel space areas for male and female speakers, respectively. The statistical analysis indicated a significant condition effect for both tense, $F(3, 10) = 28.65$, $p < .0001$, and lax, $F(3, 10) = 17.9$, $p = .0002$, vowel space areas. For tense vowels, post hoc comparisons indicated greater vowel space areas for the clear ($p=.0002$), hearing impaired ($p=.0007$), and overenunciate ($p < .0001$) conditions when compared with the habitual condition. Tense vowel space area in the overenunciate condition was also significantly greater than in the clear condition ($p = .001$). For lax vowels, post hoc comparisons indicated larger vowel space areas for clear ($p = .006$), hearing impaired ($p = .001$), and overenunciate ($p = .0003$) conditions compared with habitual.

For tense and lax vowels, the finding of greater vowel space area in the nonhabitual conditions as compared with habitual held for 12 and 10 speakers, respectively. In addition, the overenunciate condition was associated with the greatest tense and lax vowel space areas for 10 and nine speakers, respectively. The remaining speakers exhibited the greatest vowel space areas in the hearing impaired condition.

Because previous studies have suggested that lax vowels are more susceptible to the effects of speaking style than tense vowels (Picheny et al., 1985), the mean percent increase in vowel space area for the nonhabitual conditions relative to the habitual condition was calculated. As reported in Table 2, on average, lax vowels exhibited a greater percent change in vowel space area for the nonhabitual conditions when compared with the habitual condition, particularly for female speakers.

Figure 4 reports data for F1 and F2 range in the form of box and whiskers plots. Data for F1 are reported in the upper panel, and data for F2 are reported in the lower panel. For F1 range there was a significant effect of condition, $F(3, 10) = 15.97$,$p=.0004$. Post hoc analyses further indicated that F1 range was greater in all three nonhabitual conditions as compared with habitual ($p \leq .008$) but did not differ for pairs of nonhabitual conditions. This trend of a greater F1 range in the nonhabitual conditions relative to habitual held for 11 of 12 speakers. As illustrated in Figure 4, descriptive statistics further indicated that, on average, F1 range was greatest in the overenunciate condition, followed by the hearing impaired, clear, and habitual conditions.Results were similar for F2 range. That is, the statistical analysis indicated a main effect of condition, $F(3, 10) = 21.13$, $p = .0001$. Post hoc analyses further indicated that F2 range was greater in all three nonhabitual conditions as compared with habitual ($p \leq .001$), and this trend held for 11 of 12 speakers. In addition, F2 range was significantly greater in the overenunciate condition versus the clear condition ($p = .001$). Finally, as illustrated in Figure 4, descriptive statistics indicated that on average, F2 range was greatest in the overenunciate condition, followed by the hearing impaired, clear, and habitual conditions.

Intravowel Distance

Table 3 summarizes findings for ID. This table reports the number of speakers exhibiting the greatest ID for a given vowel comprising the tense and lax vowel categories within each condition. Thus, the first row of Table 3 indicates that for the clear condition, five speakers exhibited the greatest ID for /i /, six speakers exhibited the greatest ID for /u/, one speaker exhibited the greatest ID for /æ /, and no speakers exhibited the greatest ID for /A/. The implication is that in the clear condition, the tense vowels /i / and /u / were most amenable to adjustment in F1 ×F2 space as compared with /æ / and /A/. Of the tense vowels, Table 3 further suggests that

the majority of speakers produced the greatest IDs for /i, u/. For lax vowels, although not as robust, Table 3 suggests that speakers tended to produce the greatest IDs for /I, u/ within a given condition. Thus, these lax vowels tended to be more susceptible to condition effects than other lax vowels.

Vowel Spectral Change Measure (Lambda)

Descriptive statistics for lambda are reported in Table 4. The main effect of condition was significant for both tense, $F(3, 10) = 3.90$, $p = .04$, and lax, $F(3, 10) = 5.79$, $p = .01$, vowels. Post hoc comparisons for tense vowels were not significant. However, Table 4 indicates a trend for greater tense lambda values in the overenunciate and hearing impaired conditions as compared with the habitual and clear conditions. Moreover, six speakers had the greatest lambda values in the overenunciate condition, and four speakers had the greatest lambda values in the hearing impaired condition.

Post hoc tests for lax vowels indicated significantly greater lambda values, or more dynamic vowels, for the hearing impaired ($p = .02$) and overenunciate ($p = .04$) conditions when compared with habitual, as well as for the overenunciate condition versus the clear condition ($p = .01$). Consistent with these post hoc analyses, eight speakers had the largest lax lambda values in the overenunciate condition, and three speakers had the greatest lambda measures in the hearing impaired condition.

Segment Durations

Descriptive statistics for segment durations are reported in Table 4. The statistical analyses indicated a significant condition effect for both tense, $F(3, 10) = 41.84$, $p < .0001$, and lax, $F(3, 10) = 17.9$, $p < .0001$, vowel durations. For tense vowels, post hoc comparisons indicated that speakers significantly increased vowel durations for the hearing impaired ($p = .0006$) and overenunciate ($p = .0002$) conditions when compared with the habitual condition. Tense vowels were also longer in the overenunciate condition when compared to the clear condition ($p < .0001$). Post hoc comparisons for lax vowels indicated longer vowels for the hearing impaired ($p = .0001$) and overenunciate ($p < .0001$) conditions as compared with the habitual condition. The overenunciate ($p < .0001$) and hearing impaired ($p = .005$) conditions were also associated with longer vowels compared with the clear condition. Inspection of individual speaker data revealed that all but two speakers followed the trend of increased tense and lax vowel durations for the clear, hearing impaired, and overenunciate conditions relative to habitual.

Distinction of Tense-Lax Vowel Pairs

Figure 5 illustrates spectral distances for tense (filled circles) and lax (unfilled circles) vowel pairs for speaker M07 (upper panel) and M04 (lower panel). Greater distances or longer lines in Figure 5 indicate greater distinction of vowel pairs in F1 ×F2 space. For each of the four vowel pairs, the statistical analysis indicated no significant difference among conditions. However, inspection of individual speaker data indicated that for /æ -e/, /i-I /, and /u-u/, anywhere from six to eight speakers increased spectral distances for the nonhabitual conditions compared with habitual. For the /A-Ã/ tense- lax pair, however, nine of 12 speakers reduced tense- lax spectral distances in the clear condition, and five speakers increased tense-lax spectral distances in the hearing impaired and overenunciate conditions. Interestingly, for every vowel pair, M04-data for which are plotted in the lower panel of Figure 5-reduced all but one tense-lax spectral distance for the nonhabitual conditions compared with habitual.

Table 5 reports descriptive statistics for duration ratios and lambda ratios. Ratios approaching 1.0 indicate reduced distinction. For both measures, ratios did not differ significantly across conditions. Indeed, duration ratios in Table 5 for a given vowel pair vary only a small amount across conditions, although it is notable that average duration ratios for the tense-lax pair /A-Ã/ tend to approach 1.0 in the nonhabitual conditions, indicating relatively less temporal distinction, whereas duration ratios for the tense lax pair /i-I / suggest a trend toward increased temporal distinction in the nonhabitual conditions. Inspection of average lambda ratios in Table 5 further suggests a trend for all tense-lax vowel pairs to exhibit increased dynamic distinction in most of the nonhabitual conditions, as lambda ratios tend to move away from 1.0 in the nonhabitual conditions relative to

habitual. The main effect of vowel pair was significant for duration ratio, $F(3, 33) = 5.13$, $p = .005$, and lambda ratio, $F(3, 33) = 13.67$, $p < .0001$. Although this main effect was not of particular interest, it serves to demonstrate that vowel pairs behaved differently with respect to ratio measures.

Articulation Rate and Speaking Rate

Table 6 reports descriptive statistics for global measures of speech timing. For articulation rate, the statistical analysis indicated a significant condition effect, $F(3, 10) = 78.46$, $p < .0001$. Post hoc comparisons indicated slower articulation rates for the clear ($p = .001$), hearing impaired ($p < .0001$), and overenunciate ($p < .0001$) conditions when compared with habitual. Articulation rates were also reduced for the overenunciate condition when compared with the clear ($p < .0001$) and hearing impaired ($p = .01$) conditions. Findings for speaking rate were identical to those for articulation rate. Inspection of individual speaker data further indicated that nine of 12 speakers followed the trend of having the fastest articulation and speaking rates in the habitual condition followed by the clear, hearing impaired, and overenunciate conditions. In addition, 11 of the 12 speakers had a slower articulation rate and speaking rate in the overenunciate condition when compared with the clear and hearing impaired conditions.

Pause Frequency and Duration

Pause frequency and pause duration data also are reported in Table 6, which indicates that speakers used the greatest number of pauses in the overenunciate condition. This trend held for nine of 12 speakers. Table 6 further indicates longer average pause durations in the nonhabitual conditions as compared with the habitual condition.

SPL

Figure 6 reports mean sentence-level SPL and SDs. The statistical analysis indicated a significantmain effect of condition, $F(3, 10) = 3.80$, $p = .04$. No post hoc comparisons were significant. However, inspection of individual speaker data further indicated that six of 12 speakers increasedmean vocal intensity by approximately 1-2dBfor the hearing impaired condition compared with the habitual condition, and three speakers increased mean vocal intensity by approximately 1-2 dB for the overenunciate condition relative to the habitual condition.

Discussion

Different clear speech instructions were associated with differentmagnitudes of acoustic change for measures of vowel production, speech timing, and vocal intensity. The instruction to "overenunciate" tended to elicit the greatest adjustments in vowel production and speech timing, followed by "speak to someone with a hearing impairment." For half of the speakers studied, this latter condition also elicited the greatest adjustments in vocal intensity. Finally, "speak clearly" elicited the smallest acoustic adjustments relative to the habitual condition. Results and their implications are considered below.

Static and Dynamic Measure of Vowel Production, Speech Timing, and SPL

In agreement with previous clear speech studies (Bradlow et al., 2003; Ferguson &Kewley-Port, 2002, 2007; Moon &Lindblom, 1994; Picheny et al., 1985), speakers in the present study significantly increased tense and lax vowel space areas for all nonhabitual conditions relative to the habitual condition. Descriptive statistics further indicate that both tense and lax vowel space areas were consistently maximized in the overenunciate condition, with analyses for F1 and F2 ranges suggesting that speakers achieved adjustments in vowel space area by producing greater excursions in both tongue height and tongue advancement, with a trend toward the greatest excursions for the overenunciate condition.

To further explore whether particular vowels were more amenable to the effects of clear speech instructions than others, and by inference those vowels contributing to vowel space area change in the nonhabitual conditions, ID measures were calculated to measure each vowel's shiftin F1 ×F2 space across conditions. In general, more speakers tended to produce the greatest ID measures for the high vowels /i, I, u, and u/ in the clear, hearing impaired, and overenunciate conditions. Given the fact that all speakers increased tense and lax vowel space area in the nonhabitual conditions, findings for ID measures suggest that shifts in high tense and

lax vowels contributed most to vowel space expansion.

In addition to clarity-related changes in midpoint vowel formant frequencies, tense and lax lambda measures-corresponding to the amount of spectral change in F1 and F2 between 20% and 80% of vowel duration and by inference within-vowel variation in tongue height and advancement-also differed significantly among conditions. Findings were similar to those for vowel space area in that lambda measures were significantly greater in the nonhabitual conditions compared with habitual. Moreover, both tense and lax lambda measures were greatest in the overenunciate condition (Table 4).

The different clear speech instructions also yielded different magnitudes of change in measures of speech timing, with the greatest change in the form of longer segment durations, longer pauses, greater numbers of pauses as well as slow articulation and speech rates for the overenunciate condition, followed by the hearing impaired, clear, and habitual conditions. Although previous clear speech studies have reported much greater numbers of pauses than reported in the current study (Krause &Braida, 2004; Picheny et al., 1985), the criterion for determining pauses used in these studies was much shorter (i.e., 10 ms) than that used in the current study, as well as in other studies (i.e., 200 ms or greater). Finally, on average, mean SPL for nonhabitual conditions only increased by 1-2 dB compared with that in the habitual condition. Half of the speakers produced a 3- to 6-dB increase in average SPL for the hearing impaired condition, however, and three speakers increased mean SPL by approximately 1-2 dB in the overenunciate condition relative to habitual. These SPL adjustments are less consistent than previously reported (Dromey, 2000; Moon &Lindblom, 1994; Picheny et al., 1985). However, as noted by Smiljanic and Bradlow (2009), an increased vocal intensity or increased vocal effort might not necessarily be expected for clear speech, as talkers presumably use clear speech to maximize intelligibility rather than vocal loudness.

The fact that the various clear speech instructions yielded different magnitudes of change in vowel space area, F1 and F2 range, lambda, and speech timing suggests caution in directly comparing these kinds of measures in studies that use different cues or instructions for eliciting adjustments in speech clarity. Results also have implications for clear speech training programs. That is, findings from the present study suggest that the cue "overenunciate" may prove most effective in a clear speech training program for increasing lingual excursion and thus vowel space area as well as vowel spectral dynamics. This cue also may be most effective for eliciting reductions in speech and articulation rate, at least relative to the other clear speech instructions studied. In contrast, the cue "speak to someone with a hearing impairment" would appear to be more effective than "overenunciate" or "speak clearly" in a clear speech training program that aims to increase average vocal intensity. Given the fact that only about half of the speakers increased vocal intensity in the hearing impaired condition, however, it is not necessarily expected that a clear speech training program would yield consistent changes in vocal intensity. Future studies are needed to investigate these suggestions. Additional studies also are needed to determine the extent to which the different magnitudes of acoustic change reported in the current study are perceptually relevant. Astrong prediction is that clear speech instructions associated with relatively greater acoustic change would also be associated with a relatively larger clear speech benefit.

An explanation for why the various clear speech instructions or cues elicited different amounts of acoustic change may be related to the nature of the speech modifications suggested by each cue. Given that the clear condition consistently yielded the smallest acoustic adjustments, it would appear that the general instruction "speak clearly" may not adequately inform a speaker about how to adjust speech output. Ferguson (2004) also suggested that some speakers may require more specific instructions than "speak clearly" to maximize the benefits of clear speech. In contrast, the cues to "overenunciate" or "speak to someone with a hearing impairment" appear to have provided speakers with more focused information as to how to modify speech. The instruction to overenunciate appeared to direct speakers' attention to segmental articulation and speech durations, and the instruction "talk to someone with a hearing impairment" appeared to direct speakers' attention-for at least approximately half of the speakers-to vocal intensity as well as segmental articulation and

speech duration, albeit to a lesser extent than "overenunciate."

Tense-Lax Vowel Distinctiveness

Chen (1980) reported that repeated productions of a given vowel (i.e., vowel clustering) become closer in F1 ×F2 acoustic working space in clear speech, thus creating greater spectral distinction among vowel categories. More recent studies have shown that this type of spectral distinctiveness among neighboring vowels is important for intelligibility (H. Kim, Hasegawa-Johnson, &Perlman, 2011; Neel, 2008). Vowel clustering of the nature reported by Chen (1980) and H. Kim et al. (2011) was not computed in the present study due to the number of occurrences of each vowel (N = 3-5) per condition and the connected speech context. Instead, distinctiveness of tense-lax vowel pairs was examined via spectral distance in F1 ×F2 space measures, duration ratios, and lambda ratios.

Although there was a trend for the four tense-lax vowel pairs to exhibit increased dynamic distinction in the non-habitual conditions, measures of spectral and temporal distinctiveness for tense-lax vowel pairs did not differ significantly among conditions. Apparently, speaking-condition related enhancement in distinctiveness for tense-lax vowel pairs is subtle-a finding also supported by Y. Kim (2011) in a recent study investigating the impact of increased vocal intensity on spectral distinctiveness of tense-lax vowel pairs. However, vowel distinctiveness in the present studywas notwhollyunaffected by clear speech instructions. That is, as noted by Smiljanic and Bradlow (2009), results for vowel space area as well as F1 and F2 range suggest enhanced spectral distinctiveness among both tense vowels and lax vowels.

Interestingly, one speaker (M04) reduced almost all spectral distances for tense-lax vowel pairs in the nonhabitual conditions. Inspection of M04's duration and lambda ratios suggested that this speaker did tend to enhance tense-lax vowel contrast in the nonhabitual conditions with duration or dynamic spectral cues, but the magnitude of the enhancement was modest. Informal listening to M04's sentences further suggested only subtle perceptual differences among conditions. More formal perceptual judgments are warranted, but M04's data support the hypothesis that spectral and temporal acoustic contrast in clear speech is perceptually important.

Clear Speech and Articulatory Effort

Perkell and colleagues (2002) reported that clear speech was associated with greater peak movement speeds, longer movement durations, and greater movement distances. Although there is no widely accepted metric of articulatory effort, Perkell et al. (2002) interpreted these adjustments as evidence of increased articulatory effort for clear speech much in the same way that an increased SPL has been interpreted to reflect increased respiratory-phonatory effort (see Fox et al., 2006). It has further been suggested that acoustic adjustments associated with clear speech, such as increased intensity, lengthened sound segments, expanded vowel space areas, increased formant transition extents, increased formant transition slopes, and greater spectral distances, are associated with changes in the duration and/or velocity of articulatory movements (Moon &Lindblom, 1994; Perkell et al., 2002).

In the present study, greater movement distances for the nonhabitual conditions are suggested by increased vowel space areas, F1 and F2 ranges, lambda values, and IDs. The nonhabitual conditions also yielded changes in segment durations, articulation rate, and speaking rate. To the extent that these types of acoustic changes for the nonhabitual conditions may be a reflection of or byproduct of articulatory effort, the implication is that speakers used the greatest articulatory effort when instructed to overenunciate. Relatedly, results for SPL suggest a trend for increased respiratory- phonatory effort in the hearing impaired condition, for approximately half of the speakers.

Caveats and Future Directions

Several factors should be kept in mind when interpreting results of the present investigation. First, speakers included for study were healthy, young adults who spoke Standard American English with a dialect characteristic of the western New York region. Whether findings can be generalized to other ages, dialects, and languages is unknown. In addition, only neurologically healthy speakers were studied. Results may not translate

in a straightforward manner to clinical populations, such as patients with dysarthria, for whom clear speech is used therapeutically. Future studies evaluating the effects of different clear speech instructions for a variety of populations, including dysarthria, are of importance.

As a result of the ordering of conditions, the cumulative effect of the clear condition on the following nonhabitual conditions is unknown. However, in an effort to minimize carry-over effects across conditions, participants were engaged in a few minutes of conversation in between conditions. We also acknowledge that there was not a training component associated with the various clear speech instructions, nor was feedback provided regarding the adequacy with which speakers were able to produce clear speech. Thus, results should not be directly extrapolated to clear speech training programs or real-world clear speech situations in which listener feedback is available. Another factor to consider is the potential impact of clear speech instruction on measures of speech production that were not of interest in the present study. For example, clear speech has been shown to affect consonant production characteristics (Maniwa, Jongman, &Wade, 2009) as well as f0 (Bradlow et al., 2003), although Uchanski (2005) noted a fair amount of cross-speaker variability in the impact of clear speech on this latter measure. Future studies can now build on the present investigation to improve our understanding of how clear speech instruction affects a broader range of speech production measures. Studies also are needed to determine the perceptual consequences of different clear speech instructions. Finally, because many studies continue to use a hybrid of instructions to elicit clear speech (Bradlow et al., 2003; Picheny et al., 1985; Smiljanic &Bradlow, 2008), additional studies are needed to determine how a combination of clear speech definitions affects both speech production and perception.

Acknowledgments

This research was supported by National Institute onDeafness and Other Communication Disorders Grant R01DC004689. Portions of this study were presented at the November 2010 Convention of the American Speech-Language-Hearing Association.

Suhami Associates Ltd; Agency Reviews Patent Application Approval Request for "Cellphone Managed Hearing Eyeglasses"

Publication info: Telecommunications Weekly (Nov 28, 2012): 325.
ProQuest document link

Abstract: [...]it can also replace many of the functions of the cellular phone.

Full text: 2012 NOV 28 (VerticalNews) -- By a News Reporter-Staff News Editor at Telecommunications Weekly -- Suhami Associates Ltd has been issued patent application serial number 430728, according to news reporting originating out of Washington, D.C., by VerticalNews editors.
The patent's inventors are Suhami, Avraham (Petah Tikva, IL).
This patent application was filed on March 27, 2012 and was cleared for further review on November 15, 2012.
From the background information supplied by the inventors, news correspondents obtained the following quote:
"A Hearing Aid enhances hearing by amplifying voices detected by a sensitive microphone, while bringing an individual's reduced hearing response at various audible frequencies, to the level of hearing of a normal person, which is defined roughly as the ability to hear sounds on an absolute scale of 0 to 25 dB. The modified sound is then delivered into the user's ear canal.
"Hearing Aids also use various algorithms to suppress noise, echo and eliminate receiver-to-microphone acoustic feedback.
"Hearing devices may be situated behind-the-ear (BTE), in-the-ear (ITE) or completely-in-the-ear canal, (CIC).
"In recent years the use of cellphones in relaying voice messages from one person to another has increased enormously. The advent of cellular phones has caused many problems for the hearing impaired people wearing one of the hearing aids in or behind the ear, starting from the electromagnetic interferences between the two devices that are in close distance one from the other and the physical encumbrance caused by placing the cellphone over the hearing aid. Several solutions to these problems have been devised, including the use of inductive communication between the cellphone and the hearing aid device through the use of telecoils or resolving the causes of interferences. However to the best of our knowledge no radical solution to the hearing impaired people in the cellular phone age has been suggested nor implemented.
"One of the technological problems of the (BTE), (ITE) or (CIC) type hearing aids is the determination of the direction of the sound reaching the ear; precise determination of the direction of sound enables to eliminate

unwanted sources of sound and greatly improve SNR. This problem is currently dealt by using directional microphones that alleviate the problem (see U.S. Pat. No. 3,770,911). Some previous art solutions have suggested using two microphones and measuring the phase delay between them for determining the sound direction, however if the two microphones are very close the determined direction is not accurate. There have been several applications to put several microphones on the eyeglasses temples (see U.S. Pat. No. 3,247,330, U.S. Pat. No. 4,773,095; U.S. Pat. No. 7,192,136; U.S. Pat. Nos. 7,031,483; 7,609,842, 20090252360) for finding the direction of sounds however the technological implementations of these devices have been unsuccessful. There are also no cellphones that, working collaboratively with 'hearing eyeglasses', eliminate unwanted directional or non-directional sound."

Supplementing the background information on this patent application, VerticalNews reporters also obtained the inventors' summary information for this patent: "The invention describes a Hearing Aid device composed of a cellphone and eyeglasses where some of the programs are carried out by components embedded onto the temples of eyeglasses and some programs by components which are inherently part of cellphones. The combined device improves the intelligibility of voice messages arriving both through the cellphone speaker, the connected earphones and directly through the free air. The user can call diverse programs suitable for different situations, by using inertial sensors embedded either in the eyeglasses or are inherently part of the cellphone.

"It has to be realized that the core architecture of the classical hearing aid is to detect voice, 'correct' it, and deliver it to the ear of the hearing impaired person.

"A cellphone, in principle can do all these functions, with some reservation though. It can detect voice, directly or through the cellular network, it can determine interactively with the hearing impaired person his hearing profile, it has the computing power to 'boost' certain intensities, and eliminate certain sources of noise and when its speaker is juxtaposed to the ear, it can deliver the 'corrected' sound to the ear of the hearing impaired person.

"There are things that the cellphone cannot do though. In its current architecture, it cannot differentiate between directional sound and surround sound and eliminate unwanted sound and mainly, it cannot be worn all the day connected to the ear.

"Here is where the eyeglasses come. They can be worn inconspicuously all the time, and components embedded on its temples may carry out many of the functions that neither the cellular phone nor the miniscule behind or in the ear hearing aids can. In fact it can also replace many of the functions of the cellular phone.

"The design of the device presented in this application goes half way.

"It comprises a cellphone in its current architecture and eyeglasses where electronic sensors, processors, device conditioners and transceivers are embedded on its temples and can interact with the cellphone through its ports using coded audio instructions. Together they provide to a hearing impaired person, hearing loss corrected speech and sound, arriving either directly or by wireless communications.

"Hearing impaired people communicate with other people directly or using line and wireless communication devices, telephones and cellphones. Intelligibility of a received message is conditional to a faithful reconstruction of the parts of the message that are missing, due to the hearing losses. Amplifying the received message across the board, at all frequencies, is the basic tool that improves intelligibility. When the hearing losses are minimal, amplification may be sufficient. However amplifying both relevant speech and noise may not achieve much. Therefore reduction noise as much as possible is the next goal. In our system we try to substantially eliminate noise using two strategies. One strategy is by letting the hearing impaired person, to limit his 'listening cone' to cover only the space covered by his interlocutor(s). If the noise is omnidirectional, this tool by itself will reduce noise by up to two orders of magnitude. If the noise, on the other hand, is coming from the same direction as his interlocutor, this strategy may not achieve much. Setting a 'listening code' requires at least 4 microphones around the head of the person; consequently this strategy requires to place the microphones on the eyeglasse worn by the user. To increase the accuracy of the limited listening code and the ability to change

it quickly in real time, powerful DSPs, that continuously compute cross-correlations between the various microphones, are installed on both temples of the eyeglasses.

"The second strategy we use for reducing noise, is to follow speech components in time with a time resolution of 1-2 milliseconds and try to locate the natural 'pauses' between phonemes, syllables and words. As noise is, with high degree of probability, present both during 'pauses' and during speech segments, subtracting the noise frequencies amplitudes from the following speech frequencies, improves the SNR during speech. This strategy is applicable both to the sound detected by the microphones situated on the eyeglasses temples as it is applicable to the microphone of the cellular phone. The cellphone controls the processors on the temples by emitting high frequency audio instructions in the form of ringtones not heard by most persons.

"The next tool we have, in our endeavour to improve intelligibility of the detected speech is to compensate for the loss of hearing of selected audio notes, mostly at low and high frequencies at each ear. These losses may be measured by the user himself using his cellphone, and the required amplifications at selected frequencies, applied both to the speech detected by the microphones situated on the eyeglasses and at the incoming calls by wireless, before being sent to the respective left and right speakers of the eyeglasses and the cellphone speaker and earphones.

"Next, it is essential to differentiate between the voice of the user and that of other people in order to refrain from amplifying the user's voice and sending it to the respective speakers, thereby starting a regenerative audio loop. This identification of the user's voice may be achieved by cross-correlating the voice segments detected by the microphones at the two opposite sides of the mouth and eliminating those voice segments that are fully correlated. In addition the voice segments detected by the microphones of the eyeglasses or the cellphone, may be compared to the preloaded voice signature of the user, where high correlation approves the identity of the user and therefore are prevented to reach the respective speakers.

"Current Hearing Aid devices, suffer from deficiencies some of which are due to the limited space of several cm.sup.3, into which all the components, including the microphone, the receiver and the batteries, have to be squeezed in. An example is trying to find the direction of sound with two microphones that are 1 cm apart. The limited space, also dictates the use of power-limited data processors that are not powerful enough to perform complex comparisons fast enough.

"In this context it is important to stress the need to process speech rapidly, in order to combine it with speech arriving directly to the ear through the free air, so that the ear will seamlessly integrate the two. Digital hearing loss compensation comprising spectral decomposition with filters, non-linear amplification depending on the hearing threshold and spectral reconstruction ought to be carried out preferably in milliseconds or less, in order to enable the audio signals emitted by the receiver to be integrated with the sound reaching the ear directly through free air, without much delay.

"The noise subtraction schemes should also abide by the same constraint of speed; they should be able to define and subtract 'noise' from speech, preferably within several milliseconds from the detection by the microphone of said sound wavefront. This kind of quick reaction requires fast and powerful 32 bit DSPs that are hard to squeeze into the miniscule behind-the-ear hearing aids. RF Transceivers embedded on the eyeglasses enable two way communications with the digital world and communication between the temples of the eyeglasses.

"Consequently placing the required powerful DSPs and batteries much larger than the miniscule Zn-air batteries, on the eyeglasses temples, is a major advantage.

"Current 'Hearing Aids' are individualized devices optimized for certain situations by different programs. Change of programs need professional adjustments, requiring frequent visits to the hearing clinic. In this context too, the ability to change programs using the cellphone is a major advantage.

"We also maintain that there is no single solution to hearing impairment. The various situations encountered with different interlocutors and/or sound sources in different locations, are hard to accommodate with one

'ingenious' device. Detecting automatically, the various situations and allocations and maximizing Speech intelligibility accordingly although feasible, is not part of the functionality of the current invention. Different programs are needed to maximize speech intelligibility, in a quiet or noisy room of different sizes, in a Park or in a concert hall. One-on-one dialog is different from Listening to everyone talking at the same time in a meeting. Listening to music at home is different than Listening in a concert hall. Given the breadth of situations, our system opted for letting the user to make the selection between programs, depending on the situation he is in. In our architecture change of programs is done by the user, using his cellular phone by emitting the proper instruction using coded ringtones detected by the microphones embedded on the eyeglasses frames. Some functions like selecting the apertures of the 'Listening cone' may be executed with a number of 'taps' on the 'tap' sensors located on both temples. The selection is then acknowledged by a short message delivered through the receiver of the hearing aid. Large memories are placed on each temple of the eyeglasses to accommodate programs that best satisfy the various situations.

"The Ringtones emitted by the user's cellphone serve a dual purpose, to generate bands of tones of different pitch and timbre of varying intensities for determining the threshold of hearing, and also generate sequences of sounds for controlling the various functions of the system. The coded audio instructions embedded into Ringtones when detected by the microphones of the eyeglasses or that of the cellphone are interpreted by the embedded microcontrollers which then instruct to execute the various functions. A side advantage of relaying instructions to the system by audio is that some people may also relay instructions by just 'whistling' from a distant location. External commands may also be transmitted by the wireless Bluetooth transceiver of the cellphone and detected by the Bluetooth transceiver installed on the eyeglasses.

"The ability to record his own hearing responses, using his cellphone Ringtones, enables the user to do so in real life situations, which is very different from determining a threshold of hearing using pure tones delivered through earphones in a booth of an audio clinic.

"In this context it is important to realize that the 'structure' of the ear changes the spectrum of the sound reaching the inner ear; while higher frequencies are amplified, the lower ones are weakened. Moreover these changes are dependent on the direction of the sound reaching the ear. Consequently, it has to be realized that the 'hearing threshold' measured in the audio clinic with pure tones, is only a first approximation when it comes to improve the hearing ability in real life situations, where sounds arrive from different directions. The correction implemented in hearing aids usually consists in amplifying the various frequencies in different amounts, given the 'hearing threshold' measured in the clinic, so that the resultant frequency response is that of a 'normal person'. We maintain that this procedure is grossly incorrect; the correction should be different when for example the sound is coming from someone in front of you, from the side or from a 'surround sound' system with 6 loudspeakers in a room.

"Another aspect of defining a suitable 'threshold of hearing' is the intelligibility aspect, which takes in account the brain perception of speech. A person will 'hear' a sound's higher harmonics although he may not hear the fundamental frequency and will substitute the unheard frequency in trying to decode a word that should have contained the unheard or unresolved frequency. This substitution will help the brain 'understand' the word.

"An additional aspect of measuring the 'hearing threshold' is the 'masking' effect, where a note at certain frequency may be masked from being 'heard' if another note at a near frequency but higher energy, is present within a 'short' time window. Thus for example a 250 Hz note followed within 200 millisecond by a 350 Hz note of the same amplitude (double the energy) will prevent the 250 Hz note of being heard. These and other brain related effects make the 'hearing threshold' measured with pure tones in a noiseless booth with earphones that discard the amplification effects of the ear pinna, less of an objective measurement of hearing loss. Consequently we maintain that the 'threshold of hearing' should not be measured with pure tones only but with complex Ringtones that include in addition to the fundamental notes also several of their harmonics. As the hearing mechanism is energy cumulative, the loudness of the complex notes for testing the 'hearing threshold'

should at least be 200 msec long.
"Therefore the different 'thresholds of hearing' should be measured in the field and stored for use in these very different situations.
"We foresee at least 5 different 'thresholds of hearing' for each ear: when the sound is coming from the front, from a side or from all around the person, from earphones or from a cellphone juxtaposed to the ear. Consequently at least 10 'hearing thresholds' should be measured, stored and used as a base for amplification in similar situations.
"Measuring the hearing threshold with the cellular phone is beneficial not only for oneself for correcting incoming calls, before reaching the ears, but may also be used for correcting outgoing calls, given the threshold of hearing of the receiving party. The threshold of hearing may be measured and recorded either by oneself or from remote through a Q&A session for finding the hearing threshold of the party at the other end of the line. Thus, when transmitting a call, the specific correction needed for the receiving party to better understand the call, can be inserted into the transmission. Consequently, the 'Hearing correction' should figure side by side with the cellphone number of a party if this person is interested to receive calls better suited to his hearing quality.
"In a preferred embodiment the Hearing Eyeglasses components embedded in each of the eyeglasses temples include a Codec, a Microcontroller, a DSP, a large Flash memory, a Bluetooth RF transceiver, a rechargeable battery, an efficient receiver, 3 microphones and several MEMS sensors, all commercial off-the-shelf components. The microcontrollers situated in the temples may communicate between them by NFC (Near Field Communication) or by wire embedded in the temples of the eyeglasses or by a loose micro-cable connecting the back tips of the temples.
